Are we close to putting the anomalous perihelion precessions from Verlinde’s emergent gravity to the test?

ABSTRACT

In the framework of the emergent gravity scenario by Verlinde, it was recently observed by Liu and Prokopec that, among other things, an anomalous pericenter precession would affect the orbital motion of a test particle orbiting an isolated central body. Here, it is shown that, if it were real, its expected magnitude for the inner planets of the Solar System would be at the same level of the present-day accuracy in constraining any possible deviations from their standard perihelion precessions as inferred from long data records spanning about the last century. The most favorable situation for testing the Verlinde-type precession seems to occur for Mars. Indeed, according to recent versions of the EPM and INPOP planetary ephemerides, non-standard perihelion precessions, of whatsoever physical origin, which are larger than some $\approx 0.02 - 0.11$ milliarcseconds per century are not admissible, while the putative precession predicted by Liu and Prokopec amounts to 0.09 milliarcseconds per century. Other potentially interesting astronomical and astrophysical scenarios like, e.g., the Earth’s LAGEOS II artificial satellite, the double pulsar system PSR J0737-3039A/B and the S-stars orbiting the Supermassive Black Hole in Sgr A* are, instead, not viable because of the excessive smallness of the predicted effects for them.

keywords gravitation—celestial mechanics–ephemerides

1. Introduction

In the framework of the novel emergent gravity theory proposed by Verlinde (2016) to account for the Dark Matter phenomenology, Liu & Prokopec (2016) observed that, among other things, a test particle orbiting an isolated body of mass $M$ would experience an additional pericenter shift per orbit

$$\Delta \sigma_{\text{theo}} = \pi \sqrt{\frac{2\mu H_0}{3c^3}},$$

where $\sigma$ is the longitude of pericenter, $\mu \equiv GM$ is the gravitational parameter of the central object, $G$ is the Newtonian gravitational constant, $c$ is the speed of light in vacuum, and $H_0$ is the Hubble parameter. From Equation (1) it is useful to infer an analytical expression for a secular pericenter precession which can be conveniently compared with recent observational determinations of such an orbital effect like, e.g., the supplementary perihelion precessions of some planets of the Solar System (Fienga et al. 2011; Pitjeva & Pitjev 2013; Fienga et al. 2016).

---

1It is a broken, “dogleg” angle, defined as (Murray & Dermott 2000) $\sigma = \omega + \Omega$, where $\omega$, $\Omega$ are the argument of pericenter and the longitude of the ascending node, respectively.
Since the orbital period of a test particle is

\[ P_b = \frac{2\pi}{n_b} = 2\pi \sqrt{\frac{a^3}{\mu}}, \]

where \( n_b \) is the Keplerian mean motion and \( a \) is the semimajor axis of the orbit, it turns out

\[ \dot{\varpi}_{\text{theo}} = \frac{\Delta \varpi_{\text{theo}}}{P_b} = \mu \sqrt{\frac{H_0}{6a^3 c^3}}. \]

It is important to note that if, on the one hand, Equation 3 is proportional to \( \mu \), on the other hand, it falls off as

\[ \dot{\varpi}_{\text{theo}} \propto a^{-3/2} \]

for a given value of the central mass; thus, the more the particle is close to its parent star, the larger its expected extra-precession is. Moreover, Equation 4 is a distinctive feature of the modified model of gravity considered here which would be of great help, in principle, in discriminating Verlinde’s theory from the anomalous precessions due to other more or less viable alternative models (Adkins & McDonnell 2007; Adkins, McDonnell & Fell 2007; Iorio 2009) by taking, e.g., the ratio of the perihelion rates for a pair of planets (Iorio 2009, 2015).

The paper is organized as follows. Section 2 deals with the inner planets of the Solar System by comparing their theoretically predicted precessions \( \dot{\varpi}_{\text{theo}} \) as per Equation 2 with the most recent determinations \( \Delta \dot{\varpi}_{\text{obs}} \) of the supplementary perihelion precessions from planetary ephemerides. In Section 3, other potentially appealing astronomical and astrophysical scenarios are investigated: the terrestrial artificial satellite LAGEOS II, the double pulsar PSR J0737-3039A/B, and the S-stars orbiting the Supermassive Black Hole in the center of the Galaxy. Section 4 is devoted to our conclusions.

2. The perihelion precessions of the planets of the Solar System

The last decades have witnessed remarkable advances in the field of planetary orbit determination for almost all of the major bodies of the Solar System in view of the availability of increasingly long records of radiotechnical data (ranges and range-rates) collected by a host of spacecraft targeted to many of them. As a consequence, any possible deviations from standard, i.e. general relativistic and Newtonian, perihelion precessions are nowadays tightly constrained for several planets.

