ABSTRACT: Ben-Sasson and Sudan (RSA 2006) showed that taking the repeated tensor product of linear codes with very large distance results in codes that are locally testable. Due to the large distance requirement the associated tensor products could be applied only over sufficiently large fields. Then Meir (SICOMP 2009) used this result to present a combinatorial construction of locally testable codes with largest known rate. As a consequence, this construction was obtained over sufficiently large fields.

In this paper we improve the result of Ben-Sasson and Sudan and show that for any linear codes the associated tensor products are locally testable. Consequently, the construction of Meir can be taken over any field, including the binary field.

Moreover, a combination of our result with the result of Spielman (IEEE IT, 1996) implies a construction of linear codes (over any field) that combine the following properties:

• have constant rate and constant relative distance;
• have blocklength \( n \) and are testable with \( n^{\epsilon} \) queries, for any constant \( \epsilon > 0 \);
• linear time encodable and linear-time decodable from a constant fraction of errors.

Furthermore, a combination of our result with the result of Guruswami et al. (STOC 2009) implies a similar corollary for list-decodable codes. © 2013 Wiley Periodicals, Inc. Random Struct. Alg., 46, 572–598, 2015

Keywords: tensor products; locally testable codes; locally correctable codes; efficient decoding

1. INTRODUCTION

Over the last decades coding theory and complexity theory have benefited from numerous interesting interconnections. Recent major achievements in complexity theory, e.g., showing...
IP = PSPACE [38, 46, 47] and giving a PCP characterization of NP [3, 4] have strongly relied on connections with coding theory either explicitly or implicitly.

Most of the well-studied and practically used codes are linear codes. A linear code $C \subseteq F^n$ is a linear subspace over the field $F$, where $n$ is called the blocklength of $C$ and $\dim(C)$ denotes the dimension of the code. The rate of the code is defined by $\operatorname{rate}(C) = \frac{\dim(C)}{n}$. We define the distance between two words $x, y \in F^n$ to be $\Delta(x, y) = \{|i | x_i \neq y_i\}$ and the relative distance to be $\delta(x, y) = \frac{\Delta(x, y)}{n}$. The distance of the code $C$ is defined by $\Delta(C) = \min_{x, y \in C} \Delta(x, y)$ and its the relative distance is denoted $\delta(C) = \frac{\Delta(C)}{n}$. Typically, one is interested in the codes whose distance is linear in the blocklength.

The central algorithmic problem in coding theory is the explicit construction of error-correcting codes with best possible parameters together with fast encoding and decoding algorithms. I.e., given a message $w \in F^k$ the goal is to efficiently encode this message (in the best case we have linear running time), and given a corrupted codeword the goal is to efficiently decode it and obtain the original message (again, in the best case this can be done in linear time). These features were proved to be useful also in cryptography and computational complexity (see e.g., [51, Section 1]).

Besides the efficient encoding/decoding algorithms there are interesting well-studied properties: local testing and local decoding (correction). The combination of these properties is highly useful, e.g., PCPs based on the Hadamard code [3] relied on the fact that the Hadamard code is testable with 3 queries [16] and locally decodable (correctable) with 2 queries.

Given the fact that error-correcting codes play an important role in complexity theory, and in particular, in different interactive protocols (see e.g., [7]), it might be helpful to develop a general scheme for constructing error-correcting codes that combine several different properties. E.g., it might be helpful to have high-rate codes which combine such properties as local testing, efficient encoding and decoding from a constant fraction of errors. This is what we do in this paper. In the rest of the introduction we provide a brief background and explain our contribution.

1.1. Locally Testable Codes

Locally testable codes (LTCs) are error correcting codes that have a tester, which is a randomized algorithm with oracle access to the received word $x$. The tester reads a sublinear amount of information from $x$ and based on this “local view” decides if $x \in C$ or not. It should accept codewords with probability one, and reject words that are far (in Hamming distance) from the code with noticeable probability.

Such codes are of interest in computer science due to their numerous connections to probabilistically checkable proofs (PCPs) and property testing (see the surveys [23, 51] for more information). LTCs were implicit already in [6] (cf. [23, Sec. 2.4]) and they were explicitly studied by Goldreich and Sudan [25]. By now several different constructions of LTCs are known including codes based on low-degree polynomials over finite fields [2, 3, 16], constructions based on PCPs of proximity/assignment testers [9, 20]1 and sparse random linear codes [15, 30, 33]. In this paper we study a different family of LTC constructions, namely, tensor codes. Given two linear error correcting codes $C \subseteq F^{w_1}, R \subseteq F^{w_2}$ over a

---

1As was pointed out in [25], not all PCP constructions are known to yield LTCs, but some of them (e.g., PCPs of proximity/assignment testers) can be adapted to yield LTCs.
finite field $F$, we define their tensor product to be the subspace $R \otimes C \subseteq F^{n_1 \times n_2}$ consisting of $n_1 \times n_2$ matrices $M$ with entries in $F$ having the property that every row of $M$ is a codeword of $R$ and every column of $M$ is a codeword of $C$. In this case, we say that $C$ and $R$ are base-codes. If $C = R$ we use $C^2$ to denote $C \otimes C$ and for $i > 2$ define $C^i = C \otimes C^{i-1}$. Note that the blocklength of $C^i$ is $n_1^i$.

Recently, tensor products were used to construct new families of LTCs [12, 37], new families of list-decodable codes [26], and to give an alternative proof [38] for IP = PSPACE theorem of [46, 47].

Ben-Sasson and Sudan [12] suggested to use tensor product codes as a means to construct LTCs combinatorially. Let $C \subseteq F^{n_1}$ be a linear code and let us consider the following approach. Suppose that the task is to test whether an input word $M \in F^{n_1 \times n_1}$ belongs to $C^2$, where $M$ is far from $C^2$. One could expect that in this case the typical row/column of $M$ is far from $C$, and hence the tester for $C^2$ can choose a random row (or column) of $M$. Then this selected row/column could be tested on being in $C$. However, as was shown in [18, 24, 52] this approach fails in general and is known to work only under assumptions that $C$ has some non-trivial properties [13, 14, 21] (see also [39]).

In spite of this fact, Ben-Sasson and Sudan [12] showed that taking the repeated tensor products of any code $C \subseteq F^{n_1}$ with sufficiently large distance results in a locally testable code with sublinear query complexity. Although it was not explicitly stated in [12], it follows that [12, Theorem 2.6] gives the following result.

