Abstract

Auxiliary Classifier GANs (AC-GANs) [15] are widely used conditional generative models and are capable of generating high-quality images. Previous work [18] has pointed out that AC-GAN learns a biased distribution. To remedy this, Twin Auxiliary Classifier GAN (TAC-GAN) [5] introduces a twin classifier to the min-max game. However, it has been reported that using a twin auxiliary classifier may cause instability in training. To this end, we propose an Unbiased Auxiliary GANs (UAC-GAN) that utilizes the Mutual Information Neural Estimator (MINE) [2] to estimate the mutual information between the generated data distribution and labels. To further improve the performance, we also propose a novel projection-based statistics network architecture for MINE∗. Experimental results on three datasets, including Mixture of Gaussian (MoG), MNIST [12] and CIFAR10 [11] datasets, show that our UAC-GAN performs better than AC-GAN and TAC-GAN. Code can be found on the project website†.

1. Introduction

Generative Adversarial Networks (GANs) [6] are generative models that can be used to sample from high dimensional non-parametric distributions, such as natural images or videos. Conditional GANs [13] is an extension of GANs that utilize the label information to enable sampling from the class conditional data distribution. Class conditional sampling can be achieved by either (1) conditioning the discriminator directly on labels [13, 9, 14], or by (2) incorporating an additional classification loss in the training objective [15]. The latter approach originates in Auxiliary Classifier GAN (AC-GAN) [15].

∗This is an extended version of a CVPRW’20 workshop paper with the same title. In the current version the projection form of MINE is detailed.
†https://github.com/phymhan/ACGAN-PyTorch

Despite its simplicity and popularity, AC-GAN is reported to produce less diverse data samples [18, 14]. This phenomenon is formally discussed in Twin Auxiliary Classifier GAN (TAC-GAN) [5]. The authors of TAC-GAN reveal that due to a missing negative conditional entropy term in the objective of AC-GAN, it does not exactly minimize the divergence between real and fake conditional distributions. TAC-GAN proposes to estimate this missing term by introducing an additional classifier in the min-max game. However, it has also been reported that using such twin auxiliary classifiers might result in unstable training [10].

In this paper, we propose to incorporate the negative conditional entropy in the min-max game by directly estimating the mutual information between generated data and labels. The resulting method enjoys the same theoretical guarantees as that of TAC-GAN and avoids the instability caused by using a twin auxiliary classifier. We term the proposed method UAC-GAN because (1) it learns an unbiased distribution, and (2) MINE [2] relates to Unnormalized bounds [16]. Finally, our method demonstrates superior performance compared to AC-GAN and TAC-GAN on 1-D mixture of Gaussian synthetic data, MNIST [12], and CIFAR10 [11] dataset.

2. Related Work

Learning unbiased AC-GANs. In CausalGAN [10], the authors incorporate a binary Anti-Labeler in AC-GAN and theoretically show its necessity for the generator to learn the true class conditional data distributions. The Anti-Labeler is similar to the twin auxiliary classifier in TAC-GAN, but it is used only for binary classification. Shu et al. [18] formulates the AC-GAN objective as a Lagrangian to a constrained optimization problem and shows that the AC-GAN tends to push the data points away from the decision boundary of the auxiliary classifiers. TAC-GAN [5] builds on the insights of [18] and shows that the bias in AC-GAN is caused by a missing negative conditional entropy term. In
addition, [5] proposes to make AC-GAN unbiased by introducing a twin auxiliary classifier that competes in an adversarial game with the generator. The TAC-GAN can be considered as a generalization of CausalGAN’s Anti-Labeler to the multi-class setting.

**Mutual information estimation.** Learning a twin auxiliary classifier is essentially estimating the mutual information between generated data and labels. We refer readers to [16] for a comprehensive review of variational mutual information estimators. In this paper, we employ the Mutual Information Neural Estimator (MINE) [2].