Table 1 shows the latest determinations \( \Delta \dot{\varpi}_{\text{obs}} \) of the admissible ranges for whatsoever possible anomalous perihelion precessions obtained by independent teams of astronomers with different planetary ephemerides. From a comparison with the analytically computed Verlinde-type perihelion rates \( \dot{\varpi}_{\text{theo}} \) of Equation 3 listed in Table 1 as well, it can be noted that their magnitudes are very close to the present-day level of accuracy in constraining the planetary apsidal precessions.
Table 1: The column $\dot{\varpi}_{\text{theo}}$ collects the theoretically predicted perihelion precessions, calculated for some planets of the Solar System according to Equation 3 with $H_0 = 67.6 \text{ km s}^{-1} \text{ Mpc}^{-1}$ (Grieb et al. 2016). The columns $\Delta \dot{\varpi}_{\text{obs}}$ display the supplementary perihelion precessions observationally determined for the same planets with the planetary ephemerides EPM2011 (Pitjeva & Pitjev 2013), INPOP10a (Fienga et al. 2011), INPOP15a (Fienga et al. 2016) by reducing almost one century of data of many different types with fully relativistic dynamical and measurement models; the Verlinde-type effect was not modeled in any of the ephemerides considered. They should be regarded as representative of the ranges of admissible values for any possible anomalous planetary perihelion precessions induced by whatsoever non-standard dynamical effect: they are all statistically compatible with zero. Recently, Park et al. (2017) constrained the secular precession of the orbital element $\omega + \Omega \cos I$ of Mercury to an accuracy of 1.5 mas cty$^{-1}$. About Saturn, Hees et al. (2014), in looking for possible anomalous effects on it due to a certain version of MOND, managed to constrain its perihelion precession to the 0.43 mas cty$^{-1}$ level. All the figures quoted here for the precessions, both theoretical and experimental, are in milliarcseconds per century (mas cty$^{-1}$). For the benefit of the reader, we converted the results by Pitjeva & Pitjev (2013) from milliarcseconds per year (mas yr$^{-1}$) to mas cty$^{-1}$.

|         | $\dot{\varpi}_{\text{theo}}$ | $\Delta \dot{\varpi}_{\text{obs}}$ (EPM2011) | $\Delta \dot{\varpi}_{\text{obs}}$ (INPOP10a) | $\Delta \dot{\varpi}_{\text{obs}}$ (INPOP15a) |
|---------|------------------|---------------------------------|---------------------------------|---------------------------------|
| Mercury | 0.7              | $-2.0 \pm 3.0$                  | $0.4 \pm 0.6$                   | $0.0 \pm 2.1$                  |
| Venus   | 0.3              | $2.6 \pm 1.6$                   | $0.2 \pm 1.5$                   | $-$                             |
| Earth   | 0.2              | $0.19 \pm 0.19$                 | $-0.2 \pm 0.9$                  | $-$                             |
| Mars    | 0.09             | $-0.020 \pm 0.037$              | $-0.04 \pm 0.15$                | $-$                             |
| Jupiter | 0.014            | $58.7 \pm 28.3$                 | $-41 \pm 42$                    | $-$                             |
| Saturn  | 0.006            | $-0.32 \pm 0.47$                | $0.15 \pm 0.65$                 | $0.6 \pm 2.6$                  |
from observations, at least as far as the inner planets are concerned. Instead, the orbits of the
gaseous giants Jupiter and Saturn, which, in principle, might be regarded as potentially interesting
targets because of the relative smallness of other competing precessions induced by otherwise
accurately modeled $N$-body perturbations, are known with insufficient accuracies with respect
to Equation $\mathbf{3}$. Given that the uncertainties quoted in Table $\mathbf{1}$ for Saturn already come from
analyses of multi-year radiotechnical data from the Cassini spacecraft, it is unlikely that even
the reduction of the entire data record of this probe, which, after more than 12 years in Saturn
orbit, will end its mission in September 2017 by plunging through the planet’s atmosphere
(Spilker, Edgington & Allobbi [2016]), will ameliorate the situation so much to allow for a
detection of the Verlinde-type precession of the ringed giant.