**Theorem 1.1** (Informal). For every $\epsilon > 0$ there exists a sufficiently large field $F = F(\epsilon)$ such that letting $m = \lceil \frac{1}{\epsilon} \rceil$ for every $C \subseteq F^n$, if $(\frac{\Delta(C) - 1}{n})^m \geq \frac{7}{8}$ then $C^m$ is testable with $N^\epsilon$ queries, where $N = n^m$ is the blocklength of $C^m$. The rejection probability of the tester depends on $m$.

Let us explain some issues that remained open. First of all, it remained unclear if the assumption about the very large distance of the base codes is necessary. Moreover, the requirement on the distance of the base code ($\Delta(C)$) is dependent on the number of tensor products ($m$) one should apply. Note that for smaller query complexity (relative to the blocklength) more tensor product operations should be applied. Thus the distance of the base code must be increased when the number of queries is decreased. We notice also that the assumption of larger $\Delta(C)$ implies a larger underlying field $F$. As a consequence, a similar theorem to Theorem 1.1 could not be argued for a fixed field, like the binary field.

In this paper we ask the following question: is it possible to achieve a similar result to [12] but with no assumptions about the base codes at all? A positive result to this question might seem surprising since it would imply that any linear error-correcting code can be involved in the construction of LTCs via tensor products. Nevertheless, we give a positive answer on this question and show that no assumptions about the base codes (or underlying fields) are needed. I.e., informally, we show the following result (stated formally in Theorem 3.1).

**Theorem 1.2** (Informal). For every $\epsilon > 0$ and for every field $F$ letting $m = \lceil \frac{1}{\epsilon} \rceil$ it holds that for every $C \subseteq F^n$ we know that $C^m$ is testable with $N^\epsilon$ queries, where $N = n^m$ is the blocklength of $C^m$. The rejection probability of the tester depends on $\Delta(C)$ and $m$.

\[2\] Meir [38] showed that the “multiplication” property and the “sum-check” protocol can be designed by tensor products. We consider this surprising, since previously such features were achieved only by low degree polynomials.

Random Structures and Algorithms DOI 10.1002/rsa
This contrasts with the previous works on the combinatorial constructions of LTCs due to Ben-Sasson and Sudan [12] and Meir [37] which required very large base-code distance, and as a consequence required the large field size. Moreover, the constructions of best known LTCs [11, 19, 37] were obtained over large fields (when finally, the field size can be decreased through code concatenation). Our improvement over the result of [12] implies that the construction of Meir [37] (which achieves LTCs of best known parameters\(^3\)) can be taken directly over any field (including the binary field). Thus our results imply that LTCs having the best known parameters can be constructed directly over any field. On the other hand, we think that this improvement has a non-negligible role since the LTCs construction of Meir [37] is combinatorial and the combinatorial constructions of LTCs (or PCPs) should be independent, as much as possible, of the algebraic terms such as “polynomials,” “fields” etc. Furthermore, our proof is much simpler than the proof provided in [12] and simultaneously we obtain some quantitative improvements in the related parameters (see Section 4 and in particular Remark 4.5).

1.2. Efficient Encoding and Decoding

Let us ask the following natural question. Whether tensor products of codes can be encoded efficiently? It is quite simple to show (Claim A.1) that if the code \(C\) has an efficient (linear time) encoder then \(C^m\) has an efficient (linear time) encoder.

Let us turn to the decoding properties of the tensor products, e.g., the natural question here would be whether tensor products of codes preserve the decoding properties provided that the base codes are efficiently decodable. Gopalan et al. [26] showed that tensor products preserve the list-decoding properties, i.e., if \(C\) is list-decodable in polynomial time then \(C^m\) is list-decodable in polynomial time.\(^4\) Our contribution to this question is as follows. We show (Proposition A.2) that if \(C\) is decodable from a constant fraction of errors in linear time then \(C^m\) is decodable from a constant fraction of errors in linear time.

Then, we show (Corollaries 3.9, 3.12) that a combination of our results with the results of [26, 49] implies the construction of constant-rate codes which are both testable with sub-linear query complexity, linear-time encodable and efficiently decodable (or list-decodable) from the constant fraction of errors.

1.3. Tensor Product of Codes Preserves the Local Decoding (Correction) Properties

Informally, locally decodable codes (LDCs) and locally correctable codes (LCCs) are error-correcting codes that allow to retrieve each bit of the message (codeword) using a small number of queries to the codeword even after a constant fraction of it is adversely corrupted. The most famous LDCs (LCCs) include Hadamard and Reed-Muller codes [42]. In theoretical computer science, locally decodable codes have played an important part in the Proof-Checking Revolution [3, 4, 6, 7, 35, 36, 46] as well as in other fundamental results in complexity theory [5, 8, 29, 45, 50].

\(^3\)The best known LTCs achieve constant relative distance, inverse poly-logarithmic rate, constant query complexity and constant rejection probability. This range of parameters was initially achieved by Dinur [19] based on the results of Ben-Sasson and Sudan [11]. Later, Meir [37], based on [12] and [19], gave a combinatorial construction of LTCs that matched the same range of parameters.

\(^4\)The main focus in [26] was done on the designing polynomial-time list-decoding algorithms and on the combinatorial bounds for the list-decoding tensor products of codes and interleaved codes.

Random Structures and Algorithms DOI 10.1002/rsa
In Section 3.3 we prove that tensor product of codes preserve the local correction property. That means if \( C \) is an LCC with query complexity \( q \) then \( C^2 \) is an LCC with query complexity \( q^2 \). On the one hand, this observation discovers additional families of locally correctable codes and on the other hand, it suggests a simple way to combine two different properties: local correction and local testing. E.g., let \( C \subseteq \mathbb{F}^n \) be a linear LCC with query complexity \( q \) and let \( C' = C^{10} \subseteq \mathbb{F}'^{10} \). Then \( C' \) has blocklength \( N = n^{10} \), \( C' \) is an LCC with query complexity \( q^{10} \) and is an LTC (with query complexity \( N^{0.2} \)).

1.4. Organization of the Paper

In the following section we provide background regarding tensor codes and locally testable codes. In Section 3 we state our main results. We state our main technical theorem (Theorem 3.1) appears in Section 6 and the proofs of auxiliary statements appear in Section 6.

2. PRELIMINARIES

All codes discussed in this paper are linear. Throughout this paper, we let \([n] = \{1, \ldots, n\}\).

