Abstract: Trimethoprim (TMP) is a pharmaceutical compound, which is commonly found in the water environment. The UV/chlorine process forms several reactive species, including hydroxyl radicals (HO•) and reactive chlorine species, to degrade contaminants. The influencing factors and the optimal operational conditions for the degradation of TMP by the UV/chlorine process were investigated. The degradation of TMP was much faster by the UV/chlorine process as compared to the UV alone or free chlorine alone process. A kinetic model was developed to simulate the degradation of TMP and determine the unknown rate constants. This study also predicted the relative contributions of each of the reactive species and photolysis using the developed kinetic model. It was found that the ClO• radical was the major reactant responsible for the degradation of TMP. Furthermore, the most important finding was the identification of the best operational conditions. The best operational conditions resulted in the lowest use of energy and electrical energy per order (EE/O), namely, (1) for the ultrapure water, the optimum intensity of the UV light and the free chlorine dosage were 2.56 Einstein/L·s and 0.064 mM, respectively, with a minimum EE/O of 0.136 kWh/m³; and (2) for the water matrix containing 3 mg/L NOM, the optimum intensity of the UV light and the free chlorine dosage were 3.45 Einstein/L·s and 0.172 mM, respectively, with a minimum EE/O of 0.311 kWh/m³.

Keywords: UV/free chlorine; advanced oxidation; trimethoprim oxidation; reactive chlorine species

1. Introduction

In recent years, many emerging contaminants (such as herbicides, odoriferous substances, pharmaceuticals and personal care products (PPCPs), etc.) have been found in the water environment. Antibiotics are the common PPCPs and now more than 10,000 kinds of antibiotics are widely applied in the treatment and prevention of the bacterial infections [1]. For example, Trimethoprim (TMP) is an antibiotic, which is mainly used in the treatment of the bladder infections [2]. The concentration of TMP has been reported to be 0.1–5 ng/L, 2.2–10.9 ng/L and 0–19.8 ng/L in the effluents of the wastewater treatment plant, surface water and the finished drinking water, respectively [3]. However, once the antibiotics are released into the water matrix, they have some adverse effects on human health and the aquatic ecosystem: (1) Antibiotics entering the soil will directly affect the species, quantity and community structure of microorganisms in the soil environment, thus causing an imbalance in the soil ecological environment. (2) Antibiotics entering the water environment will cause harm to various invertebrates and aquatic plants. (3) Due to the enrichment of food-chain antibiotics in plants and animals, these substances will
eventually enter the human body. Antibiotic residues in the human body will cause teratogenicity, carcinogenesis, mutation and immunosuppression. Therefore, pollutants entering the water environment should be minimized. However, the process of biological treatment to degrade these antibiotics is insufficient due to the antibiotics (including the TMP) being persistent organic contaminants. Although many advanced physical chemical treatment processes (e.g., membrane, ion exchange and air stripping) only transfer the fate of the antibiotics from one phase to another, AOPs can mineralize them if appropriately designed [4]. Conventional wastewater treatment technologies (such as ozone oxidation and adsorption) are also unable to effectively remove the antibiotics [1].

Advanced oxidation processes (AOPs) are highly efficient technologies for wastewater treatment. The AOPs are effective to destroy the refractory organic contaminants (such as antibiotics) due to the generation of the various reactive radicals at a certain temperature and pressure. These reactive radicals eventually oxidize organic contaminants into carbon dioxide (CO$_2$) and water (H$_2$O). Recently, the ultraviolet light (UV)/free chlorine (HOCl/OCl$^-$) process has become one of the most promising AOPs. In the UV/free chlorine process, the UV irradiation cleaves the bonds in the HOCl to form the hydroxyl radical (HO•) and chlorine radical (Cl•). The HO• is a strong oxidant, which generally reacts with the organic contaminants. The Cl• is a selective oxidant, which rapidly reacts with the compounds containing aromatic rings and double bonds [3]. Subsequently, the ClO• and Cl$_2$•$^-$ are generated through the chain reactions of the complex radicals, which also oxidize the organic compounds. Many studies have reported that the UV/free chlorine process can successfully remove some of the persistent organic contaminants (such as desethylatrazine, sulfamethoxazole, carbamazepine, diclofenac, benzotriazole, nitrobenzene, trichloroethylene, etc.) [5,6] Furthermore, the UV/chlorine process has also been more effective than the UV/H$_2$O$_2$ process (a common UV-based AOP) to destroy some of the micro-pollutants (such as trichloroethylene) [7]. These previous studies have highlighted the degradation of some selected organic contaminants in the UV/free chlorine process. However, the mechanism of the degradation of TMP in the UV/free chlorine process is still not fully understood, due to which further investigations are needed.