According to Table $\mathbf{1}$ the most favorable situation seems to occur, at present, for Mars.
Indeed, its predicted theoretical perihelion precession amounts to

$$\dot{\sigma}_{\text{theo}} = 0.09 \, \text{milliarcseconds per century (mas cty$^{-1}$)},$$

while the accuracy in constraining any possible anomalous precession from observations is

$$\sigma_{\Delta \dot{\sigma}_{\text{obs}}} = 0.037 \, \text{mas cty}^{-1}$$

if the EPM2011 ephemerides are considered (Pitjeva & Pitjev [2013]). Actually, the EPM2011-
based supplementary rate (Pitjeva & Pitjev [2013]) would even rule out the expected emergent
anomalous effect at a $3 - \sigma$ level since

$$\frac{|\dot{\sigma}_{\text{theo}} - \Delta \dot{\sigma}_{\text{best}}^{\text{best}}|}{\sigma_{\Delta \dot{\sigma}_{\text{obs}}}} = 3.$$  

For all the other planets, and also for Mars if the supplementary rate by the INPOP10a
ephemerides is considered, the Verlinde-type precessions $\dot{\sigma}_{\text{theo}}$ are compatible with the admissible
ranges $\Delta \dot{\sigma}_{\text{obs}}$. Recently, Park et al. [2017] considered the in-plane precession $\dot{\omega} + \Omega \cos I$
of the pericenter of Mercury by constraining it to the 1.5 mas cty$^{-1}$ level. It is still 2.1 times larger
than the Verlinde-type in-plane precession which coincides with Equation $\mathbf{3}$ since the node is not
affected by the modified model of gravity considered here.

In view of the potential opportunity offered by Mars, it is important to assess as accurately as
possible the main systematic errors which may plague such a measurement.

It has been known for a long time (Williams [1984]; Mouret et al. [2009]; Somenzi et al. [2010];
Kuchynka & Folkner [2013]) that a major source of perturbation for the orbit of Mars is represented
by the asteroids crowding in the belt located between the orbits of the red planet and Jupiter.
It is so because of the uncertainty still affecting our knowledge of some of their key physical
parameters, mainly their masses. Luckily, recent advances in modeling their dynamical action

---

Park et al. [2017] use the symbol $\sigma$ for the in-plane, unbroken angle $\omega + \Omega \cos I$. 
allowed for a sufficiently accurate determination of their overall mass for our purposes. Indeed, Pitjeva & Pitjev (2016), by means of the EPM2014 ephemerides, modeled the ensemble of such perturbers, including both the individual 301 largest asteroids and the minor ones, as a planar annulus with internal and external radii equal to 2.06 au and 3.27 au, respectively, being able to determine its total mass as

$$m_{\text{belt}} = (12.25 \pm 0.19) \times 10^{-10} \, M_\odot. \quad (8)$$

In their Table 3, Pitjeva & Pitjev (2016) worked out the nominal perihelion advance of Mars for ten revolutions due to an annulus with the aforementioned radii and $m = 10^{-10} \, M_\odot$: it amounts to

$$\Delta \omega_{10 \, \text{rev}} = 0.497285998 \, \text{mas}. \quad (9)$$

It is straightforward to infer a mismodeled perihelion precession as little as

$$\sigma_{\dot{\omega}_{\text{belt}}} = 0.04 \, \text{mas cty}^{-1}, \quad (10)$$

which is 2.25 times smaller than the expected Verlinde-type precession. Incidentally, Equation (10) explicitly shows how the asteroids, in fact, are just the dominant source of uncertainty in constraining the perihelion precession of Mars.

Another potential source of major systematic uncertainty is represented by the $N$-body perturbations due to the other planets, especially Jupiter and Saturn. We will, now, demonstrate that, luckily, they can be modeled with sufficiently high accuracy. The perihelion precession induced by a distant pointlike perturber $P$ is proportional to (Cook 1962)

$$\dot{\omega}_P \propto \frac{\mu_P}{a_P^3 n_b}, \quad (11)$$

where $n_b$ is the Keplerian mean motion of the disturbed planet. The present-day uncertainty in the Jupiter’s mass is (Le Maistre et al. 2016)

$$\sigma_{\mu_{\text{Jup}}} = 1.5 \times 10^9 \, \text{m}^3 \, \text{s}^{-2}, \quad (12)$$

which corresponds to a relative accuracy of

$$\frac{\sigma_{\mu_{\text{Jup}}}}{\mu_{\text{Jup}}} = 1 \times 10^{-8}. \quad (13)$$

Thus, Equation (11) tells us that the mismodeled perihelion precession of Mars due to Jupiter is of the order of

$$\sigma_{\dot{\omega}_{\text{Jup}}} \lesssim 0.02 \, \text{mas cty}^{-1}; \quad (14)$$

it is 4.5 times smaller than Equation (5). The ongoing Juno mission will allow, among other things, for a remarkable improvement in our knowledge of $\mu_{\text{Jup}}$ (Le Maistre et al. 2016). According to Jacobson et al. (2006), the current uncertainty in the mass of Saturn is

$$\sigma_{\mu_{\text{Sat}}} = 1.1 \times 10^9 \, \text{m}^3 \, \text{s}^{-2}, \quad (15)$$
corresponding to a relative accuracy of

\[ \frac{\sigma_{\mu_{\text{Sat}}}}{\mu_{\text{Sat}}} = 3 \times 10^{-8}. \]  

(16)

Thus, according to Equation 11, the resulting mismodeled perihelion precession of Mars due to Saturn is of the order of

\[ \sigma_{\dot{\varpi}_{\text{Sat}}} \lesssim 0.002 \text{ mas cty}^{-1}, \]  

(17)

which is negligible with respect to Equation 5.