For \( w \in \mathbb{F}^n \) let \( \text{supp}(w) = \{i \mid w_i \neq 0\} \), \( \|w\| = |\text{supp}(w)| \) and \( \text{wt}(w) = \frac{|w|}{n} \). For \( x \in \mathbb{F}^n \) and a linear code \( C \subseteq \mathbb{F}^n \), let \( \delta(x, C) = \min_{y \in C} \{\delta(x, y)\} \) denote the relative distance of \( x \) from the code \( C \). If \( \delta(x, C) \geq \epsilon \) we say that \( x \) is \( \epsilon \)-far from \( C \), and otherwise we say that \( x \) is \( \epsilon \)-close to \( C \). We let \( C^\perp = \{u \in \mathbb{F}^n \mid \forall c \in C : \langle u, c \rangle = 0\} \) be the dual code of \( C \), where \( \langle u, c \rangle \) denotes the vector inner product between \( u \) and \( c \).

For \( w \in \mathbb{F}^n \) and \( S = \{j_1, j_2, \ldots, j_m\} \subseteq [n] \), where \( j_1 < j_2 < \ldots < j_m \), we let \( w|_S = (w_{j_1}, \ldots, w_{j_m}) \) be the restriction of \( w \) to the subset \( S \). We let \( C|_S = \{c|_S \mid c \in C\} \) denote the restriction of the code \( C \) to the subset \( S \).

2.1. Tensor Product Codes

The definitions appearing here are standard in the literature on tensor-based LTCs (e.g., [12, 14, 21, 37, 52]).

For \( x \in \mathbb{F}^d \) and \( y \in \mathbb{F}^l \) we let \( x \otimes y \) denote the tensor product of \( x \) and \( y \) (i.e., the matrix \( M_{ij} = x_i y_ j \) where \((i,j) \in I \times J\)). Let \( R \subseteq \mathbb{F}^d \) and \( C \subseteq \mathbb{F}^l \) be linear codes. We define the tensor product code \( R \otimes C \) to be the linear space spanned by words \( r \otimes c \in \mathbb{F}^{d \times l} \) for \( r \in R \) and \( c \in C \). Some known facts regarding the tensor products (see e.g., [21]):

- The code \( R \otimes C \) consists of all \([l] \times [J]\) matrices over \( \mathbb{F} \) whose rows belong to \( R \) and whose columns belong to \( C \),
- \( \dim(R \otimes C) = \dim(R) \cdot \dim(C) \),
- \( \text{rate}(R \otimes C) = \text{rate}(R) \cdot \text{rate}(C) \),
- \( \delta(R \otimes C) = \delta(R) \cdot \delta(C) \),
- The tensor product operation is associative, i.e., for any linear codes \( C_1, C_2 \) and \( C_3 \) it holds that \( (C_1 \otimes C_2) \otimes C_3 = C_1 \otimes (C_2 \otimes C_3) \).

We let \( C^1 = C \) and \( C^t = C^{t-1} \otimes C \) for \( t > 1 \). Note by this definition, \( C^0 = C \) and \( C^t = C^{2^{t-1}} \otimes C^{2^{t-1}} \) for \( t > 0 \). We also notice that for a code \( C \subseteq \mathbb{F}^n \) and \( m \geq 1 \) it holds that \( \text{rate}(C^m) = (\text{rate}(C))^m, \delta(C^m) = (\delta(C))^m \) and the blocklength of \( C^m \) is \( n^m \).
The main drawback of the tensor product operation is that this operation strongly decreases the rate and the distance of the base codes. We refer the reader to [37] which showed how one can use tensor products and avoid the decrease in the distance and the strong decrease in the rate.\(^5\)

### 2.2. Locally Testable Codes (LTCs)

A standard \(q\)-query tester for a linear code \(C \subseteq F^n\) is a randomized algorithm that on the input word \(w \in F^n\) picks non-adaptively a subset \(I \subseteq [n]\) such that \(|I| \leq q\). Then \(T\) reads all symbols of \(w|_I\) and accepts if \(w|_I \in C|_I\), and rejects otherwise. This definition of the tester is less general than the common definition of testers for LTCs (e.g., the one used in the introduction), but in [10, Theorem 2] shows that for linear codes we can use this definition without loss of generality. Hence a \(q\)-query tester can be associated with a distribution over subsets \(I \subseteq [n]\) such that \(|I| \leq q\).

**Definition 2.1 (Tester of \(C\) and Test View).** A \(q\)-query tester \(D\) is a distribution \(D\) over subsets \(I \subseteq [n]\) such that \(|I| \leq q\). Let \(w \in F^n\) (think of the task of testing whether \(w \in C\)) and let \(I \subseteq [n]\) be a subset. We call \(w|_I\) the view of a tester. If \(w|_I \in C|_I\), we say that this view is consistent with \(C\), or when \(C\) is clear from the context we simply say \(w|_I\) is consistent.

Although the tester in Definition 2.1 does not output accept or reject, the way a standard tester does, it can be converted to output accept, reject as follows. Whenever the task is to test whether \(w \in C\) and a subset \(I \subseteq [n]\) is selected by the tester, the tester can output accept if \(w|_I \in C|_I\) and otherwise output reject.

When considering a tensor code \(C^m \subseteq F^{nm}\), an associated tester will be a distribution over subsets \(I \subseteq [n]^m\). We identify \([n]^m\) with \([n]^m\).

**Definition 2.2 (LTCs).** A code \(C \subseteq F^n\) is a \((q, \epsilon)\)-LTC if it has a \(q\)-query tester \(D\) such that for all \(w \in F^n\), we have \(\Pr_{I \sim D}[w|_I \notin C|_I] \geq \epsilon \cdot \delta(w, C)\).

**Remark 2.3.** Let us stress that LTCs defined in Definition 2.2 are usually called strong LTCs (see e.g., [25, 31, 37]). For brevity of notation, we omit the word “strong” in this paper.

Note that given a code \(C \subseteq F^n\), the subset \(I \subseteq [n]\) uniquely defines \(C|_I\). We notice that the linearity of \(C\) implies that \(C|_I\) is a linear subspace of \(F^I\).

### 3. MAIN RESULTS

The main result of this paper is stated in Theorem 3.1. Informally, Theorem 3.1 says that tensor products of third and higher powers of any linear code over any field are locally testable with sublinear query complexity. This theorem is quite powerful and we shall use it later to conclude that tensor products of linear codes can enjoy the combination of local testability and decodability in a new range of parameters, which was not previously known.

\(^5\)Meir [37] demonstrated how one can combine the tensor product operation with two additional operations: random projections and distance amplification. In this way, on the one hand repeated tensor products could be applied, while on the other hand these supplementary operations prevent the distance loss and the strong rate reduction.
Theorem 3.1 (Main Theorem). Let $C \subseteq F^n$ be a linear code and $m \geq 3$ be an integer. Then $C^m$ is a $(n, \alpha_m)$-LTC, where $\alpha_m = \frac{1}{2} \cdot \frac{(\delta(C))^{3m}}{18^m \log_{1.5} m}$. Note that the blocklength of $C^m$ is $n^m$.