The objectives of this study included (1) to investigate the impacts of the operational conditions and the components of the surface water matrix (such as free chlorine dosage, pH, chloride ion (Cl$^-$), bicarbonate/carbonate ions (HCO$_3^-$/CO$_3^{2-}$) and natural organic matter (NOM)) on the degradation rate of TMP; (2) to develop a kinetic model to simulate the degradation of TMP and estimate the unknown rate constants; (3) to explore the relative contributions of each of the reactive species and photolysis; and (4) to optimize the operational conditions towards the lowest energy consumption. Overall, this study further provided insight into the understanding of the mechanisms of the degradation of TMP in the UV/free chlorine process.

2. Materials and Methods
2.1. Experimental Section
2.1.1. Experimental Materials

Ultrapure water was used in the experimentation process except as noted. The below-mentioned chemicals were purchased from Sigma: (1) chromatographically pure methanol; (2) trimethoprim (98%); (3) Suwannee River NOM (natural organic matter) (Cat. No. 2R101N); (4) sodium hypochlorite (with an effective free chlorine concentration of 10%); and (5) sodium thiosulfate. These solutions were buffered using the phosphate solution. All the reagent solutions were prepared using Nanopure water and purified water (Barnstead–Dubuque, Iowa, America). Other chemicals (such as buffers, colorimetric agents, reductants, etc.) used in the experimentations were of reagent-grade quality or better, obtained from Thermo Fisher Scientific, Waltham, MA, USA.
2.1.2. UV Reactor

The UV reactor consisted of three parts (shown in Figure S1), which included (1) a closed cardboard large container; (2) 2 UV low pressure mercury lamps with the power sources of 40 W, which produced 254 nm UV light; and (3) a magnetic stirrer. The temperature was maintained at 25 °C. The UV photon flux ($I_0$), entering the solution was determined to be 0.567 µEs$^{-1}$ using iodide/iodate chemical actinometry (shown in Figure S2a). The volume of the UV reactor was 0.6 L and the UV intensity ($P_{UV}$) was determined to be 9.45 $\times$ 10$^{-7}$ Einstein/L s. The effective path length ($L$) was determined to be 3.01 cm by measuring the kinetics of the photolysis of the diluted H$_2$O$_2$ (shown in Figure S2b). The average UV fluence rate ($E_{P0}$) was estimated to be 0.0028 µEs$^{-1}$ cm$^{-2}$ (shown in Text S1.3).

2.1.3. Experimental Procedures

In order to prepare the stock solution of TMP, a 0.01-mM TMP was added to 1.0 L water. The TMP solution had a concentration of 2.9 mg/L. The UV lamps were turned on for 60 min before the start of the experiment. A 100-mL TMP solution prepared above was added to the beaker next to the UV lamps and an appropriate dosage of 1 mM of the sodium hypochlorite solution was added to the test solution containing a 2 mM phosphate buffer of 15 mL. The pH value was controlled with the solution of the buffer solution from 6.1 to 8.2. The magnetic stirrer was set at a speed of 400 rpm. The UV lamps irradiated the solution in the beaker for 20 min. At various time intervals within the 20 min, a 1 mL solution sample was taken, followed by the addition of a few drops of 0.1 M sodium thiosulfate into the solution sample in order to quench the residual chlorine. The experimentation processes for the UV alone, UV/hydrogen peroxide (H$_2$O$_2$) and UV/free chlorine were conducted with the same experimental procedures, and the experimentation process for free chlorine alone was similarly conducted without the UV light input.

2.1.4. Analysis Method

The concentrations of TMP were determined using high-performance liquid chromatography. The column used in the experimentation was a symmetry C18 column and the mobile phase was composed of 0.3% acetonitrile and acetic acid with a v/v ratio of 20:80. The detection wavelength was set to 280 nm with the flow rate and the column temperature to 1.0 mL/min and 28 °C, respectively. The detection limit of TMP was 3.2 µg/L.

In this study, the concentration of the H$_2$O$_2$ was measured using the (N,N-diethyl-p-phenylenediamine) DPD colorimetric method. The main measuring principle of the DPD colorimetric method was that in the presence of the catalyst horseradish catalase in the solution, the DPD added to the solution would be rapidly oxidized into a stable reddish substance with the molar absorption coefficient of 2.1 $\times$ 10$^4$ M$^{-1}$ cm$^{-1}$ under the condition of UV light with a wavelength of 515 nm. For the specific detection process, a 10 mL tube was prepared, and a 0.5 M phosphate buffer solution was added to it. Then, 3 mL of the sample, which was needed to be tested, was added to the solution, which was diluted to 10 mL and poured into a 3 cm cuvette, followed by the rapid addition of the 50 µL of the DPD solution and mixing for 15 s. It was marked zero at 551 nm with a UV–visible spectrophotometer. Then 50 µL of the POD solution was added and mixed well for 50 s, and the absorbance of the solution was measured at 551 nm with a UV–visible spectrophotometer. The free chlorine stock solution, which was prepared by dilution of the 10% NaOCl solutions, were standardized using iodometry or spectrophotometry [8].