### 3. Background

#### 3.1. Bias in Auxiliary Classifier GANs

First, we review the AC-GAN [15] and the analysis in [5, 18] to show why AC-GAN learns a biased distribution. The AC-GAN introduces an auxiliary classifier $C$ and optimizes the following objective

$$
\min_{\mathcal{G}} \max_{C} \mathcal{L}_{\text{AC}}(\mathcal{G}, C, D) = \min_{\mathcal{G}} \max_{C} \mathcal{L}_{\mathcal{G}}(\mathcal{G}, C, D) + \mathcal{L}_{\text{div}}(\mathcal{G}, D, C, \mathcal{Q}^{mi})
$$

where $\mathcal{L}_{\mathcal{G}}$ is the value function of a vanilla GAN, and $\mathcal{L}_{\text{div}}$ corresponds to cross-entropy classification error on real and fake data samples, respectively. Let $Q^{Y|X}$ denote the conditional distribution induced by $C$. As pointed out in [5], adding a data-dependent negative conditional entropy $-H_{\mathcal{G}}(Y|X)$ to $\mathcal{L}_{\text{div}}$ yields the Kullback-Leibler (KL) divergence between $P_{Y|X}$ and $Q^{Y|X}$,

$$
-H_{\mathcal{G}}(Y|X) + = E_{z \sim p_{z}, y \sim p_{y}} D_{KL}(P_{Y|X} || Q_{Y|X}^{mi}).
$$

Similarly, adding a term $-H_{\mathcal{G}}(Y|X)$ to $\mathcal{L}_{\text{div}}$ yields the Kullback-Leibler (KL) divergence between $Q_{Y|X}$ and $Q_{W|X}$,

$$
-H_{\mathcal{G}}(Y|X) + = E_{x \sim Q_{X}} D_{KL}(Q_{Y|X} || Q_{Y|X}^{mi}).
$$

As illustrated above, if we were to optimize 2 and 3, the generated data posterior $Q_{Y|X}$ and the real data posterior $P_{Y|X}$ would be effectively chained together by the two KL-divergence terms. However, $H_{\mathcal{G}}(Y|X)$ cannot be considered as a constant when updating $\mathcal{G}$. Thus, to make the original AC-GAN unbiased, the term $-H_{\mathcal{G}}(Y|X)$ has to be added to the objective function. Without this term, the generator tends to generate data points that are away from the decision boundary of $C$, and thus learns a biased (degenerate) distribution. Intuitively, minimizing $-H_{\mathcal{G}}(Y|X)$ over $\mathcal{G}$ forces the generator to generate diverse samples with high (conditional) entropy.

### 3.2. Twin Auxiliary Classifier GANs

Twin Auxiliary Classifier GAN (TAC-GAN) [5] tries to estimate $H_{\mathcal{G}}(Y|X)$ by introducing another auxiliary classifier $C^{mi}$. First, notice the mutual information can be decomposed in two symmetrical forms,

$$
I_{Q}(X; Y) = H(Y) - H_{\mathcal{G}}(Y|X) = H_{\mathcal{G}}(X) - H_{\mathcal{G}}(X|Y).
$$

Herein, the subscript $Q$ denotes the corresponding distribution $Q$ induced by $\mathcal{G}$. Since $H(Y)$ is constant, optimizing $-H_{\mathcal{G}}(Y|X)$ is equivalent to optimizing $I_{Q}(X; Y)$. TAC-GAN shows that when $Y$ is uniform, the latter form of $I_{Q}$ can be written as the Jensen-Shannon divergence (JSD) between conditionals $\{Q_{X|Y=1}, \ldots, Q_{X|Y=K}\}$. Finally, TAC-GAN introduces the following min-max game

$$
\min_{\mathcal{G}} \max_{C^{mi}} \mathcal{V}_{\text{TAC}}(\mathcal{G}, C^{mi}) = E_{x \sim p_{x}, y \sim p_{y}} \log C^{mi}(\mathcal{G}(z), y),
$$

