Introduction

Placenta previa (PP) occurs when the placenta is wholly or partially implanted in the lower uterine segment. The classical features of bleeding in placenta previa is sudden onset, painless, causeless and recurrent [1]. The exact cause of PP is not known, but its association with various risk factors such as advanced maternal age, multiparity, previous miscarriages, previous caesarean section or previous uterine surgeries, and cigarette smoking is well documented [2,3]. The estimated global prevalence of PP is 5.2 per 1000 pregnant women, although there is significant international variation, whereby the prevalence is found to be highest among Asian studies [4]. Given the rising incidence of caesarean section combined with increasing maternal age, the number of cases of PP and its complications, including placenta accreta (PA), will continue to increase. The condition is associated with significant maternal morbidity like haemorrhagic shock, increased operative interventions and sepsis and perinatal morbidity and mortality like preterm delivery and its related complications like low birth weight, birth asphyxia and neonatal sepsis [5]. The indication for emergency peripartum hysterectomy in recent years has been changed from atonic uterus to abnormal placentation which has now become a common indication due to the increased number of pregnant women with previous caesarean scar [6]. We undertook the current study to evaluate the risk factors and also assess the feto maternal outcomes for various types of PP.

Aims and Objectives

Aim

To evaluate maternal and fetal outcomes in women with placenta previa.

Objectives

To assess the demographic features, risk factors, obstetric management and pregnancy outcomes in women with placenta previa.

Materials and Methods

We performed a retrospective review, covering a 6-year period from August 2013 to August 2019, of women admitted to the obstetric unit of Ramiah Medical College Hospital, a tertiary referral teaching hospital in Bangalore, India. Data were collected
from the case notes of women who were found to have PP on transabdominal or transvaginal ultrasound scanning and in whom the diagnosis was confirmed during Caesarean section. Calculation of gestational age was determined by the last menstrual periods and first-trimester ultrasound. The transabdominal ultrasound examinations were performed with the bladder half-full, and the distance between the lower edge of the placenta and the internal os was measured. The transvaginal ultrasound examinations were performed with the bladder empty. The diagnosis of placenta accreta was suspected in the presence of the following sonographic features: irregularly shaped lacunae of placenta, thinning of the myometrium overlying the placenta, protrusion of the placenta into the bladder, loss of the retro placental space.

All singleton pregnancies with placenta previa beyond 28 weeks of gestational age, confirmed by ultrasonography, irrespective of their parity, type of placenta previa were included in the study. For practical purpose of management, if placenta was more than two centimetres from the internal os, and asymptomatic, antenatal mother was allowed a trial of vaginal delivery.

Demographic characteristics of women included in the study, together with details of surgical findings and procedures, the volume of blood transfusions, and complications like development of hypovolemic shock, DIC, renal failure and maternal deaths were extracted from the medical records. The neonatal outcomes including gestational age at delivery, APGAR score, birth weight, need for NICU admission, still birth rate, neonatal mortality rate, presence of congenital anomalies was extracted from the neonatal case notes. Additional procedures required like uterine packing, balloon tamponade, B-Lynch Sutures/stepwise devascularization of uterus; internal iliac artery ligation and hysterectomy when needed to control bleeding were recorded. Both the mother and baby were followed up throughout the period of their hospitalization till discharge. Statistical analysis was performed using SPSS version 20. Qualitative data like age, parity, previous mode of delivery etc, was calculated by simple frequencies and percentages. Nonparametric one sample test such as chi square test and binomial tests were used. A pvalue of < 0.05 was considered statistically significant.