2.2. Equilibrium Calculation

2.2.1. Free Chlorine Equilibrium

The equilibrium concentrations of the free chlorine at various pH values were calculated by Equations (1)–(3).

\[
\text{HOCl} \leftrightarrow \text{OCl}^- + \text{H}^+ \quad (1)
\]

\[
[\text{HOCl}] = \frac{10^{-\text{pH}}}{10^{-\text{pH}} + 10^{-\text{pK}_a}} [\text{Total HOCI}] \quad (2)
\]
\[ [\text{OCI}^-] = \frac{10^{-pK_{a1}}}{10^{-pH} + 10^{-pK_{a1}}} [\text{Total HOCl}] \]  

(3)

2.2.2. TMP Equilibrium

The equilibrium concentrations of TMP at various pH values were calculated by Equations (4) through (11).

\[ \text{TMP}^{2+} \leftrightarrow \text{TMP}^+ + \text{H}^+ \quad \text{pKa}_1 = 3.2 \]  

(4)

\[ \text{TMP}^+ \leftrightarrow \text{TMP} + \text{H}^+ \quad \text{pKa}_2 = 7.1 \]  

(5)

\[ \delta_{\text{TMP}^{2+}} = \frac{[\text{TMP}^{2+}]}{[\text{TMP}^{2+}] + [\text{TMP}^+] + [\text{TMP}]} = \frac{1}{\frac{1}{1 + \frac{\text{H}^+}{[\text{H}^+]}} + \frac{1}{\text{pK}_{a1}} \frac{\text{H}^+}{[\text{H}^+]}} \]  

(6)

\[ \delta_{\text{TMP}^+} = \frac{[\text{TMP}^+]}{[\text{TMP}^{2+}] + [\text{TMP}^+] + [\text{TMP}]} = \frac{1}{\frac{1}{1 + \frac{\text{H}^+}{[\text{H}^+]}} + \frac{1}{\text{pK}_{a2}} \frac{\text{H}^+}{[\text{H}^+]}} \]  

(7)

\[ \delta_{\text{TMP}} = \frac{[\text{TMP}]}{[\text{TMP}^{2+}] + [\text{TMP}^+] + [\text{TMP}]} = \frac{1}{\frac{1}{\text{pK}_{a1}} \frac{\text{H}^+}{[\text{H}^+]}} + \frac{1}{\frac{1}{\text{pK}_{a2}} \frac{\text{H}^+}{[\text{H}^+]}} \]  

(8)

\[ [\text{TMP}^{2+}] = \delta_{\text{TMP}^{2+}} [\text{ToTal TMP}] = \frac{(10^{-pH})^2}{(10^{-pH})^2 + (10^{-pH})(10^{-pK_{a1}}) + (10^{-pK_{a2}})} [\text{ToTal TMP}] \]  

(9)

\[ [\text{TMP}^+] = \delta_{\text{TMP}^+} [\text{ToTal TMP}] = \frac{(10^{-pH})(10^{-pK_{a1}})}{(10^{-pH})^2 + (10^{-pH})(10^{-pK_{a1}}) + (10^{-pK_{a1}})(10^{-pK_{a2}})} [\text{ToTal TMP}] \]  

(10)

\[ [\text{TMP}] = \delta_{\text{TMP}} [\text{ToTal TMP}] = \frac{(10^{-pK_{a1}})(10^{-pK_{a2}})}{(10^{-pH})^2 + (10^{-pH})(10^{-pK_{a1}}) + (10^{-pK_{a1}})(10^{-pK_{a2}})} [\text{ToTal TMP}] \]  

(11)

where, \( \delta_{\text{TMP}^{2+}} \), \( \delta_{\text{TMP}^+} \) and \( \delta_{\text{TMP}} \) are the distributed decentralization of TMP\(^{2+}\), TMP\(^+\) and TMP, respectively.

2.3. Kinetic Model Development

A kinetic model was developed for the UV/free chlorine process regarding the degradation of TMP. Because the experimental sample data is cumbersome and the numerical value is large, the numerical value calculated by using the sample derivation (SD) is small. The unknown rate constants were estimated by fitting the experimental data and the genetic algorithm (GA) was implemented to minimize the sample derivation (SD) (SD was also the objective function (OF)), which is given by Equation (12).

\[ \text{SD} = \sqrt{\frac{1}{n-1} \sum [(C_{\text{exp}} - C_{\text{cal}})/C_{\text{exp}}]^2} \]  

(12)

where \( n \) is the number of the points in the experimental data and \( C_{\text{exp}} \) (mM) and \( C_{\text{cal}} \) (mM) are the experimental and calculated concentrations of TMP at each time point, respectively.

