Strong One-Dimensional Characteristics of Hole-Carriers in ReS\textsubscript{2} and ReSe\textsubscript{2}

B. S. Kim\textsuperscript{1,2,3}, W. S. Kyung\textsuperscript{1,2,2}, J. D. Denlinger\textsuperscript{4}, C. Kim\textsuperscript{1,2} & S. R. Park\textsuperscript{3}

Each plane of layered ReS\textsubscript{2} and ReSe\textsubscript{2} materials has 1D chain structure, from which intriguing properties such as 1D character of the exciton states and linearly polarized photoluminescence originate. However, systematic studies on the 1D character of charge carriers have not been done yet. Here, we report on systematic and comparative studies on the energy-momentum dispersion relationships of layered transition metal dichalcogenides ReS\textsubscript{2} and ReSe\textsubscript{2} by angle resolved photoemission. We found that the valence band maximum or the minimum energy for holes is located at the high symmetric Z-point for both materials. However, the out-of-plane ($k_{z}$) dispersion for ReSe\textsubscript{2} (20 meV) is found to be much smaller than that of ReS\textsubscript{2} (150 meV). We observe that the effective mass of the hole carriers along the direction perpendicular to the chain is about 4 times larger than along the chain direction for both ReS\textsubscript{2} and ReSe\textsubscript{2}. Remarkably, the experimentally measured hole effective mass is about twice heavier than that from first principles calculation for ReS\textsubscript{2}, although the in-plane anisotropy values from the experiment and calculations are comparable. These observation indicate that bulk ReS\textsubscript{2} and ReSe\textsubscript{2} are unique semiconducting transition metal dichalcogenides having strong one-dimensional characters.

Layered transition-metal dichalcogenides (TMDs) have been extensively studied in recent years because of their potential as electronic materials for future devices. Their intriguing characters of the electronic structures such as the valley degeneracy\textsuperscript{1} and spin-valley-layer locking\textsuperscript{2–4}, provide added value for valley- and spintronic applications. While some of them even exhibit superconductivity and charge density waves originating from the electron-phonon and electron-electron interactions due to their low electronic dimensionality (e.g. in NbSe\textsubscript{2}\textsuperscript{5,6}), most of the studies have been focused on Mo and W compounds due to their semi-conducting properties and close to ideal 2 dimensionality\textsuperscript{7–11}.

Very recently, layered ReS\textsubscript{2} and ReSe\textsubscript{2} began to draw attention as their layer-layer interactions are much weaker than other layered TMDs\textsuperscript{12}. More interestingly, ReS\textsubscript{2} and ReSe\textsubscript{2} have one-dimensional (1D) characters in their structure as well as optical and electrical properties due to the formation of Re chain structure stemming from the distortion in the 1T structural phase\textsuperscript{12–14}. High-resolution transmission electron microscopy and electron diffraction studies reveal distorted 1T structure with Re chain formation\textsuperscript{12}. Such structure distortion is directly related to the high anisotropy in the Raman response from in-plane lattice vibrations\textsuperscript{14–19}. It also affects optical properties, e.g., anisotropic character in optical absorption or photoluminescence comes from that of excitons\textsuperscript{20–24}. Electrical conductivity is also found to be much higher along the chain direction than the direction perpendicular to the chain\textsuperscript{13,25,26}.

As the above-mentioned intriguing 1D properties are determined by the characteristics of hole and electron band dispersions, electronic structure studies by angle resolved photoemission spectroscopy (ARPES) are naturally desired. Especially, the effective mass is a fundamental parameter that can be obtained from the energy and momentum dispersion relationship and governs the electrical and optical properties such as mobility, conductivity, light absorption and photoluminescence. In fact, a couple of ARPES studies on ReS\textsubscript{2} and ReSe\textsubscript{2} have been reported and the results indicate an in-plane anisotropy in the hole band dispersion as expected from the chain structures in ReS\textsubscript{2}\textsuperscript{27–29} and in ReSe\textsubscript{2}\textsuperscript{30}. However, obtaining very high-quality data needed to determine the effective mass for all directions turned out to be challenging. For example, the photon energy dependence of the
Valence band dispersion for ReS₂ appears to be very different among the reported results²⁷,²⁹. In addition, direct comparison between measured valence band dispersions of ReS₂ and ReSe₂, for which lattice parameters are quite different³¹, are difficult because the data were taken in different Brillouin zones for ReS₂ and ReSe₂²⁹,³⁰.