**Result**

**Table 1:** Demographic variables and risk factors associated with placenta previa.

| Variable         | PP without PA [n(%)] | PP with PA [n(%)] | P value |
|------------------|----------------------|-------------------|---------|
| Maternal Age (Years) |                      |                   |         |
| <25 years        | 5(12.8%)             | 1(2.6%)           | 0.641   |
| 25-35 years      | 23(59%)              | 7(17.9%)          |         |
| > 35 years       | 3(7.7%)              | 0(0%)             |         |
| Parity           |                      |                   |         |
| Nulliparous      | 10(25.6%)            | 1(2.6%)           | 0.00*   |
| <2               | 16(41%)              | 4(10.3%)          |         |
| >/=2             | 5(12.8%)             | 3(7.7%)           |         |
| Booking Status   |                      |                   |         |
| Booked cases     | 2(5.1%)              | 2(5.1%)           | 0.00*   |
| Referred cases   | 29(74.4%)            | 6(15.4%)          |         |

**Figure 1:** Non parametric one sample test such as chi square test and binomial tests were used. A p value of < 0.05 was considered statistically significant.
A total of 39 cases with placenta previa were included in our study during the study period. The mean age of the study individuals was 26.9 years with majority women falling between 25-35 years of age group.

Table 2: Types of placenta previa among the study population.

| Type       | PP with PA [N(%)] | PP without PA | p value |
|------------|-------------------|---------------|---------|
| TYPE I     | 2 (5.1%)          | 5 (12.8%)     |         |
| TYPE IIa (anterior) | 0 (0%)         | 8 (20.5%)     |         |
| TYPE IIb (posterior) | 0 (0%)          | 3 (7.7%)      |         |
| TYPE III   | 0 (0%)            | 5 (12.8%)     |         |
| TYPE IV    | 6 (15.4%)         | 10 (25.6%)    | 0.001*  |

Table 2 With respect to types of placenta previa based on classification given by Jaunix and Campbell, 41% of the cases with PP had type IV or central/complete placenta previa and accounted for majority of cases with placenta accreta (75%). 17.9% of cases had type I PP and least common was type IIb (posterior) PP accounting for 7.7% cases.

Table 3: Types of placenta previa among the study population.

|                | N(%)          | P Value |
|----------------|---------------|---------|
| Gestational Age at Delivery [Mean249.8 days] |               |
| <34 weeks (<238 days) | 8 (20.5%)    |         |
| 34-37 weeks (238-259 days) | 15 (38.5%)   | 0.232   |
| >37 weeks (>259 days) | 16 (41%)      | -       |
| Preterm delivery 37 weeks | 23 (59%)     | -       |

Table 3: Mean gestational age at delivery was 249.8 days in our study with 59% cases having preterm delivery. 61.5% of the cases landed up with emergency caesarean section as they were referred to our hospital with complications. Only one case (2.6%) with type 1 PP had a successful vaginal delivery. Significant blood loss of more than 1000ml was seen in only 10.3% cases in our study.

Table 4: Maternal outcomes.

|                          | N (%)    | P Value |
|--------------------------|----------|---------|

| Congenital malformations | 0 (0%)   | -       |

**Discussion**

The prevalence of placenta previa in our study was 0.48% which was higher than those reported by Ramli et al. [7] Rabia Akram et al. [8] The present study indicates that maternal morbidity is significantly increased if PP is complicated by PA. Majority of women belonged to 25-35 years age group with 71.8% cases being parous women. Similar findings were noted in a study done by Prasad Usha et al. [9] that showed the highest number of cases with PP was in the age group 25-29 with 46 cases (54.76%) and the incidence was highest among multiparous women (66 cases) with 78.57%. The incidence of placenta accreta in our study was 20.5%. The high incidence of accreta in our study could be attributed to our hospital being a tertiary referral centre. Sarojini et al. [10] reported that 0.64% of the deliveries were complicated with placenta previa and that 4.7% had adherent placenta.

Gilliam et al. [11] also reported an increasing incidence of PP as both parity and number of previous Caesarean sections increased and found that the joint effect of parity and prior Caesarean section was greater than that of either variable alone; the likelihood of PP in a woman with parity greater than four and with more than four previous Caesarean sections was almost nine-fold greater (OR 8.76; 95% CI 1.58-48.53). Likewise, our study also showed significant association of parity and history of previous caesarean section with the incidence of placenta previa. The incidence of previous section among patients with PP in our study was 61.5%. Therefore, it would be reasonable to consider stringent measures to reduce the rate of primary and repeat caesarean sections without increasing maternal-fetal compromise. Many strategies are proposed, among them reducing caesarean sections upon maternal request and encouraging a trial of vaginal delivery after caesarean section. Counselling of such patients should include the remote complications of repeat caesarean section, such as PA. The mean gestational age at delivery in our study was 249 days which is similar to that reported by SK Das et al. [12].