In order to describe the kinetic behavior of the degradation of TMP, the mass balance equation of each of the species in the UV/free chlorine process consisted of an ordinary
differential equations (ODEs) system. The genetic algorithm was implemented to solve the ODEs system. This method is more accurate and advanced in the process of fitting and modeling, so it is adopted by us. This is not involved in the results of Wu et al. in 2016 [3].

The meaning of Equation (12) is to express the standard relative mean square error limit of the theoretical calculated data and the experimental data. The goal of the objective function’s optimization is to reduce the gap between the theoretical calculated results and the experimental values as far as possible, so as to improve the accuracy of the fitting, characterize the TMP degradation dynamics and solving the ODEs system more accurately. It aims to minimize as much as possible the error between the calculated and experimental values of the differential equation using the fitting rate constant as a parameter. Moreover, the genetic algorithm can deal with any form of target function and has the global search ability in the probabilistic sense, so we use the genetic algorithm to minimize Equation (12). Hence, its convergence performance is better, which is also more advanced in the fitting and modeling process than Wu et al. 2016 [3].

3. Results and Discussion

3.1. Effect of pH

According to the literature, the TMP had three forms, such as TMP$^{2+}$, TMP$^+$ and TMP (shown in Figure S4) [9]. Table 1 lists the molar distributions for the free chlorine and TMP, ranging from pH 5 to pH 8 (calculated according to Equations (1)–(11)). At a pH of 5, the HOCl and TMP$^+$ were the dominant species. As the pH increased to 8, the OCl$^−$ and TMP became the dominant species.

Table 1. Ionic species of the HOCl and TMP for the various pH values.

| pH | HOCl (Mole %) | OCl$^−$ (Mole %) | TMP$^{2+}$ (Mole %) | TMP$^+$ (Mole %) | TMP (Mole %) |
|----|---------------|------------------|---------------------|------------------|-------------|
| 5  | 99.7060       | 0.2940           | 1.5480              | 97.6760          | 0.7760      |
| 6  | 97.1330       | 2.8670           | 0.1470              | 92.5050          | 7.3480      |
| 7  | 77.2130       | 22.7870          | 0.0090              | 55.7260          | 44.2650     |
| 8  | 25.3090       | 74.6910          | 0.0002              | 11.1816          | 88.8183     |

3.1.1. Effect of pH on the Oxidation of the Free Chlorine

The initial degradation rate of the TMP induced by the free chlorine alone (which was the initial chlorination rate of TMP) was calculated by Equation (13).

$$-\frac{d[\text{TMP Total}]}{dt} = k_{\text{HOCl/TMP}}^{\text{2+}} [\text{HOCl}]_0 [\text{TMP}^{2+}]_0 + k_{\text{HOCl/TMP}}^{\text{+}} [\text{HOCl}]_0 [\text{TMP}^+]_0 + k_{\text{HOCl/TMP}} [\text{HOCl}]_0 [\text{TMP}]_0$$

$$+ k_{\text{OIC}−/\text{TMP}^{2+}} [\text{OIC}−]_0 [\text{TMP}^{2+}]_0 + k_{\text{OIC}−/\text{TMP}^+} [\text{OIC}−]_0 [\text{TMP}^+]_0 + k_{\text{OIC}−/\text{TMP}} [\text{OIC}−]_0 [\text{TMP}]_0$$

(13)

where $k_{\text{HOCl/TMP}^{2+}}$, $k_{\text{HOCl/TMP}^+}$, $k_{\text{HOCl/TMP}}$, $k_{\text{OIC}−/\text{TMP}^{2+}}$, $k_{\text{OIC}−/\text{TMP}^+}$ and $k_{\text{OIC}−/\text{TMP}}$ were the estimated rate constants of the second-order reactions between the free chlorine and each form of TMP, measured in M$^{-1}$s$^{-1}$; the [HOCl]$_0$ was the initial concentration of the HOCl, measured in M; the [OCl$^−$]$_0$ was the initial concentration of the OCl$^−$, measured in M; the [TMP$^{2+}$]$_0$ was the initial concentration of the TMP$^{2+}$, measured in M; the [TMP$^+$]$_0$ was the initial concentration of the TMP$^+$, measured in M; and the [TMP]$_0$ was the initial concentration of TMP, measured in M. The [HOCl]$_0$, [OCl$^−$]$_0$, [TMP$^{2+}$]$_0$, [TMP$^+$]$_0$ and [TMP]$_0$ were calculated by Equations (1)–(11). The initial chlorination rates of TMP under the various pH conditions are shown in Figure 1. Accordingly, the TMP had the fastest initial chlorination rate at a pH of 7.2. The kinetic model also predicted the time required for the degradation of 90% and 99% of the TMP using the free chlorine alone under the various pH conditions (shown in Figure S7). It was predicted that the TMP needed more than 1000 h to achieve the degradation of 99%, if the pH was maintained at 8.2.
Figure 1. The initial chlorination rates of TMP under the various pH conditions.

