Investigation performed at Shimada Hospital, Habikino, Japan

Background: Few studies have attempted to identify risk factors associated with irreparable meniscal tears at anterior cruciate ligament reconstruction (ACLR) and to describe follow-up data, such as the failure rate, after meniscal repair.

Purpose: To investigate the associations of age, sex, body mass index (BMI), time to surgery (TTS), and preinjury Tegner score with the presence of meniscal injuries and irreparable meniscal tears at primary ACLR.

Study Design: Cross-sectional study; Level of evidence, 3.

Methods: A retrospective review was performed on 784 patients who underwent primary ACLR by a single surgeon between 2005 and 2017 (406 men and 378 women; mean age, 25.8 years; mean BMI, 23.1; median TTS, 3 months; median preinjury Tegner score, 7). All patients had a minimum follow-up of 12 months (mean postoperative follow-up, 33.0 months). Multivariate logistic regression analysis was conducted to determine the association of patient variables with the presence of meniscal injuries and irreparable meniscal tears during primary ACLR.

Results: The risk factor for medial meniscal injuries was TTS ≥3 months (odds ratio [OR], 4.213; 95% CI, 3.104-5.719; P < .001). The presence of irreparable medial meniscal tears increased with older age (OR, 1.053; 95% CI, 1.024-1.084; P < .001), higher BMI (OR, 1.077; 95% CI, 1.003-1.156; P = .042), and TTS ≥3 months (OR, 1.794; 95% CI, 1.046-3.078; P = .034). On multivariate analysis, none of the variables were significantly associated with lateral meniscal injuries and irreparable meniscal tears. The failure rate, defined as patients who needed additional medial meniscal surgery after medial meniscal repair, was 4.6%.

Conclusion: Time from ACL injury to reconstruction of ≥3 months was strongly associated with medial meniscal injuries and irreparable medial meniscal tears at primary ACLR. Older age and increased BMI were also risk factors for the presence of irreparable medial meniscal tears at ACLR.

Keywords: knee; anterior cruciate ligament; meniscus; irreparable meniscal tear

Anterior cruciate ligament (ACL) injury is one of the most common injuries in sport. Although return-to-play rates after ACL reconstruction (ACLR) are higher12,23,31 than those after nonoperative treatment,11,34,37 some athletes with ACL deficiency resume previous levels of activity without surgery.21 However, an ACL deficiency results in abnormal knee kinematics and instability and leads to meniscal and cartilage injury due to recurrent pivoting trauma.13,14,15 Even less active patients have an increased risk of medial meniscal and cartilage injuries compared with active patients.36

Several previous studies28,33,40 have reported the presence of meniscal injury after ACL injury and have recommended early ACLR. Although the meniscus should be preserved as much as possible at ACLR, some meniscal tears are irreparable owing to their complexity and severity.5,10 In addition, it is likely that some of the repaired menisci might rerupture and require additional surgery after a simultaneous ACLR and meniscal repair. However, few studies have attempted to identify risk factors related to irreparable meniscal tear at ACLR and describe follow-up data of the investigated patients regarding progress of the meniscus after a simultaneous ACLR and meniscal repair, such as the failure rate after meniscal repair. Furthermore, most previous studies3,5,7,9,10,17,18,25 have entailed data from multiple surgeons with different
treatment decisions and surgical techniques for meniscal tears.

The purpose of this retrospective study was to investigate the associations of age, sex, body mass index (BMI), time from injury to surgery (TTS), and preinjury Tegner score with the presence of meniscal injuries and irreparable meniscal tears at primary ACLR by a single surgeon (T.T.). We hypothesized that (1) the presence of medial meniscal injuries would be increased in young and active patients and (2) older age and increased BMI could lead to meniscal degeneration and thereby reduce the repairability of medial menisci at ACLR.

METHODS

This was a retrospective cohort study of 784 patients (406 men and 378 women) who underwent primary ACLR by a single surgeon (T.T.) between 2005 and 2017. The study protocol was approved by the ethics committee of our institution, and informed consent was obtained from all participants. The study inclusion criterion was in-person postoperative follow-up of >12 months. Exclusion criteria were multiligament knee injury, revision ACLR, previous knee injury or surgery on the affected or contralateral knee, follow-up <12 months, age >50 years at the time of surgery, and TTS >120 months. The flowchart of patient inclusion is shown in Figure 1.