(4)

to minimize the JSD between multiple distributions. The overall objective is

$$
\min_{\mathcal{G}, C^{mi}} \mathcal{L}_{\text{TAC}}(\mathcal{G}, D, C, \mathcal{Q}^{mi}) = \mathcal{L}_{\text{AC}} + \mathcal{V}_{\text{TAC}}.
$$

### 3.3. Insights on Twin Auxiliary Classifier GANs

**TAC-GAN from a variational perspective.** Training the twin auxiliary classifier minimizes the label reconstruction error on fake data as in InfoGAN [3]. Thus, when optimizing over $\mathcal{G}$, TAC-GAN minimizes a lower bound of the mutual information. To see this,

$$
\mathcal{V}_{\text{TAC}} = \mathbb{E}_{x, y \sim Q_{xy}} \log C^{mi}(x, y) = \mathbb{E}_{x \sim Q_{x}} \mathbb{E}_{y \sim Q_{y|x}} \log \frac{Q^{mi}(y|x)}{Q(y|x)}
$$

$$
= \mathbb{E}_{x \sim Q_{x}} \mathbb{E}_{y \sim Q_{y|x}} \log Q(y|x)
$$

$$
- \mathbb{E}_{x \sim Q_{x}} D_{KL}(Q_{Y|X} || Q_{Y|X}^{mi})
$$

$$
\leq - H_{\mathcal{G}}(Y|X).
$$

(6)

The above shows that $\mathcal{V}$ is a lower bound of $-H_{\mathcal{G}}(Y|X)$. The bound is tight when classifier $C^{mi}$ learns the true posterior $Q_{Y|X}$ on fake data. However, minimizing a lower bound might be problematic in practice. Indeed, previous literature [10] has reported unstable training behavior of using an adversarial twin auxiliary classifier in AC-GAN.

**TAC-GAN as a generalized CausalGAN.** A binary version of the twin auxiliary classifier has been introduced as Anti-Labeler in CausalGAN [10] to tackle the issue of label-conditioned mode collapse. As pointed out in [10], the use of Anti-Labeler brings practical challenges with gradient-based training. Specifically, (1) in the early stage,
the Anti-Labeler quickly minimizes its loss if the generator exhibits label-conditioned mode collapse, and (2) in the later stage, as the generator produces more and more realistic images, Anti-Labeler behaves more like Labeler (the other auxiliary classifier). Therefore, maximizing Anti-Labeler loss and minimizing Labeler loss become a contradicting task, which ends up with unstable training. To account for this, CausalGAN adds an exponential decaying weight before the Anti-Labeler loss term (or \( \mathbb{R} \) in 5 when optimizing \( G \)). In fact, the following theorem shows that TAC-GAN can still induce a degenerate distribution.

**Theorem 1.** Given fixed \( C \) and \( C^{mi} \), the optimal \( G^* \) that minimizes \( \odot + \mathfrak{A} \) induces a degenerated conditional \( Q^*_{Y \mid X} = \text{onehot}(\arg\min_{k} \frac{Q^{mi}(Y=k\mid x)}{Q^c(Y=k \mid x)}) \), where \( Q^{mi}_{Y \mid X} \) is the distribution specified by \( C^{mi} \).

**Proof.** If \( G \) learns the true conditional, and \( C \) and \( C^{mi} \) are both optimally trained so that \( Q^{*}_{Y \mid X} = Q^{mi}_{Y \mid X} = P_{Y \mid X} \), then \( \odot + \mathfrak{A} = 0 \) and the game reaches equilibrium.