The experimental and calculation data for the oxidation of TMP by the free chlorine alone under the various conditions of the pH are shown in Figure 2. In order to estimate the rate constants for the second-order reactions between the free chlorine and each form of TMP (Reaction Nos. 71–76 in Table S1), all the experimental data of the free chlorine alone, which oxidized TMP, were fitted simultaneously. The GA was used to achieve the minimum objective function (OFmin, Equation (12)), with the value of 0.124. The fitting results are shown in Figure 1. The values of the estimated rate constants are listed in Table S1.

Figure 2. Fitting results of the chlorination of TMP under various pH. Conditions: [TMP]₀ = 0.01 mM, [free chlorine]₀ = 0.05 mM.

For the oxidation of the free chlorine alone, the impact of pH on the chlorination rate of TMP could be explained as below. The TMP was the best nucleophile (due to the non-protonation of the nucleophilic N groups) and the non-protonated TMP had the largest rate constant with the HOCl. The chlorination of TMP had the fastest rate at a pH of around 7.2 due to the dominancy of the HOCl, TMP⁺ and TMP species under this condition and the large rate constants between the HOCl and TMP⁺ or HOCl and TMP.
With the increase in pH (which was larger than 8), the chlorination rate of TMP became very slow due to the fact that the OCI− and the TMP were the dominant species under this condition, and the rate constant between the OCI− and the TMP was very small (0.01 M−1s−1). Therefore, as discussed above, the time required to degrade 99% of TMP was extremely long at a pH larger than 8. However, the UV/free chlorine process can achieve faster degradation of TMP and transform it into small molecules with less toxicity by strong oxidative free radicals.

3.1.2. Effect of pH on the UV/Free Chlorine Process

The experimental data for the degradation of TMP in the UV/free chlorine process under the various pH conditions are shown in Figure S5. The kinetic data for the reaction of TMP with each of the reactive radicals has rarely been reported in the literature. Hence, in order to estimate the rate constants of the second-order reactions between theCl•, Cl2•−, and ClO•, and each form of TMP (Reaction Nos. 59–70 in Table S1), all the experimental data of the UV/free chlorine process, which oxidized TMP under the various pH conditions, were simultaneously fitted. The GA was used to achieve the minimum objective function (OFmin was achieved to be 0.506). The fitting results are shown in Figure 3.

![Figure 3. Fitting results for the UV/free chlorine process degradation of TMP under various pH levels.
Conditions: [TMP]0 = 0.01 mM, [free chlorine]0 = 0.05 mM, UV light intensity = 9.45 × 10−7 Einstein/L.s.](image)

According to Figure 3, for all the pH conditions, the differences between the model simulation and the experimental data were large when the time exceeded 1000 s. After 1000 s, the experimental data showed that the TMP was almost not degraded, which meant that the residual free chlorine was small. However, the results of the model simulation showed that the TMP was still degrading after 1000 s, and the model predicted that the residual free chlorine ranged from 30% to 40% after a time of 1200 s for the pH values ranging from 6.1 to 8.2 (shown in Figure S8). The large differences between the model results and the experimental data were attributed to the fact that the TMP was a large molecule, which generated many by-products during the degradation of TMP and some of the by-products might react rapidly with the free chlorine. However, the current version of the kinetic model did not include the by-products and the relevant reactions.

For the UV/free chlorine process, the higher pH (such as pH > 8) inhibited the degradation rate of TMP due to the fact that the free chlorine existed as the HOCl in the acidic or weakly basic conditions (pH < 7.35); existed as the HOCl and the OCI− in the neutral or weakly alkaline conditions (7.35 < pH < 8); and existed as the OCI− in the alkaline conditions (pH > 8) [10]. HOCl’s molar absorption coefficient and lower extinction coefficient compared to OCI− resulted in an increasing efficiency in UV utilization as
well as the generation of more HO• and Cl•. Another reason for the inhibition of the degradation rate of TMP was that the free chlorine alone destroyed TMP slower at a high pH than low pH, as discussed before.

3.2. Effect of Oxidant Dosage on UV/Free Chlorine Process

For the AOPs based on the UV, the oxidant dosage affected not only the degradation rate of the organic contaminant but also the energy consumption and the operational costs. Therefore, it was critical to consider the efficiency of the treatment process combined with the energy consumption. One such measurement was the EE/O, the electrical energy required to decrease the concentration of the organic contaminants by one order of magnitude. In a batch reactor, the EE/O was calculated as given by Equation (14).