The proof of Theorem 3.1 appears in Section 6 and it is based on the main technical theorem (Theorem 4.4). Theorem 4.4 is introduced in Section 4 and is proved in Section 5. The introduction and the proof of Theorem 4.4 involves technical concepts such as “robust testing” and “composition of testers” defined in [12], following the PCP related notions [9, 20]. To prove Theorems 3.1, 4.4 we provide a new analysis of the standard “hyperplane tester” suggested in [12]. As was mentioned earlier, our analysis is more tight and much simpler than [12] (see Sections 4 and 5).

Remark 3.2. We would like to point out that for any linear code $C \subseteq F^n$ it holds that $C^2$ is a $(n, \frac{1}{2})$-LTC. Note blocklength of $C^2$ is $n^2$. This folklore Claim 6.2 is stated and proved in Section 6. So, in this way we can easily obtain a simple construction of an LTC with query complexity equal to the square root of the blocklength. Nevertheless, that is a much more difficult task to obtain a smaller query complexity via tensor products (see e.g., [12, 13, 37] for more information).

Usually, in the areas of locally testable and locally decodable codes the main interest was given to the constant query complexity. Recently, Kopparty et al. [34] showed the construction of locally decodable codes with sublinear query complexity and arbitrary high rate (see [34] for the motivation behind this range of parameters). Since then, the interest in the other range of parameters, and in particular, in sublinear query complexity has increased.

Tensor Products of Codes can have large distance. As was said in Section 2.1, Meir [37] explained that one of the standard procedures for distance amplification of the code [1] can be combined together with the repeated tensor product operations. He also proved that this procedure preserves the local testability of the underlying code. The simplest way to see this is as follows. Let $\text{DistAmp}(-)$ be a procedure that increases the relative distance of the code $C' \subseteq F^n_2$, e.g., from 0.001 to 0.49. I.e., if $\delta(C') \geq 0.001$ then $\delta(\text{DistAmp}(C')) \geq 0.49$. Moreover, it holds that if $C'$ was locally testable then $\text{DistAmp}(C')$ is locally testable, where the query complexity of the code $\text{DistAmp}(C')$ is increased by only a constant factor, independent on the other parameters of the code. It can be readily verified that the distance amplification procedure preserves the encoding time, and in particular, if $C'$ was linear-time encodable then $\text{DistAmp}(C')$ is linear-time encodable. Thus, one can pick any linear-time encodable code $C$ with linear distance, obtain a linear-time encodable LTC $C' = C^{10}$ and then increase its distance by $\text{DistAmp}(C')$. We refer the reader to [37, Section 4.3] for further information about distance amplification procedures and its affect on local testability.

In this paper we won’t use any distance amplification procedures and restrict our attention only to the tensor product operation.

We proceed as follows. In Section 3.1 we explain how local testability can be combined with decodability, and in particular, we show that tensor products can be used to provide linear codes of high rate which are locally testable, and at the same time can be efficiently encoded and decoded. Then, in Section 3.2 we show that a combination of Theorem 3.1 with a result of [26] implies asymptotically good codes that can be encodable in linear time, testable with sublinear query complexity and list-decodable in polynomial time. Finally, in Section 3.3 we argue that tensor products preserve the local decoding (correction) properties.
Thus a tensor product of a locally decodable (correctable) code combines both properties: local testing and local decoding (correction).

3.1. Locally Testable and Linear-Time Encodable and Decodable Codes

We continue to investigate the “encoding” and “decoding” properties of tensor products. Any linear error correcting code \( C \subseteq F^n \) can be associated with an encoding function \( E_C : F^k \to F^n \) that on the message \( x \in F^k \) returns the codeword \( E_C(x) \in F^n \). The words \( x \in F^k \) are called messages and the elements \( x_i \) for \( i \in [k] \) are called message symbols. A code \( C \subseteq F^n \) is called linear-time encodable if its encoding function can be computed in time \( O(n) \).

In Claim A.1 we show that if a linear code \( C \) is linear-time encodable then so is \( C^m \) for any constant \( m \). The proof of Claim A.1 is postponed to Section 6. Note that every linear code can be encoded is quadratic time (multiplication by a generator matrix).

Now, we combine Theorem 3.1 and Claim A.1 to show in Corollary 3.3 a simple construction of LTCs with arbitrary polynomially small query complexity and arbitrary high rate from any linear code with sufficiently high rate.

**Corollary 3.3.** Let \( F \) be any field. Let \( C \subseteq F^n \) be a linear code and let \( m \geq 3 \) be a constant. Then \( C^m \subseteq F^{mn} \) is a \((n, \alpha_m)\)-LTC, where \( \alpha_m > 0 \) is a constant that depends only on \( m \) and \( \delta(C) \). In particular, for every \( \epsilon > 0 \), \( m = \lceil \frac{1}{\epsilon} \rceil \), \( N = n^m \) and \( C \subseteq F^k \) such that rate\((C) \geq (1 - \epsilon)^{1/m} \) we have that \( C^m \subseteq F^N \) is a \((N^\epsilon, \alpha)\)-LTC and rate\((C^m) \geq 1 - \epsilon \), where \( \alpha > 0 \) is a constant that depends only on \( \epsilon \). Moreover, if \( C \) is a linear-time encodable then \( C^m \) is a linear-time encodable.

**Remark 3.4.** We notice that there are linear error-correcting codes with arbitrary high rate that can be encodable in the linear time (see e.g., [44]). Thus Corollary 3.3 provides a construction of high-rate LTCs with constant relative distance and arbitrary polynomially low query complexity that can be encoded in linear time. Moreover, this construction can be taken over any field. To the best of our knowledge no such results were known before.

We also notice that any simple approach, based on testing of (low-degree) polynomials [2], to achieve the similar result to Corollary 3.3 fails. In particular, let us consider the testing of Reed-Muller codes of degree \( d \) and recall that informally, Reed-Muller codes of degree \( d \) can be tested by making \( \approx 2^d \) queries. If \( d \) is large then the associated codes must be constructed over a very large field (depending on the blocklength of the code), since otherwise cannot have constant relative distance. However, if \( d \) is small then the rate of the associated code is very low. It could also be verified that concatenation of a Reed-Muller code with a good binary code does not obtain the combination of properties presented in Corollary 3.3. Furthermore, the linear-time encoding of the codes based on high-degree polynomials is problematic.