Tear Classifications

ACLR was performed using bone–patellar tendon–bone autograft or via ACL double-bundle reconstruction using hamstring autograft. Based on surgical findings, meniscal tear patterns were classified as simple (horizontal, vertical longitudinal, and small), bucket-handle, and complex (multiplane combinations, flap, oblique, parrot beak, and degenerative). In addition, meniscal tears were graded according to the classification of Anderson and Anderson and Laible et al (grade 0, intact; grade 1, nonsurgical tear; grade 2, reparable tear of <50% thickness; grade 3, reparable bucket-handle tear; grade 4, irreparable tear of >50% thickness; and grade 5, irreparable bucket-handle tear).

Meniscal reparable was defined based on standard meniscal repair guidelines during ACLR. Simple or bucket-handle meniscal tears without degeneration were repaired, whereas complex or degenerative meniscal tears were partially resected. Reparable meniscal tears were fixed using the inside-out technique. For relatively small meniscal tears, such as ramp lesions of medial meniscus and popliteomeniscal fascicle tears of lateral meniscus, the

Figure 1. Flowchart of patient inclusion in the study. ACLR, anterior cruciate ligament reconstruction; TTS, time to surgery.

FasT-Fix (Smith and Nephew Endoscopy) all-inside meniscal repair was preferred. Irreparable meniscal tears (classified as grades 4 and 5) were those unable to retain the entire normal (medial/lateral) meniscal shape at primary ACLR. Meniscal repair failure was defined as the need for additional meniscal surgery at the same location of the initial repair.

Rehabilitation

The same postoperative rehabilitation was carried out for all patients. A knee brace was applied for 1 week postoperatively. The patients were allowed partial weightbearing at 1 week and full weightbearing at 4 weeks. In patients with meniscal repairs, full weightbearing was allowed at 6 weeks. Vigorous sports activity was allowed at about 8 months postoperatively.

Postoperative Clinical Evaluation

The presence of meniscal tear at primary ACLR was collected from the analysis of surgical reports. The postoperative clinical evaluation was carried out at 6-month intervals until 24 months postoperatively or at the last follow-up (in patients with >24 months of follow-up).
Statistical Analysis

The t test and chi-square test were used to compare continuous variables and categorical variables, respectively. To investigate the association of age, BMI, and Tegner score with the presence of meniscal injuries (tear grades 1-5) and irreparable meniscal tears (grades 4 and 5) during primary ACLRs, a fixed-effect multivariate logistic regression analysis was conducted. The analysis was separately performed on medial and lateral sides. The model was adjusted for characteristic data (patient sex) and potential confounding factors (TTS ≥ 3 months) in addition to age, BMI, and Tegner score. The cutoff value for TTS, used to predict patients with an increased risk for medial meniscal injuries, was evaluated using receiver operating characteristic (ROC) curve analysis. Statistical tests were considered significant at \( P < .05 \). All \( P \) values were 2-sided. All analyses were performed using SAS Version 9.4 (SAS Institute).

RESULTS

Patient Characteristic Data

ACLR procedures were performed using bone–patellar tendon–bone autografts in 268 patients and hamstring autografts in 516 patients. The mean postoperative follow-up period of the 784 study patients was 33 months. The characteristic data of the 784 study patients are shown in Table 1.

Multivariate Analyses

Presence of Meniscal Injuries at ACLR. Multivariate analyses with age per 1-year increase, male sex, BMI per 1-unit increase, TTS/C21 3 months, and preinjury Tegner score of ≥7 revealed that the risk factor for medial meniscal injuries was TTS/C21 3 months (odds ratio [OR], 4.213; 95% CI, 3.104-5.719; P < .001). On multivariate analysis, none of the variables were significantly associated with lateral meniscal injuries (Table 5).