\[
EE/O = \frac{P \times t}{V \times \log(C_i/C_f)} + \frac{C \times E \times 0.0022lb}{gram \times \log(C_i/C_f)},
\]

where \( P \) is the total power of the lamp, measured in kW; \( t \) is the irradiation time, measured in s; \( V \) is the working volume; measured in m\(^3\); \( C_i \) and \( C_f \) are the initial and final concentrations of the target organic compound, measured in M; \( C \) is the oxidant concentration, measured in g/L; and \( E \) is the energy used for the production of the oxidant, measured in kWh/lb. Figure 4a shows the heat map of the EE/O for the degradation of TMP with UV. According to the heat map of the EE/O, there was a minimum EE/O, which depended on the free chlorine dosage and the UV light intensity. For a certain UV light intensity (such as \( 2.56 \times 10^{-7} \) Einstein/L s), a low dosage free chlorine absorbed a very small fraction of the photons and produced the insufficient reactive radicals, which caused the large EE/O. With the increase in the free chlorine dosage, more photons were absorbed, which produced more reactive radicals and decreased the EE/O. With the further increase in the free chlorine dosage from the optimum dosage (such as increasing one time from 0.064 mM to 0.128 mM), the more HO• and Cl• were scavenged by the free chlorine to generate more ClO•, which was the dominant species to destroy TMP (as discussed in Section 3.6). However, the concentration of the ClO• increased by less than one fold (which meant that when the free chlorine dosage increased from 0.064 mM to 0.128 mM, the integral average concentration of the ClO• increased from \( 1.16 \times 10^{-9} \) M to \( 1.84 \times 10^{-9} \) M), which was due to the slower decay rate of the free chlorine with the increase in its dosage (Figure S9). Overall, the energy consumption by the free chlorine was increased one fold but the degradation rate of TMP was enhanced by less than one fold, which increased the EE/O.

3.3. Effect of Chloride Ion on the UV/Free Chlorine Process

The chloride ion (Cl\(^-\)) was ubiquitous in the surface water. According to Figure 5a, the 1 mM to 5 mM concentration of the Cl\(^-\) slightly reduced the degradation rate of TMP. The Cl\(^-\) had negligible effect due the reasons that (1) the HO• was not scavenged by the Cl\(^-\), as reported by many studies [11]; and (2) the Cl\(^-\) rapidly reacted with the Cl• to form the Cl\(_2\)• (Cl• + Cl\(^-\) → Cl\(_2\)•). However, the Cl\(_2\)• dissociated fast to generate the Cl• again (Cl\(_2\)• → Cl\(^-\) + Cl•) rather than reacting fast with the TMP.
3.4. Effect of Bicarbonate/Carbonate on the UV/Free Chlorine Process

The bicarbonate and carbonate ions (HCO$_3^-$/CO$_3^{2-}$) were the common components in the water matrix. At the pH of 7, the molar distribution of the H$_2$CO$_3$ was 17.96%, the molar distribution of the HCO$_3^-$ was 82% and the molar distribution of the CO$_3^{2-}$ was 0.04% [12]. Therefore, HCO$_3^-$ was the dominant species at the neutral condition. The reactions, given in Equations (15)–(18), indicated that HCO$_3^-$ reacted fast with HO•, Cl•, Cl$_2$•$^-$ and ClO•$^-$ to generate CO$_3^{2-}$:

\[
\begin{align*}
\text{HO•} + \text{HCO}_3^- & \rightarrow \text{H}_2\text{O} + \text{CO}_3^{2-} \quad k = 8.5 \times 10^6 \text{ M}^{-1}\text{s}^{-1} \quad (15) \\
\text{Cl•} + \text{HCO}_3^- & \rightarrow \text{H}_2\text{O} + \text{CO}_3^{2-} \quad k = 2.2 \times 10^8 \text{ M}^{-1}\text{s}^{-1} \quad (16) \\
\text{Cl}_2\cdot^- + \text{HCO}_3^- & \rightarrow \text{CO}_3^{2-} + 2\text{Cl}^- + \text{H}^+ \quad k = 8.0 \times 10^7 \text{ M}^{-1}\text{s}^{-1} \quad (17) \\
\text{ClO•}^- + \text{HCO}_3^- & = \text{CO}_3^{2-} + \text{ClO}^- + \text{H}^+ \quad (18)
\end{align*}
\]
3.3. Effect of Chloride Ion on the UV/Free Chlorine Process

The chloride ion (Cl$^-$) was ubiquitous in the surface water. According to Figure 5a, the 1 mM to 5 mM concentration of the Cl$^-$ slightly reduced the degradation rate of TMP. The Cl$^-$ had negligible effect due to the reasons that (1) the HO• was not scavenged by the Cl$^-$, as reported by many studies [11]; and (2) the Cl$^-$ rapidly reacted with the Cl• to form the Cl2• (Cl• + Cl$^-$ → Cl2•$^-$). However, the Cl2•$^-$ dissociated fast to generate the Cl• again (Cl2•$^-$ → Cl• + Cl$^-$) rather than reacting fast with the TMP.