The stationary component of the general relativistic field of the Sun, yielding the gravitomagnetic Lense-Thirring effect (Lense & Thirring 1918) due to the solar angular momentum \( S_\odot \), has not yet been modeled in all the modern ephemerides; thus, in principle, it may act as a further source of systematic uncertainty. In a coordinate system with its fundamental plane aligned with the Sun’s equator, the nominal Lense-Thirring perihelion precession of Mars amounts to (Lense & Thirring 1918)

\[ \dot{\varpi}_{\text{LT}} = \frac{2GS}{c^2a^3(1-e^2)^{3/2}} = -0.03 \text{ mas cty}^{-1}, \]  

(18)

whose magnitude is 3 times smaller than Equation 5. In Equation 18, \( e, I \) are the orbital eccentricity and the inclination\(^3\) of the orbital plane to the equator of the Sun, respectively.

A further potential systematic bias is represented by the competing perihelion precession (Capderou 2005)

\[ \dot{\varpi}_{J_2} = \frac{3n_bR^2J_2(3 - 4\cos I + 5\cos 2I)}{8a^2(1-e^2)^2}, \]  

(19)

due to the Sun’s quadrupole mass moment \( J_2 \) which was recently determined by Park et al. (2017) to 4% as

\[ J_2 = (2.25 \pm 0.09) \times 10^{-7}. \]  

(20)

In Equation 19, which holds in a coordinate system whose fundamental plane is aligned with the Sun’s equator, \( R \) is the solar equatorial radius. It turns out that the mismodeled perihelion precession of Mars due to the Sun’s oblateness is

\[ \sigma_{\dot{\varpi}_{J_2}} = 0.008 \text{ mas cty}^{-1}, \]  

(21)

which is about 10 times smaller than Equation 5.

The static, Schwarzschild-like component of the general relativistic field of the Sun, which is fully modeled in the softwares of the astronomers who produce the planetary ephemerides, yields a nominal gravitoelectric perihelion precession of Mars as large as

\[ \dot{\varpi}_{\text{GE}} = \left( \frac{2 + 2\gamma - \beta}{3} \right) \frac{3n_b\mu}{c^2a^2(1-e^2)} = 1350.93 \text{ mas cty}^{-1}. \]  

(22)

\(^3\)The inclination of the orbital plane of Mars to the Sun’s equator is \( I = 5.65 \text{ deg}. \)
In Equation 22, $\gamma$, $\beta$ are the most important PPN parameters, which are equal to 1 in general relativity. The actual mismodeling in Equation 22 is due to the uncertainties in $\gamma$, $\beta$. The most accurate determination of $\gamma$ is currently at the (Bertotti, Iess & Tortora 2003)

$$\sigma_\gamma = 2 \times 10^{-5}$$

level, while $\beta$ was recently determined with an accuracy (Park et al. 2017)

$$\sigma_\beta = 4 \times 10^{-5}.$$ 

Thus, the resulting uncertainty in the gravitoelectric perihelion precession of Mars is

$$\sigma_{\dot{q}_{\text{GE}}} = 0.025 \text{ mas ct}^{-1},$$

which is 3.6 times smaller than Equation 5.

Table 2 summarizes the competing precessions of the perihelion of Mars.

However, caution is in order since dedicated, covariance-based, global data reduction for all the major bodies of the Solar System for which accurate radio-tracking is available should be performed by explicitly modeling the exotic gravitational dynamics considered here. That is in order to avoid, or, at least, reduce, the risk that part of the putative anomalous signature, if really existent, may be removed from the post-fit residuals being partly absorbed in the estimated values of, say, the planetary initial conditions. On the other hand, our analysis shows that the perspectives of effectively putting the Verlinde-type emergent gravity to the test in the Solar System seems promising, especially if Mars is considered in view of the steady improvements in its orbit determination allowed by the accurate tracking of the remarkable number of present and future landers and orbiters (Konopliv et al. 2011). Furthermore, also the orbit of Mercury should be improved in the next years thanks to the steady analysis of the entire data record of the MESSENGER spacecraft, of which the work by Park et al. (2017) is a first step and the