**Remark 3.5.** We stress that a tester of an LTC can be invoked several times to increase the rejection probability. Hence if \( C \) is a \((N^\epsilon, \alpha)\)-LTC, where \( 0 < \alpha < 1 \) is a constant, then \( C \) is also, e.g., a \((\frac{10}{\epsilon} \cdot N^\epsilon, 0.9)\)-LTC. In this way, the arbitrary high rejection probability can be easily combined with arbitrary polynomially small query complexity.

---

6This result improves the previous result of [28] and presents the construction of linear codes that lie close to the singleton bound, and have linear time encoding/decoding algorithms.

Random Structures and Algorithms DOI 10.1002/rsa
Next we turn to the decoding properties of tensor products. Let us first recall the definition of decodable codes.

**Definition 3.6 (Decodable codes).** Let $C \subseteq F^n$ be a code and let $\alpha < \delta(C)/2$. We say that $C$ is decodable from $\alpha n$ errors in time $T$ if there exists a decoder $D_C$ which on the input word $w \in F^n$ such that $\delta(w, C) \leq \alpha$ outputs $c \in C$ such that $\delta(w, c) \leq \alpha$ and its running time is upper-bounded by $T$. If $T = O(n)$ we say that $C$ is decodable in linear time.

Proposition A.2 (stated and proved in Section 6) shows that the tensor product operation preserves the decoding property. In particular, if $C \subseteq F^n$ is a linear code that is linear time decodable from $\alpha \cdot n$ errors then $C^m$ is linear-time decodable from $\alpha m \cdot n^m$ errors (for every constant $m \geq 1$). Hence Claim A.1 and Proposition A.2, together with a result of, e.g., [49], can result in the construction of asymptotically good locally testable codes with sublinear query complexity that can be linear-time encoded and decoded to the closest codeword from a constant fraction of errors.

Spielman [49] (based on [48]) was first who provided the (explicit) construction of linear codes that can be encoded in linear time and decoded in linear time from the constant fraction of errors. The construction of these codes was achieved over the binary field, but it can be easily extended to any other field as well.

**Theorem 3.7 ([49]).** There exists an (explicit) family of linear error correcting codes $C \subseteq F_2^n$ such that $\text{rate}(C) = \Omega(1), \delta(C) = \Omega(1), C$ is a linear-time encodable and linear-time decodable from the constant fraction of errors.

The work of Spielman [49] was improved later (e.g., [28, 44]) and in particular, the construction of codes with arbitrary high rate was achieved over constant-size fields. The next theorem is due to Guruswami and Indyk [28].

**Theorem 3.8 ([28]).** For every $\epsilon > 0$ there exist a field $F = F(\epsilon)$ and an (explicit) family of linear error correcting codes $C \subseteq F^n$ such that $\text{rate}(C) \geq 1 - \epsilon, \delta(C) = \Omega^\epsilon(1), C$ is a linear-time encodable and linear-time decodable from the constant fraction ($\Omega^\epsilon(1)$) of errors, where $F$ is a field of constant size (independent of the blocklength).

Note that the underlying field $F$ has a constant size that depends only on the parameter $\epsilon$.

A combination of Theorems 3.7, 3.8, Claim A.1 and Proposition A.2 together with Theorem 3.1 results in the following corollary.

**Corollary 3.9.** For every constant $\epsilon > 0$:  

1. There exists an (explicit) family of linear error correcting codes $C \subseteq F_2^n$ (obtained by tensor products on the codes from Theorem 3.7) that

---

---

7The code constructions suggested in [28, 44] correct a larger fraction of errors than in [49], and even almost optimal given the distance parameter. However, for our result (Corollary 3.9) it is sufficient to say that the codes are decodable from the constant fraction of errors.

8The Theorem was improved later by Roth and Skachek [44].
• have rate and relative distance $\Omega(1)$,
• linear time encodable and linear time decodable from the constant fraction $(\Omega_\epsilon(1))$ of errors,
• are $(N^\epsilon, \alpha)$-LTCs, where $\alpha = \alpha(\epsilon) > 0$ is a constant.

2. There exist a field $F$ and an (explicit) family of linear error correcting codes $C \subseteq F^n$ (obtained by tensor products on the codes from Theorem 3.8) that
• have rate at least $1 - \epsilon$ and relative distance $\Omega(1)$,
• linear time encodable and linear time decodable from the constant fraction $(\Omega_\epsilon(1))$ of errors,
• are $(N^\epsilon, \alpha)$-LTCs, where $\alpha = \alpha(\epsilon) > 0$ is a constant.

The proof of Corollary 3.9 is postponed to Section 6. Note that Corollary 3.9 presents a construction of error-correcting codes that combines local testability with efficient encoding and decoding algorithms. The difference between these two bullets of the corollary is in the binary field versus a larger field and the constant rate versus arbitrary high rate.

3.2. Locally Testable and List-Decodable Codes

In this section we recall some constructions of list-decodable codes. We start by defining list-decodable codes.

**Definition 3.10 (List-decodable codes).** Let $C \subseteq F^n$ be a code. Let $l(C, \eta)$ be the list-size for radius $\eta$, i.e., $l(C, \eta) = \max_{w \in F^n} |\{c \in C \mid \delta(c, w) \leq \eta\}|$. A code $C$ is a $(\eta, L)$-list decodable if we have $l(C, \eta) \leq L$. The code is said to be $(\eta, L)$-list decodable in time $T$ if there exists algorithm which on the input $w \in F^n$ outputs all codewords $c \in C$ such that $\delta(c, w) \leq \eta$ (at most $L$ codewords).

Gopalan et al. [26] showed that the list-decodability and the running time of the list-decoder are pretty much preserved in the tensor product operation. In particular, they proved the following theorem, stated in [26, Theorem 5.8], which says that tensor products of linear codes that are list-decodable in polynomial time enjoy this property as well.

**Theorem 3.11 ([26]).** Let $C \subseteq F^n$ be a linear code, list decodable up (in polynomial time) to an error rate $\eta$. For every constant $m \geq 1$, the $m$-wise tensor product code $C^m$ can be list decoded (in polynomial time, depending on $m$) up to an error rate $(\delta(C))^m - \eta$ with a list size $\exp((O(\frac{\ln l(C, \eta)}{\gamma^2}))^m)$ for any $\gamma > 0$.

We use the combination of Theorem 3.11, Claim A.1 and Corollary 3.3 to conclude Corollary 3.12 which shows that the tensor products can be used to combine local testability together with linear-time encoding and polynomial time list-decoding algorithms.