Presence of Irreparable Meniscal Tears at ACLR. The presence of irreparable medial meniscal tears increased with older age (OR, 1.053; 95% CI, 1.024-1.084; P < .001), increased BMI (OR, 1.077; 95% CI, 1.003-1.156; P = .042), and TTS ≥3 months (OR, 1.794; 95% CI, 1.046-3.078; P = .034). The presence of irreparable lateral meniscal tears was not significantly associated with any factors (Table 6).

DISCUSSION

The study results indicated that a delay in TTS of ≥3 months was strongly associated with the presence of medial meniscal injuries and irreparable medial meniscal tears at ACLR, whereas lateral meniscal injuries and irreparable lateral meniscal tears were not related to TTS. Additionally, older age and higher BMI affected the presence of irreparable medial meniscal tears at ACLR.

Age

Increased age was not related to the presence of medial meniscal injuries in this study. Similarly, Yoo et al47 reported no statistically significant relationship between changes in medial meniscal lesions and patient age in a preoperative magnetic resonance imaging study. Previous studies6,24,26 among adolescent patients have claimed that the presence of secondary meniscal injuries, defined as tears that develop after the initial ACL injury, was relatively high and the rate of medial meniscal injury increased with the delay in ACLR. In contrast to studies of young patients, Hagmeijer et al10 found a lower rate of secondary meniscal tears after ACL injury in older patients and suggested that the lower activity level of older patients might explain the lower rate of secondary meniscal injuries. Although increased age would lead to degenerative changes in menisci, older patients did not have medial meniscal injuries presumably because of the low risk of secondary meniscal injuries.

In terms of irreparable meniscal tears during primary ACLRs, increased age was a significant risk factor for the medial menisci in the current study. Chhadia et al5 investigated relationships between some variables (age, sex, and TTS) and meniscal repair rates and showed that increasing age was associated with a decreased rate of medial meniscal repair. Everhart et al7 also indicated that increased patient age was an independent predictor of a degenerative tear requiring meniscectomy. Increased age should lead to degenerative changes of the medial menisci and promote irreparable medial meniscal tears.

Patient Sex

Male sex was not a risk factor for the presence of medial meniscal injuries at primary ACLR in the current study, whereas previous studies5,9,30 have shown that male patients demonstrated higher rates of medial meniscal injury than did female patients. Investigators have suggested that the association between increased meniscal injury and sex (male) could be related to a higher activity level and higher energy trauma.3 In contrast, Slauterbeck et al38 and Chhadia et al15 pointed out that female patients having surgery were younger and had a shorter time from ACL injury to surgery. Using a binary logistic regression
model to adjust the potential confounders, Chhadia et al showed that sex (male) was not associated with the presence of medial meniscal injury.

Sex (male) was not associated with irreparable tears of the medial menisci in the current study. Krutsch et al reported that the rate of prognostically disadvantageous medial meniscal resection in women increased >6 months after ACL injury. O'Connor et al showed that, when ACLR was performed >26 weeks after injury, both men and women had increased risk of meniscal injuries but the rate at which the risk increased was much higher for women. Compared with men, women generally have weaker muscles supporting the knees, and higher ligament laxity, which may explain their results. Although men had an overall higher risk of meniscal injuries across all time intervals, women tended to incur subsequent additional meniscal injuries, which were less likely to be preserved due to degenerative changes, at a higher rate over time. Thus, sex (male) might not contribute to irreparable medial meniscal tears.

Data are presented as mean ± SD or n (%). Bolded P values indicate statistically significant difference between groups (P < .05). BMI, body mass index; LM, lateral meniscal; MM, medial meniscal; TTS, time to surgery.

Determined using t test or chi-square test.
Body Mass Index

In the current study, increased BMI was significantly related to irreparable medial meniscal tears. In general, obesity (increased BMI) is likely to have both biomechanical and biochemical links to osteoarthritis. In patients with ACL injuries, higher BMI was found to be a risk factor for radiographic osteoarthritis in the medial compartment after ACLR and was associated with medial compartment chondrosis at revision ACLR. Increased BMI accelerated degeneration of medial menisci and reduced repairability of medial meniscal tears in the current study. In contrast to our result regarding irreparable medial meniscal tear, Kluczynski et al reported that BMI was not significantly related to the management of medial meniscal injuries. However, those investigators categorized their patients into 3 groups (normal, overweight, and obese) according to BMI, and the apparent discrepancy may be due to differences in statistical methods.