*For an earlier analysis based on shorter data record, see Verma et al. (2014).*

Table 2: Main unmodeled/mismodeled perihelion rates of Mars, in mas ct$^{-1}$, acting as systematic errors for a potential measurement of the Verlinde-type precession $\dot{q}_{\text{theo}} = 0.09$ mas ct$^{-1}$.

| Dynamical effect          | Uncertainty in the key parameter(s)                                                                 | Perihelion precession |
|---------------------------|-----------------------------------------------------------------------------------------------------|------------------------|
| Asteroid belt             | $\sigma_{\text{belt}} = 1.9 \times 10^{-11} M_\odot$ (Pitjeva & Pitjev 2016)                      | 0.04                   |
| Lense-Thirring            | Nominal                                                                                             | -0.03                  |
| Schwarzschild             | $\sigma_\gamma = 2 \times 10^{-5}$ (Bertotti, Iess & Tortora 2003)                                  | 0.025                  |
|                           | $\sigma_\beta = 4 \times 10^{-5}$ (Park et al. 2017)                                               |                        |
| Jupiter attraction        | $\sigma_{\mu_{\text{Jup}}} = 1.5 \times 10^9$ m$^3$s$^{-2}$ (Le Maistre et al. 2016)             | 0.02                   |
| Solar oblateness          | $\sigma_{J_2} = 9 \times 10^{-9}$ (Park et al. 2017)                                               | 0.0086                 |
| Saturn attraction         | $\sigma_{\mu_{\text{Sat}}} = 1.1 \times 10^9$ m$^3$s$^{-2}$ (Jacobson et al. 2006)              | 0.002                  |
future BepiColombo mission (Benkhoff et al. 2010; Schettino & Tommei 2016), scheduled to be launched in 2018.

Finally, as we will see in the next Section, it does not seem plausible that other astronomical and astrophysical systems can become viable test-beds for the emergent gravity scenario considered here in a foreseeable future.

3. Other astronomical and astrophysical scenarios

Indeed, as far as the Earth’s laser ranged LAGEOS II satellite is concerned, Equation 3 returns a perigee precession as little as 0.007 milliarcseconds per year (mas yr$^{-1}$) for it. Suffice it to say that the standard, Schwarzschild-like, general relativistic perigee precession of LAGEOS II, which is larger than the Verlinde-type precession by a factor of $10^6$, was recently measured with a claimed accuracy of about 2% (Lucchesi & Peron 2010, 2014).

Also the double pulsar system, PSR J0737-3039A/B (Burgay et al. 2003; Lyne et al. 2004), may not be fruitfully used. Indeed, while the current accuracy in determining its periastron precession amounts to about 2.5 arcseconds per year (arcsec yr$^{-1}$) (Kramer et al. 2006), Equation 3 tells us that its expected Verlinde-type precession is just 0.01 arcsec yr$^{-1}$.

Unfortunately, also the stellar system orbiting the Supermassive Black Hole in the Galactic center (Gillessen et al. 2009; Ghez et al. 2008) does not offer better perspectives. Indeed, according to Equation 3, the expected anomalous periastron precession of the S-star S0-102 (Meyer et al. 2012) is 31 mas cty$^{-1}$; it is hopelessly smaller than the standard general relativistic precession $\dot{\omega}_{GR} = 32.5$ arcsec yr$^{-1}$, which has not yet been measured, by a factor of $10^{-6}$.

4. Conclusions

Thus, it seems that, as far as the anomalous pericenter precession is concerned, the emergent gravity scenario by Verlinde may not be put to the test anywhere in any foreseeable future with the notable exception of the Solar System’s planetary motions. Indeed, the current accuracy in constraining any possible anomalous perihelion rates from the latest planetary ephemerides is at the same level, or perhaps even better for Mars, of the expected Verlinde-type precessions for the inner planets. Just as an example, the predicted anomalous perihelion precession of Mars amounts to 0.09 milliarcseconds per century, while the EPM2011 ephemerides are able to constrain any possible deviations from standard (prograde) perihelion precessions to the 0.017 milliarcseconds per century level. Further improvements in the orbit determination of Mercury are expected from the approved BepiColombo mission, while also the knowledge of the orbit of Mars will be steadily improved in view of the continuous tracking of an increasing number of landers and spacecraft. A global fit of purposely modified dynamical models including the Verlinde-type gravity to extended
records of accurate radiotechnical measurements for several major bodies of the Solar System would be an important step towards the practical implementation of such an ambitious goal.