**Corollary 3.12.** Let $C \subseteq F^n$ be a linear code, list decodable (in polynomial time) up to an error rate $\eta$. For every constant $\epsilon > 0$, letting $m = \lceil \frac{1}{\epsilon} \rceil$, $N = n^m$ and $C^m = C^m$, it holds that

• $C' \subseteq F^N$ is an $(N^\epsilon, \alpha)$-LTC, where $\alpha = \alpha(\epsilon) > 0$ is a constant,
• $C'$ can be list decoded (in polynomial time) up to an error rate $(\delta(C))^m - \eta$ with a list size $\exp((O(\frac{\ln l(C)}{\gamma^2}))^m)$ for any $\gamma > 0$,
rate(C') = (rate(C))^m and δ(C') = (δ(C))^m,
• if C can be encoded in linear time, then C' can be encoded in linear time.

The Corollary follows immediately from Theorem 3.1, Theorem 3.11 and Claim A.1. We stress that there are several constructions of linear list-decodable codes of constant rate and constant relative distance over any field (see e.g., [27,43]).

3.3. Tensor Products Preserve Local Correction Properties

Informally, locally decodable codes (LDCs) allow to recover each message entry with high probability by reading only a few entries of the codeword even if a constant fraction of it is adversely corrupted. These codes are related to private information retrieval protocols, initiated by [17]. The best known constructions of LDCs are due to Yekhanin [53] and Efremenko [22]. On the other hand, locally correctable codes (LCCs) are error-correcting codes that allow to retrieve each codeword symbol using a small number of queries even after a constant fraction of it is adversely corrupted. So, the difference between LDCs and LCCs is local decoding of message entries vs. codeword entries. It is also worth pointing out that all linear LCCs are LDCs, however, the opposite does not hold [32].

In this section we explain that the tensor product of codes preserves the local decoding (correction) properties as well as local testability. Although it is not hard to see that the repeated tensoring preserves these properties, this fact seems to have remained unnoticed.

Let us start from the formal definition of LCCs.

**Definition 3.13 (LCCs).** Let \( C \subseteq F^n \) be a code. Then \( C \) is a \((q, \epsilon, \delta)\)-LCC if there exists a self-corrector\(^9\) (\( SC \)) that reads at most \( q \) entries and the following condition holds:

\[ \text{• For all } c \in C, i \in [n] \text{ and } \hat{c} \in F^n \text{ such that } \Delta(c, \hat{c}) \leq \delta n \text{ we have } \Pr[SC[\hat{c}][i] = c_i] \geq 1 - \epsilon, \text{ i.e., with probability at least } 1 - \epsilon \text{ entry } c_i \text{ will be recovered correctly.} \]

The parameter \( q \) is known as the query complexity, \( \epsilon \) is the error probability of the self-corrector and \( \delta \) is the distance threshold.

Sometimes, the LCCs are defined using the requirement \( \Pr[SC[\hat{c}][i] = c_i] \geq \frac{1}{|F|} + \epsilon \) to stress that the success probability of the self-corrector should be higher than trivial \( (1/|F|) \). In this paper, we use the requirement \( \Pr[SC[\hat{c}][i] = c_i] \geq 1 - \epsilon \) to treat the \( \epsilon \) as the error probability.

The standard range of parameters for an LCC is related to \( q, \epsilon, \delta > 0 \) are constants.

**Remark 3.14.** We stress that the error probability \( \epsilon \) may be arbitrary small when the distance threshold \( \delta \) converges to 0. For example, the well-known Hadamard code is a \((2, \epsilon = 2\delta, \delta)\)-LCC and hence \( \epsilon \) can be picked as arbitrary small constant.

The following proposition shows that the tensor product preserves the local correction property. It can be readily verified that a similar statement holds for the locally decodable

\(^9\)Sometimes, a self-corrector is called local corrector.

*Random Structures and Algorithms* DOI 10.1002/rsa
codes for the case of systematic codes (the codes whose first codeword entries are message symbols).10

**Proposition 3.15.** Let $C \subseteq \mathbb{F}^n$ be a code. If $C$ is a $(q, \epsilon, \delta)$-LCC then $C^2 = C \otimes C$ is a $(q^2, (q + 1) \cdot \epsilon, \delta^2)$-LCC. In particular, $C^{2i} \subseteq \mathbb{F}^{n_i}$ is a $(q^{2i}, (\Pi_{j=1}^{i}(q^{2j-1} + 1))\epsilon, \delta^{2i})$-LCC (which is non-trivial when $(\Pi_{j=1}^{i}(q^{2j-1} + 1))\epsilon < \frac{[|F|-1]}{|F|}$).

The proof of Proposition 3.15 appears in Section 6. Note that we required that the error probability $\epsilon$ can be arbitrary small when $\delta$ is taken arbitrary small.

In this way, the LCCs can be involved in the tensor products resulting in the codes which are both locally testable and locally correctable, similarly to the combination of local testability and efficient decodability (see Section 3.1).

### 4. MAIN TECHNICAL THEOREM—THEOREM 4.4

We start this section by defining the notion of robustness (Definition 4.1) as was introduced in [12].

Informally, we say that a tester is robust if for every word that is far from the code, the tester’s view is far on average from any consistent view. This notion was defined for LTCs following an analogous definition for PCPs [9, 19]. We are ready to provide a general definition of robustness.

**Definition 4.1 (Robustness).** Let $C \subseteq \mathbb{F}^n$ be a code. Note that $\Delta(w|I, c|I) = \min_{c \in C} \{\Delta(w|I, c|I)\}$ and $\delta(w|I, C|I) = \min_{c \in C} \{\delta(w|I, c|I)\}$. Given a tester (i.e., a distribution) $D$ for the code $C \subseteq \mathbb{F}^n$, we let

$$\rho^D(w) = \mathbb{E}_{I \sim D} [\delta(w|I, C|I)]$$

be the expected relative local distance of input $w$.

We say that the tester $D$ has robustness $\rho^D(C)$ on the code $C$ if for every $w \in \mathbb{F}^n$ it holds that $\rho^D(w) \geq \rho^D(C) \cdot \delta(w, C)$.

Let $\{C_n\}_n$ be a family of codes where $C_n$ is of blocklength $n$ and $D_n$ is a tester for $C_n$. A family of codes $\{C_n\}_n$ is robustly testable with respect to testers $\{D_n\}_n$ if there exists a constant $\alpha > 0$ such that for all $n$ we have $\rho^{D_n}(C_n) \geq \alpha$.