If \( Q^{*}_{Y \mid X} \) and \( Q^{mi}_{Y \mid X} \) are not equal (and \( Q^{c}_{Y \mid X} \) has non-zero entries),

\[
\odot + \mathfrak{A} = -\mathbb{E}_{x \sim Q_x} \sum_k Q^*_{Y \mid X}(Y = k \mid x) \log Q^c(Y = k \mid x) + \mathbb{E}_{x \sim Q_x} \sum_k Q^{mi}_{Y \mid X}(Y = k \mid x) \log Q^{mi}(Y = k \mid x) = \mathbb{E}_{x \sim Q_x} \sum_k Q^*_{Y \mid X}(Y = k \mid x) \log \frac{Q^{mi}(Y = k \mid x)}{Q^c(Y = k \mid x)}
\]

The minimizing \( \odot + \mathfrak{A} \) is equivalent to minimizing the objective point-wisely for each \( x \),

\[
\min_{Q_{Y \mid X} \mid x} \sum_k Q^*_{Y \mid X}(Y = k \mid x) r_x(k),
\]

where \( r_x \) is the log density ratio between \( Q^{mi} \) and \( Q^c \). Then the optimized \( Q^*_{Y \mid X} \) is obtained by noticing that

\[
\sum_k Q^*_{Y \mid X}(Y = k \mid x) r_x(k) \geq \sum_k Q^{mi}_{Y \mid X}(Y = k \mid x) r_x(k_m) = r_x(k_m)
\]

\[
= \sum_k Q^*_{Y \mid X}(Y = k \mid x) r_x(k),
\]

with \( k_m = \arg\min_k r_x(k) \) and \( Q^*_{Y \mid X} = \text{onehot}(k_m) \). \( \square \)

### 4.1. Mutual Information Neural Estimator

The mutual information \( I_Q(X; Y) \) is equal to the KL-divergence between the joint \( Q_{XY} \) and the product of the marginals \( Q_X \otimes Q_Y \) (here we denote \( Q_Y = P_Y \) for a consistent and general notation),

\[
I_Q(X; Y) = D_{KL}(Q_{XY} \| Q_X \otimes Q_Y).
\]

MINE is built on top of the bound of Donsker and Varadhan [4] (for the KL-divergence between distributions \( P \) and \( Q \)),

\[
D_{KL}(P || Q) = \sup_{T : \Omega \rightarrow \mathbb{R}} \mathbb{E}_P[T] - \log \mathbb{E}_Q[e^T],
\]

where \( T \) is a scalar-valued function which takes samples from \( P \) or \( Q \) as input. Then by replacing \( P \) with \( Q_{XY} \) and replacing \( Q \) with \( Q_X \otimes Q_Y \), we get

\[
I_Q^{\text{mine}} = \max_{\mathcal{T}} V_{\text{MINE}}(G, \mathcal{T}),
\]

where

\[
V_{\text{MINE}}(G, \mathcal{T}) = \mathbb{E}_{x \sim P_x, y \sim P_y} \mathcal{T}(G(z, y), y) - \log \mathbb{E}_{z \sim P_z, y \sim P_y} e^{\mathcal{T}(G(z, y), y)}.
\]

The function \( \mathcal{T} : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R} \) is often parameterized by a deep neural network.

### 4.2. Unbiased AC-GAN with MINE

The overall objective of the proposed unbiased AC-GAN is

\[
\min_{G, C} \max_{D, \mathcal{T}} L_{UAC}(G, D, C, \mathcal{T}) = L_{AC} + V_{\text{MINE}}.
\]

Note that when the inner \( \mathcal{T} \) is optimal and the bound is tight, \( V_{\text{MINE}}(G, \mathcal{T}^*) \) recovers the true mutual information \( I_Q(X; Y) = H(Y) - H_Q(Y \mid X) \). Given that \( H(Y) \) is constant, minimizing over the outer \( G \) maximizes the true conditional entropy \( H_Q(Y \mid X) \).

### 4.3. Projection MINE

In the original MINE [2], the statistics network \( \mathcal{T} \) is implemented as a neural network without any restrictions on the architecture. Specifically, \( \mathcal{T} \) is a network that takes an image \( x \) and a label \( y \) as input and outputs a scalar, and a naive way to infuse them is by concatenation (input concat). However, we find that input concat yields bad mutual information estimations and does not work well in practice. To solve this, we propose a projection based architecture for the statistics network.