Figure 5. Effect of the water matrix components on the degradation of TMP in the UV/free chlorine process. (a) Effect of chloride ion (Cl$^-$), [TMP]$_0$ = 0.01 mM, [free chlorine]$_0$ = 0.05 mM, [Cl$^-$]$_0$ = 1 mM to 5 mM; (b) Effect of HCO$_3^-$ / CO$_3^{2-}$ [TMP]$_0$ = 0.01 mM [free chlorine]$_0$ = 0.05 mM, [HCO$_3^-$ / CO$_3^{2-}$]$_0$ = 1 mM to 5 mM; (c) effect of NOM, [TMP]$_0$ = 0.01 mM [free chlorine]$_0$ = 0.05 mM, [NOM]$_0$ = 1 mg/L to 5 mg/L. UV light intensity = 9.45 × 10$^{-7}$ Einstein/L s.
As shown in Figure 5b, the 1 mM to 5 mM concentration of the HCO$_3^-$ /CO$_3^{2-}$ slightly reduced the degradation rate of TMP. The HCO$_3^-$ /CO$_3^{2-}$ had a negligible effect, which could be explained as below. The reactive radicals were scavenged by the HCO$_3^-$ /CO$_3^{2-}$. However, the generated CO$_3^{•-}$ reacted very fast with the organic compounds containing the amine groups (such as the TMP) [13]. Other previous studies have also reported that the 1 mM concentration of the HCO$_3^-$ slightly reduced the degradation rate of the antibiotics in the UV/free chlorine process (such as trimethoprim, salbutamol, clenbuterol and ractopamine). HCO$_3^-$ has the ability to quench free radicals [14]. Therefore, the reaction equilibrium constant is more significant for Cl• radical quenching and Cl• plays an important role in the degradation process of the free chlorine process, which can explain the slight decrease in degradation rate.

3.5. Effect of NOM on the UV/Free Chlorine Process

The NOM was commonly found in the water matrix. Therefore, the impact of the NOM on the UV/free chlorine process was investigated. According to Figure 5c, (1) in the absence of the NOM, the TMP was efficiently removed by 90% in 9 min; and (2) in the presence of the NOM, ranging from 1 mg/L to 5 mg/L, the TMP was removed by 85% to 70% in 9 min. Therefore, the NOM inhibited the degradation rate of TMP due to the reasons that (1) the NOM absorbed the UV light, and its molar absorption coefficient was determined to be 0.041 L/mg cm in this study (shown in Figure S10); and (2) the NOM scavenged each of the reactive radicals. In addition, the time-dependent concentration profiles of the free chlorine under the various concentration conditions of the NOM are shown in Figure S12.

Figure 4b shows the EE/O heat map for the degradation of TMP with 3 mg/L NOM. According to Figure 4b, the minimum EE/O was calculated to be 0.311 kWh/m$^2$ photolysis, reactive radicals and the free chlorine, which degraded the TMP, are calculated by Equations (19)–(24).

3.6. Relative Contribution of the Reactive Species, Photolysis and Chlorination

In the UV/free chlorine process, the degradation of the TMP was induced by the three factors, which included (1) the oxidation by free chlorine; (2) the photolysis by the ultraviolet light; and (3) the oxidation by the reactive radicals (HO•, Cl•, Cl$_2$•$^-$ and ClO•). According to the relevant literature reports [15], the relative average contributions of the photolysis, reactive radicals and the free chlorine, which degraded the TMP, are calculated by Equations (19)–(24).

Contribution of ClO•

\[
\begin{align*}
\text{Contribution of ClO•} & = \int_{t_0}^{t_f} \left( \frac{k_{\text{ClO•}/R[ClO•][R]} \cdot \text{R} + k_{\text{Cl•}/R[Cl•][R]} \cdot \text{R} + k_{\text{Cl}_2•^-/R[Cl}_2•^->[R]} \cdot \text{R} + k_{\text{ClO•}/R[ClO•][R]} \cdot \text{R} + r_{\text{UV}} + r_{\text{HOCl}} \right) \ dt \right) / (t_f - t_0) \quad (19)
\end{align*}
\]

Contribution of HO•

\[
\begin{align*}
\text{Contribution of HO•} & = \int_{t_0}^{t_f} \left( \frac{k_{\text{HO•}/R[HO•][R]} \cdot \text{R} + k_{\text{Cl•}/R[Cl•][R]} \cdot \text{R} + k_{\text{Cl}_2•^-/R[Cl}_2•^->[R]} \cdot \text{R} + k_{\text{ClO•}/R[ClO•][R]} \cdot \text{R} + r_{\text{UV}} + r_{\text{HOCl}} \right) \ dt \right) / (t_f - t_0) \quad (20)
\end{align*}
\]