In order to resolve aforementioned issues, we have performed systematic ARPES studies on ReS₂ and ReSe₂. Our goal is to take data for the entire momentum space which is good enough to perform quantitative analysis and obtain in-plane anisotropy in the effective hole mass for the two materials for a comparative study. Our data show a striking difference from what were reported in previous experimental and theoretical studies²⁹,³⁰,³². (1) The valence band maximum (VBM) is located at the Z-point for both systems, while it was reported in a previous ARPES study that VBM of ReSe₂ may be located at non-high-symmetric momentum point³⁰,³³. (2) The k_z dispersion of ReSe₂ is much smaller than that of published quasiparticle band structure within the LDA + GdW approximation³⁴. (3) The effective hole masses along and perpendicular to the chain direction are quite different from the reported experimental and theoretical values²⁹,³⁰,³⁴.

Results and Discussion
Valence band maximum of ReSe₂ and ReS₂. ReS₂ and ReSe₂ are layered materials in which the van der Waals interaction between layers is extremely weak, even weaker than other TMDs²⁴. The crystal structure for both ReS₂ and ReSe₂ is the so-called distorted 1T structure. Re atoms show a hexagonal network but the structure is distorted to have chain structures as indicated by black lines in Fig. 1(a). The 1D chain structure makes these materials unique among TMDs in that optical and electrical properties carry 1D characteristics¹⁴–²⁶.

The inner potential can be estimated from the k_z dispersion of electronic band (Fig. 1(b) and (c)) with the reciprocal lattice vector c*. Based on the results of reported X-ray diffraction measurements³¹, the reciprocal lattice vector c* is calculated to be 1.032 Å⁻¹ (0.984 Å⁻¹) for ReS₂ (ReSe₂). The inner potential is estimated to be V₀ = 17.8 and 12.4 eV for ReS₂ and ReSe₂. These estimated values are similar to those of other TMDs³⁵,³⁶.

ARPES experiments are performed on ReS₂ and ReSe₂ to obtain the energy-and-momentum dispersion of the hole carriers. ARPES intensities as a function of the energy referenced to the valence band maximum (EVBM) are mapped along two momentum directions, parallel to chain (k_y) and perpendicular to the layer (k_z) (Fig. 1(b,c)). While several band dispersions are observed within the energy range, the top-most valence band is of interest as it determines the low energy properties of the materials such as electrical conductivity. Due to the layered structure, the top-most bands of ReS₂ and ReSe₂ show relatively weak dispersions along k_y than along in-plane momentum. Interestingly, we observed as shown in Fig. 1 that the k_z dispersion of ReSe₂ (about 20 meV) is even weaker compared to that of ReS₂ (about 150 meV) which is known as a material with very weak inter-layer interaction¹². Therefore, our results show an evidence for even smaller interaction between layers in ReSe₂.

Our photon energy dependence data reveal that VBM is located at Z for both ReS₂ and ReSe₂, as indicated by the red dashed lines in Fig. 1(b,c). While previous ARPES studies also showed that VBM of ReS₂ is located at Z, VBM of ReSe₂ has been under debate. Hart et al. reported that the k_z for VBM of ReSe₂ is the same as the Z-point but the in-plane momentum was reported to be non-zero³⁰. More recently, Eickholt et al. reported two VBM of ReSe₂³³. One of them is at Z and the other is away from Z. But their experiment could not decide which is global VBM, since data quality is not good enough. The global VBM of ReSe₂ can be decided to be located at Z due to high quality data. Please refer to the supplementary materials for more details. In fact, we find that ReSe₂ result about VBM is consistent with a recent theoretical prediction as well³².
In order to investigate the effective mass of the hole carrier, we analyze ARPES data obtained in the in-plane momentum space that includes the Z-point. As shown in Fig. 2(a,c), constant energy maps of ARPES intensities of ReS$_2$ and ReSe$_2$ at E-E$_{\text{VBM}}$ = −0.2 eV show two-fold symmetry and strong anisotropic band contours which are not closed along the direction perpendicular to the chain. These observations indicate much smaller band dispersion along the direction perpendicular to the chain. The top-most band dispersions, which we are interested in, along the chain are much stronger than those along the other for both ReS$_2$ and ReSe$_2$. For quantitative analysis, we try to fit the band dispersions with a quadratic function for which the effective mass is a free parameter. The dotted lines in Fig. 2(b,d) indicate the fit functions. So, obtained effective masses along the direction perpendicular to the chain (4.63 m$_e$ for ReS$_2$ and 4.14 m$_e$ for ReSe$_2$) are much heavier than the effective masses along the chain (1.08 m$_e$ for ReS$_2$ and 1.13 m$_e$ for ReSe$_2$). That is, the effective mass along the chain is about 4 times lighter than that perpendicular to the chain for both ReS$_2$ and ReSe$_2$. This in-plane anisotropy value in the effective hole mass is the largest among semiconducting TMDs.