The optimal solution of the statistics network is

\[
\mathcal{T}^*(x, y) = \log Q(y \mid x) - \log Q(y) + \log Z(y),
\]

where \( Z(y) = \mathbb{E}_{Q_X} e^{\mathcal{T}(x, y)} \) is a partition function that only depends on \( y \). For completeness, we include a brief derivation here [16]:

\[
I_Q(X; Y) = \mathbb{E}_{Q_{XY}} \log \frac{Q(x \mid y)}{Q(x)} + \mathbb{E}_{Q_Y} D_{KL}(Q(x \mid y) || Q^*(x \mid y)) \geq \mathbb{E}_{Q_{XY}} \log Q(x) - \log Q(x).
\]
where \( \tilde{Q}(x|y) \) is a variational approximation of \( Q(x|y) \). This is also known as the Barber & Agakov bound [1]. Then we choose an energy-based variational family and define
\[
\tilde{Q}(x|y) := \frac{Q(x)}{Z(y)} e^{T(x,y)}, \tag{13}
\]
The optimal \( T \) is obtained by setting \( \tilde{Q}(x|y) = Q(x|y) \).

Given the form of Equation 11 and inspired by the projection discriminator [14], we therefore model the \( Q(y|x) \) term as a log linear model:
\[
\log Q(y|x) := v^T_y \phi(x) - \log Z_0(\phi(x)), \tag{14}
\]
where \( Z_0(\phi(x)) := \sum_k \exp(v^T_k \phi(x)) \) is another partition function. Thus, if we denote \( \log Z_0 \) as \( \psi \), one can rewrite the the above equation as
\[
\log Q(y|x) := v^T_y \phi(x) + \psi(\phi(x)).
\]

As mentioned before, \( Q(y) = P(y) \) and is pre-defined by the dataset. If \( P(y) \) is uniform, then \( \log P(y) \) is a constant which can be absorbed into \( \psi \). If the condition is not satisfied, one can always merge the last two terms in Equation 11 and define \( c_y := -\log Q(y) + \log Z(y) \), and we get the final form of \( T \),
\[
T(x, y) := v^T_y \phi(x) + \psi(\phi(x)) + c_y, \tag{15}
\]
Intuitively, isolating \( \log Q(y) \) from \( c_y \) would help the network to focus on estimating the partition function. Moreover, in the situation where \( \log Q(y) \) might be changing, it is beneficial if we can model it during training. To explicitly model the term \( \log Q(y) \), we can introduce another discriminator to differentiate samples \( y \sim Q_Y \) and samples \( y \sim \text{Unif}(1, K) \). It is known that an optimal discriminator estimates the log density ratio between two data distributions. Let \( D_Y \) solve the following task
\[
\max_{D_Y} \mathbb{E}_{y \sim Q_Y} \log D_Y(y) + \mathbb{E}_{y \sim \text{Unif}} \log(1 - D_Y(y)) \tag{16}
\]
and \( \tilde{D}_Y \) be the logit of \( D_Y \), then the optimal \( \tilde{D}_Y = \log Q(y) + \log K \). Plug it into Equation 11 we get another form
\[
T(x, y) := v^T_y \phi(x) + \psi(\phi(x)) - \tilde{D}_Y(y) + c_y + \log K. \tag{17}
\]
Implementation-wise, a projection-based network \( T \) only adds at most an embedding layer (same as same as a fully connected layer) and a single-class fully connected layer (if replacing the LogSumExp function with a learnable scalar function). Thus, UAC-GAN only adds a negligible computational cost to AC-GANs.

5. Experiments

We borrow the evaluation protocol in [5] to compare the distribution matching ability of AC-GAN, TAC-GAN, and our UAC-GAN on (1-D) mixture of Gaussian synthetic data. Then, we evaluate the image generation performance of UAC-GAN on MNIST [12] and CIFAR10 [11] dataset.
Figure 1: Results on MNIST (a-c) and CIFAR10 (d-f) dataset. Samples are drawn from a single class “2” (a-c) and “horse” (d-f) to illustrate the label-conditioned diversity.