In the rest of the section we consider the “hyperplane tester” defined in the work of Ben-Sasson and Sudan [12], which generalized in some sense the work of Raz and Safra [41]. To do this let us define two auxiliary notations: points and hyperplanes. We identify the $m$-dimensional cube with the set $[n]^m$. So, a point in such a cube can be associated with an $m$-tuple $(i_1, i_2, \ldots, i_m)$ such that $i_j \in [n]$. We say that $\tau$ is a $(b, i)$-hyperplane if

$$\tau = \{(i_1, i_2, \ldots, i_m) \mid i_b = i \text{ and for all } j \in [m] \setminus \{b\} \text{ we have } i_j \in [n]\}.$$
Definition 4.2 (Hyperplane Tester). Let \( m \geq 3 \). Let \( M \in \mathbb{F}^{nm} \) be an input word and think of testing whether \( M \in C^m \). The hyperplane tester \( \mathcal{D} \) picks (non-adaptively) a random \( b \in [m] \) and random \( i \in [n] \), and returns \((b, i)\)-hyperplane (the corresponding local view is \( M|_{(b, i)} \)). It is not hard to prove that \( C^m|_{(b, i)} = C^{m-1} \).

For the first reading we suggest to think about the binary field \( \mathbb{F} = \mathbb{F}_2 \) and \( m = 3 \), and look on the tensor \( M \in \mathbb{F}^{nm} \) as on a 3-dimensional \( n \times n \times n \) cube with boolean entries. Throughout this paper we assume that \( m \geq 3 \) and for the case of \( m = 2 \) we refer a reader to [13, 14, 18, 21, 24, 52]).

Let us state the main result of Ben-Sasson and Sudan [12].

**Theorem 4.3 ([12]).** Let \( C \subseteq \mathbb{F}^n \) be a linear code and \( m \geq 3 \). Let \( \mathcal{D} \) be the hyperplane tester for \( C^m \). If \( \left( \frac{\Delta(C) - 1}{n} \right)^m \geq \frac{1}{8} \) then \( \rho(\mathcal{D})(C^m) \geq 2^{-16} \).

Now we state our main technical theorem, which says that the tensor product of any base code (with constant relative distance) is robustly testable. This extends the result of [12] (Theorem 4.3), which showed that this claim holds for base codes with a very large distance.11 We stress that the requirement of the very large distance implies sufficiently large underlying field \( \mathbb{F} \), which means that LTCs based on the tensor products could not be constructed directly over small fields and in particular, over the binary field. On the other hand, the Singleton bound says that a large distance requirement limits the rate of the code and thus, e.g., Corollary 3.3 could not be obtained using [12].

**Theorem 4.4 (Main Technical Theorem).** Let \( C \subseteq \mathbb{F}^n \) be a linear code and \( m \geq 3 \). Let \( \mathcal{D} \) be the hyperplane tester for \( C^m \). Then \( \rho(\mathcal{D})(C^m) \geq \frac{(\delta(C))^m}{2m^2} \).

The proof of Theorem 4.4 is postponed to Section 5. Ben-Sasson and Sudan [12] explained that hyperplane testers can be composed and the robustness of the hyperplane testers implies the local testability. So, Theorem 4.4 is our main step to conclude Theorem 3.1, and we provide a proof-sketch in Section 6 (see [12, 13] for more information about composition of the testers).12

**Remark 4.5.** First, we note that Theorem 4.4 can be extended in a straightforward manner to the tensor products of different linear base codes, i.e., \( C_1 \otimes C_2 \otimes \ldots \otimes C_m \), where the codes \( C_j \) might have different blocklength.

We also note that \( \rho(\mathcal{D})(C^m) \) in Theorem 4.4 is lower-bounded by the expression depending on \( m \). Thus one could think that for the “large” values of \( m \) this bound becomes very low. This issue can be easily improved using the next observation: \( C^m = C^{m_1} \otimes C^{m_2} \otimes C^{m_3} \), where \( m_1 + m_2 + m_3 = m \). E.g., \( C^{10} \) can be viewed as \( C^3 \otimes C^3 \otimes C^3 \), which is a 3-wise tensor product of \( C_1 = C^3, C_2 = C^3 \) and \( C_3 = C^3 \), i.e., \( m = 3 \). In this case, one can work with \( m = 3 \) such that the hyperplane tester selects the local views (hyperplanes) that will be tested recursively on the membership to \( C^{m_1} \otimes C^{m_2} \).

---

11 We notice that a similar requirement for the very large distance/field was done in the work of Raz and Safra [41], although due to the different reasons.

12 Given Theorem 4.4, the proof of a similar statement to Theorem 3.1 can be found in [12]. For the sake of completeness we provide the proof-sketch for Theorem 3.1 in Section 6.
Finally, we note that Theorem 4.4 achieves quantitative improvement versus Theorem 4.3. E.g., taking \( m = 3 \) and \( (\delta(C))^m \geq 7/8 \) (as required by [12]) Theorem 4.3 guarantees that \( \rho^D(C^m) \geq 2^{-16} \approx 0.000015 \), while our result (Theorem 4.4) guarantees that \( \rho^D(C^m) \geq 7/8 \approx 0.048611 \). We also notice that our proof of Theorem 4.4 is simpler than the proof of Theorem 4.3 in [12].

Nevertheless, it remains an open question whether higher robustness parameter \( \rho^D \) is achievable, e.g., \( \frac{1}{\text{poly}(m)} \).

**Remark 4.6.** We note that it might be interesting to compare our proof of Theorem 4.4 to the low degree test analysis in PCPs with subconstant error probability due to Raz and Safra [41], improved later in the breakthrough results of Moshkovitz and Raz [40]. One of the main ingredients in these works is a tight analysis related to the tester similar to the “hyperplane tester” in Definition 4.2. The main difference was that in [40,41] the underlying code was low-degree polynomial over the large field, and as a consequence one could select many more different “hyperplanes” than in the tensor product of general codes (see [41]). Ben-Sasson and Sudan [12] followed the proof-style (on the high level) of [41] as well.

Let \( M \in \mathbb{F}^{m^w} \) and view \( M \) as a tensor of size \( n \times n \times \ldots \times n \). We say that a hyperplane \( \tau_1 \) of \( M \) disagrees with hyperplane \( \tau_2 \) of \( M \) if both hyperplanes contain some common point \( p \), but disagree on its value, i.e., a closest consistent hyperplane to \( M|_{\tau_1} \) has a different value in the point \( p \) than a closest consistent hyperplane \( M|_{\tau_2} \). Now, the intriguing detail in the proofs of [12, 41] was that the intersection of the “problematic” hyper-planes was not sufficiently analyzed. Informally, these works argued that if two hyperplanes \( \tau_1 \) and \( \tau_2 \) disagree on some coordinate then many other hyperplanes disagree with \( \tau_1 \) or \( \tau_2 \).