With respect to types of placenta previa based on classification given by Jaunix and Campbell, 41% of the cases with PP had type IV or central/complete placenta previa and also accounted for majority of cases with placenta accreta (75%). 17.9% of cases had type I PP and least common was type IIb (posterior) PP accounting for 7.7% cases. However the most common types of PP in a study by Bhuyar S et al. [13] were Type I (28.2%) and Type IIa (28.2%) followed by Type III (21.8%), Type IIb (14.1%), and Type IV (7.8%).

61.5% cases in our study were delivered by emergency caesarean section. LSCS was preferred mode of delivery even in minor PP (type 1 and type 2a) due to associated APH and other obstetric complications like previous LSCS, non-reassuring NST and meconium stained liquor. Ojha N [14] reported that of the
total LSCS performed 40 (57%) cases were emergency operations. 29 (41%) cases presented with bleeding per vagina. Sekiguchi A et al. [15] conducted a retrospective study on 162 women who were diagnosed to have PP and studied the need for emergency caesarean delivery for torrential vaginal bleeding in incomplete and complete PP. It was observed that 15 (19.2%) patients required blood transfusion out of which 13 patients had major PP. Ojha N in a retrospective study reported one third (31.4%) of the patients had blood loss 500ml. There were four cases with blood loss ≥1000ml Among them two had loss of more than two liters. Ten patients required blood transfusion.

Kassem GA et al. [16] showed median intraoperative blood loss in cases of Placenta previa was 1 litre and in placenta accreta was 2,000 (mean 3,000) ml with a loss of ≥2,000 ml occurring in 72%, and ≥5,000ml in 20%. The median packed red blood cell transfusion requirement was 6 (mean 7.7) units and 28% received ≥10 units. However, in our study, post-partum hemorrhage was noted in 43.6% cases and blood loss exceeded 1 litre in all cases with placenta accreta accounting for 10.3% cases. The blood transfusion requirement was seen in 43.6% cases with majority requiring only 1-2 units of blood transfusion. Ligation to control bleeding was done in 12.8% cases. Hysterectomy was required in cases of Adherent placenta in 6 cases (15.4%). Duration of hospital stay of more than 2 weeks in our study was 28.2% as compared to 10.61% reported by SK Das et al. [12].

Hebbar SS et al. [17] in a retrospective study reported mean birth weight to be lower than 2.5kg. However, in our study majority babies had birth weight more than 2.5kg. In our study neonatal morbidity in terms of NICU admission was seen in 33.3% of babies and neonatal death seen in 2.6% (n=1) cases. We noted that there was a progressive decrease in neonatal morbidity in the form of improving Apgar scores and fewer admissions to the neonatal intensive care unit as gestation advanced. Similar findings were reported by Prashanth S et al. [18] in which perinatal morbidity was studied as the percentage of babies requiring resuscitation and NICU admission which was 37.35% (n=65) and there were 1.72%(n=3) perinatal deaths.

The strengths of this study are that the patient files were reviewed by the authors themselves, the PP management protocol did not change during the study period, and the authors were working in the hospital during the study, and some cases were managed by them. However, the study has some limitations, i.e., it was retrospective in nature and included a relatively small number of patients and since majority were referred cases the antenatal care received could not be adequately evaluated.

**Conclusion**

With the current increase in the rate of caesarean sections the incidence of placenta previa and placenta accrete is gradually increasing. The key risk factors for placenta previa are multigravidas, previous caesarean section, history of previous miscarriage requiring evacuation, inadequate antenatal care. This study highlights that these risk factors may be useful for screening at-risk mothers. Placenta previa was found to indicate a significant risk of severe, adverse maternal and fetal outcomes. It also heralds the need for comprehensive obstetrics care to appropriately treat placenta previa and its complications.