Time to Surgery

In our ROC curve analysis, the optimal TTS cutoff value for predicting medial meniscal injuries was 3 months. In a multivariate analysis, TTS (>3 months) was strongly associated with medial meniscal injuries. This result is similar to the results of previous studies reporting that increased TTS was a risk factor for increased medial meniscal injuries and a greater factor than was age. Although no consensus has been reached with regard to the ideal timing of ACLR in terms of reducing secondary meniscal injury in ACL-deficient knees, previous studies have reported that timelines for medial meniscal injuries were 6 months, 10, 47, 49 or 12 months, 3, 23, 36 after ACL injuries. Our TTS (>3 months) for medial meniscal injuries was relatively earlier. This discrepancy regarding the relationship of TTS to increased medial meniscal injuries could be attributable to differences in physical activity level, the studies’ sample sizes, the number of surgeons participating in the studies, and the time periods into which the surgeries are grouped.

The presence of irreparable medial meniscal tears in the current study was associated with TTS of >3 months, which was earlier compared with previous studies. Chhadia et al reported that the medial meniscal repair rate decreased with TTS beyond 12 months. Krutsch et al found that sports-related injuries predicted fewer medial meniscal injuries and meniscectomy. In particular, the number of instability episodes after ACL injury was correlated with medial meniscal tears. Therefore, medial meniscal injuries may be related to postinjury rather than preinjury activity level.

Lateral Meniscal Injury

The presence of lateral meniscal injuries was not associated with any factors (age, sex, BMI, TTS, and preinjury Tegner score) in this study. Similarly, previous studies have demonstrated that lateral meniscal injuries occurred more commonly at the time of the primary injury but not secondarily after the incident injury, whereas medial compartment injuries were caused by chronic stresses in an ACL-deficient knee. A possible reason for these results is that the lateral meniscus has a role in mobility and constraint whereas the medial meniscus is less mobile and less able to follow the increased anterior and rotational translation of the tibia, especially in dynamic situations in the absence of the ACL; thus, the medial meniscus is more likely than the lateral meniscus to undergo shear stresses.

The presence of irreparable lateral meniscal tears was not related to any factors examined in the current study. Similarly, Chhadia et al showed that the lateral meniscal repair rate did not have any statistically significant associations, although the medial meniscal repair rate decreased with TTS beyond 12 months and with increasing age.

Limitations

There are several limitations to our study. Unlike previous studies, which involved multiple surgeons or centers, primary ACLR was performed by a single surgeon in the current study. Accordingly, indications for meniscal repair depended on 1 surgeon’s experience, which might have biased the results. In addition, this study lacked cartilage data. Cartilage damage and meniscectomies are the most significant predictors of the development of osteoarthritis. It has been reported that at ACLR, meniscal injuries requiring resection increased the risk of cartilage loss. Therefore, the meniscus should be preserved to prevent cartilage damage.
The follow-up period in the current study was relatively short, and 17% of the patients did not have a 12-month follow-up. Westermann et al. reported that the average time to meniscal repair failure was 2.1 years for medial repairs and 3.7 years for lateral repairs performed at the time of ACLR and the failure rate after meniscal repairs varied from 5.5% to 14%. Although the failure rate after medial meniscal repair was 4.6% in the current study, a longer follow-up may have resulted in a higher rate of failure. In addition, the postoperative follow-up can be completed by mail or telephone; however, to evaluate clinical findings correctly, we included only those patients who could be followed up in person. Furthermore, we excluded patients with TTS >120 months, which might have influenced our results. Finally, ACLR procedures were performed using bone–patellar tendon–bone autograft or hamstring autograft (double-bundle reconstruction). Differences in the ACL grafts might have affected the subsequent meniscal status, healing process, and postoperative knee stability.

CONCLUSION

Time from ACL injury to ACLR of ≥3 months was strongly associated with medial meniscal injuries and irreparable medial meniscal tears at primary ACLR. Furthermore, older age and increased BMI were also risk factors for the presence of irreparable medial meniscal tears at ACLR, whereas male sex and preinjury Tegner score were not related to the presence of irreparable medial meniscal tears.