The valence band dispersion can also be analyzed for different theta angle and corresponding effective hole mass can be obtained. Shown in Fig. 3(a,b) are ARPES data along in-plane momentum set by the $\theta$ angle defined in Fig. 2(a). The data are subsequently analyzed and the corresponding effective hole mass is obtained for a
systematic study of direction dependence. We notice the top-most band can be fitted well with a quadratic function indicated by dotted lines, which makes us confident in our analysis. The extracted effective mass from the quadratic function is plotted in polar coordinate as a function of the theta angle in Fig. 3(c). The plot clearly shows two-fold symmetry and strong in-plane anisotropy of the effective hole mass for both ReS$_2$ (red) and ReSe$_2$ (blue).

There is an important point to discuss in comparison with the results of first principles calculations on ReS$_2$. The experimentally observed effective mass is about twice larger than that from the first principles calculations. The effective mass from the first principles calculations is 2.4 m$_e$ along the direction perpendicular to the chain and 0.8 m$_e$ along the chain$^2$. The electron-electron and electron-phonon interactions or atomic spin-orbit coupling of Re atom which were not considered in the calculation may play a crucial role in the clear enhancement of the effective hole mass.

**Conclusions**

In this study, we performed systematic ARPES studies of ReS$_2$ and ReSe$_2$ to reveal the energy-momentum dispersion relationships of the top most valence bands. We found that ReSe$_2$ have much smaller $k_z$ dispersion than ReS$_2$, indicating the more 2D-like feature in ReSe$_2$ than in ReS$_2$. We systematically investigated in-plane directional dependence of the effective hole masses of ReS$_2$ and ReSe$_2$. The effective masses show strong anisotropy, about 4 times lighter along the chain than the direction perpendicular to the chain. In-plane anisotropy of the hole effective masses in ReS$_2$ and ReSe$_2$ is larger than that in black phosphorus which also shows anisotropic electrical and optical properties$^{39,40}$. Therefore, ReS$_2$ and ReSe$_2$ are quasi 1D materials in terms of the low energy hole carrier dynamics, which makes ReS$_2$ and ReSe$_2$ promising bulk materials for 1D semiconducting electronics. The effective mass of ReS$_2$ observed by ARPES is found to be significantly enhanced compared to that from first principles calculations. Electron-electron and electron-phonon interactions or atomic spin-orbit coupling of Re atom may be attributed to the mass enhancement$^{41}$. The quasi 1D character of the hole carriers as well as possibility of the electron-electron and electron-phonon interactions may lead to charge density wave order if enough amount of hole carriers are doped into ReS$_2$ and ReSe$_2$.$^{42}$

**Methods**

**ARPES measurement.** We performed ARPES experiments at the beamline 4.0.3.2 (MERLIN) of the Advanced Light Source at the Lawrence Berkeley National Laboratory equipped with VG-Scienta R8000 electron analyzer. All samples are cleaved in-situ and data were taken at 200 K to avoid the charging effect in a vacuum better than $6 \times 10^{-11}$ Torr. with linearly polarized light. For the $k_z$ dependence experiment, photon energies between 60 and 110 eV with 2 eV energy step were used. The total energy resolution was better than 20 meV with a momentum resolution of 0.004 Å$^{-1}$.