Contribution of Cl•

\[
\begin{align*}
\text{Contribution of Cl•} & = \int_{t_0}^{t_f} \left( \frac{k_{\text{Cl•}/R[Cl•][R]} \cdot \text{R} + k_{\text{Cl•}/R[Cl•][R]} \cdot \text{R} + k_{\text{Cl}_2•^-/R[Cl}_2•^->[R]} \cdot \text{R} + k_{\text{ClO•}/R[ClO•][R]} \cdot \text{R} + r_{\text{UV}} + r_{\text{HOCl}} \right) \ dt \right) / (t_f - t_0) \quad (21)
\end{align*}
\]
where [HO•], [Cl•], [Cl−•], [ClO•] and [R] are the concentrations of the reactive radicals and the TMP as a function of time; \( r_{\text{UV}} \) is the photolysis rate of the TMP at time \( t \), measured in M·s\(^{-1}\); \( r_{\text{HOCl}} \) is the chlorination rate of the TMP at time \( t \), measured in M·s\(^{-1}\); and \( t_0 \) and \( t_f \) are the initial and final time, respectively, which were 0 s and 1200 s, respectively.

According to Figure 6, the ClO• made the highest contribution to the degradation of TMP for the various pH values. The ClO• had the highest concentration at a pH of 8.2, which was mainly due to the fact that the main form of the free chlorine was ClO• under the alkaline conditions. The rate constant of the reaction between the OH• and ClO− was 10 times that of the OH• and HClO. Therefore, the ClO• produced at a pH of 8.2 was more than those at a pH of 6.1 and 7.2. The second dominant contributor to the degradation of TMP was the free chlorine at a pH of 6.1 and 7.2, while Cl• was the second dominant contributor at a pH of 8.2. The degradation of TMP induced by the UV and Cl−• was negligible. Therefore, the relative contributions of the UV and Cl−• are not shown in the Figure 6.

Figure 6. Relative average contribution of the UV, reactive radicals and free chlorine under various pH levels. [TMP]\(_0\) = 0.01 mM, [free chlorine]\(_0\) = 0.05 mM, UV light intensity = 9.45 \times 10^{-7} \text{ Einstein/L.s}. 

\[
\text{Contribution of Cl}_2\text{•}^- = \int_{t_0}^{t_f} \left( \frac{k_{\text{Cl}_2\text{•}^-/[R][ClO•]} + k_{\text{Cl}_2\text{•}^-/[R][Cl•]} + k_{\text{Cl}_2\text{•}^-/[R][ClO•]} + r_{\text{UV}} + r_{\text{HOCl}}}{k_{\text{HO•}/[R][ClO•]} + k_{\text{Cl•}/[R][Cl•]} + k_{\text{Cl•}/[R][ClO•]} + r_{\text{UV}} + r_{\text{HOCl}}} \right) dt \right) / (t_f - t_0) \tag{22}
\]

\[
\text{Contribution of UV} = \int_{t_0}^{t_f} \left( \frac{r_{\text{UV}}}{k_{\text{HO•}/[R][ClO•]} + k_{\text{Cl•}/[R][Cl•]} + k_{\text{Cl•}/[R][ClO•]} + r_{\text{UV}} + r_{\text{HOCl}}} \right) dt \right) / (t_f - t_0) \tag{23}
\]

\[
\text{Contribution of free chlorine} = \int_{t_0}^{t_f} \left( \frac{r_{\text{HOCl}}}{k_{\text{HO•}/[R][ClO•]} + k_{\text{Cl•}/[R][Cl•]} + k_{\text{Cl•}/[R][ClO•]} + r_{\text{UV}} + r_{\text{HOCl}}} \right) dt \right) / (t_f - t_0) \tag{24}
\]
4. Conclusions

It was found that the UV/free chlorine process was more effective and faster for the oxidation of TMP than the UV alone or free chlorine alone process. In the UV/free chlorine process, it was concluded that (1) the high pH (pH > 8) and the NOM inhibited the degradation rate of TMP; (2) the HCO$_3^-$/CO$_3^{2-}$ (with a concentration of 1 to 5 mM) and Cl$^-$ (with a concentration of 1 to 5 mM) slightly reduced the degradation rate of TMP; and (3) the increase in the free chlorine dosage enhanced the degradation rate of TMP. A kinetic model was developed to simulate the degradation of TMP, and successfully estimated the unknown rate constants involved in this process. Considering the estimated kinetic data and the predicted concentrations of each of the reactive radicals, it was found that ClO$\bullet$ was the dominant species that degraded the TMP. Furthermore, the operational conditions were also optimized, resulting in the minimum EE/O, namely, (1) for the ultrapure water, the optimum intensity of the UV light and the free chlorine dosage were 2.56 Einstein/L s and 0.064 mM, respectively, with a minimum EE/O of 0.136 kWh/m$^3$; and (2) for the water matrix containing 3 mg/L NOM, the optimum intensity of the UV light and the free chlorine dosage were 3.45 Einstein/L s and 0.172 mM, respectively, with a minimum EE/O of 0.311 kWh/m$^3$. In general, this study can facilitate the most cost-effective application of the UV/free chlorine for practical application in the future.