In our proof we do analyzed the intersection area of the hyperplanes directly, and show that whenever two hyperplanes disagree then at least one of them contains many “inconsistency” points (see Lemma 5.3). This simple observation is the key ingredient behind the improvement in Theorem 4.4 versus Theorem 4.3 of [12].

### 5. PROOF OF THEOREM 4.4

We recall that \( C \subseteq \mathbb{F}^n \) is a linear code and the blocklength of \( C^m \) is \( n^m \). We shall consider an \( m \)-wise tensor product, i.e., \( C^m \subseteq \mathbb{F}^{m^w} \). For simplicity we recommend to the reader to think about the case where \( m = 3 \), \( \mathbb{F} = \mathbb{F}_2 \) and then every word in \( \mathbb{F}^{m^w} \) can be viewed as a 3-dimensional \( n \times n \times n \) cube with boolean entries. We start this section by defining the concepts of points, lines and hyperplanes (some of the terms were defined following [12]).

#### 5.1. Preliminary Notations: Points, Lines and Hyperplanes

Recall that a point in the \( n \)-dimensional cube can be associated with an \( m \)-tuple \((i_1, i_2, \ldots, i_m)\) such that \( i_j \in [n] \). Next we define the axis parallel line, or shortly, the line which can be associated with a subset of points. For \( b \in [m] \) and \( i \in [n] \) we say that \( l \) is a \((b, \bar{i}_b)\)-line, where \( \bar{i}_b \) denotes \((i_1, i_2, \ldots, i_{b-1}, i_{b+1}, \ldots, i_m)\), if

\[
l = \{(i_1, i_2, \ldots, i_{b-1}, i, i_{b+1}, \ldots, i_m) \mid \text{ where } i \in [n]\}.
\]

Note that \((b, \bar{i}_b)\)-line is parallel to the \( b \)-th axis. A line \( l \) contains a point \( p \) if \( p \in l \). Note that a \((b, \bar{i}_b)\)-line contains a point \( p = (j_1, i_2, \ldots, j_m) \) if for all \( k \in [m] \setminus \{b\} \) we have \( i_k = j_k \).

*Random Structures and Algorithms* DOI 10.1002/rsa
We recall that $\tau$ is a $(b, i)$-hyperplane if

$$\tau = \{(i_1, i_2, \ldots, i_m) \mid i_b = i \text{ and for all } j \in [m] \setminus \{b\} \text{ we have } i_j \in [n]\}.$$ 

A $(b, i)$-hyperplane contains the point $p = (j_1, j_2, \ldots, j_m)$ if $j_b = i$, i.e., the $b$-th coordinate of the point $p$ is $i$. A $(b, i)$-hyperplane contains a line $l$ if it contains all points of the line. We say that two (different) hyperplanes intersect if both hyperplanes contain at least one common point. Note that two (different) hyperplanes: $(b_1, i_1)$-hyperplane and $(b_2, i_2)$-hyperplane intersect if $b_1 \neq b_2$, moreover, they intersect on all points $p = (j_1, \ldots, j_m)$ such that $j_1 = i_{b_1}$ and $j_2 = i_{b_2}$, i.e., intersect on $n^{m-2}$ points.

Assume that $\tau_1$ is a $(b_1, i_1)$-hyperplane and $\tau_2$ is a $(b_2, i_2)$-hyperplane such that $b_1 < b_2$ (in particular $b_1 \neq b_2$). Let $\tau_1 \cap \tau_2 = \{(j_1, \ldots, j_m) \mid j_{b_1} = i_1, j_{b_2} = i_2\}$ be an intersection of two hyperplanes and $C^m|_{\tau_1 \cap \tau_2}$ be a code $C^m$ restricted to the points in $\tau_1 \cap \tau_2$. Note that $C^m|_{\tau_1 \cap \tau_2} = C^{m-2}$.

Given a word $M \in \mathbb{F}_2^m$, $b \in [m]$ and $i \in [n]$ we let $M|_{(b,i)}$ be a restriction of $M$ to the $(b, i)$-hyperplane, i.e., to all points of the hyperplane. We say that $M|_{(b,i)}$ is a $(b, i)$-hyperplane of $M$. Similarly, for the point $p = (j_1, \ldots, j_m)$ let $M|_p$ be a restriction of $M$ to the point $p$ and for the line $l$ we let $M|_l$ be a restriction of $M$ to the line $l$. We say that $M|_l$ is a line $l$ of $M$.

### 5.2. The Proof

Let $M \in \mathbb{F}_2^m$ be an input word. We prove that $\rho^D(M) \geq \frac{(\delta(C) n^{-1})}{2m^2} \cdot \delta(M, C^m)$.

For every hyperplane $\tau$ of $M$ let $r(\tau)$ be the closest codeword of $C^{m-1}$ to $M|_{\tau}$ (if there are more than one such codewords fix any of them arbitrarily). Intuitively, the hyperplane $\tau$ of $M$ "thinks" that the symbols of $M|_{\tau}$ should be changed to $r(\tau)$, or equivalently, one can assume that $r(\tau)$ is the decoding of $M|_{\tau}$ to the closest codeword of $C^{m-1}$. In this sense every hyperplane of $M$ has its own "opinion". Then we have

$$\rho^D(M) = \mathbb{E}_{\tau \sim D}[\delta(M|_{\tau}, r(\tau))]. \quad (5.1)$$

We say that the $(b_1, i_1)$-hyperplane and the $(b_2, i_2)$-hyperplane disagree on the point $p = (i_1, \ldots, i_m)$ if both hyperplanes contain the point $p$ and $r(\tau_1)|_p \neq r(\tau_2)|_p$. We say that two hyperplanes disagree on the line $l$ if both hyperplanes contain the line $l$ and $r(\tau_1)|_l \neq r(\tau_2)|_l$.

Note that if $(b_1, i_1)$-hyperplane $\tau_1$ and $(b_2, i_2)$-hyperplane $\tau_2$ intersect and disagree on at least one point then letting $\text{reg} = \tau_1 \cap \tau_2$ we have $r(\tau_1)|_{\text{reg}} \neq r(\tau_2)|_{\text{reg}}$ and moreover, $\delta(r(\tau_1)|_{\text{reg}}, r(\tau_2)|_{\text{reg}}) \geq (\delta(C))^{m-2}$. This is true since $r(\tau_1)|_{\text{reg}} \neq r(\tau_2)|_{\text{reg}} \in C^{m-2}$ and $\delta(C^{m-2}) = (\delta(C))^{m-2}$.

Let $E \in \{0, 1\}^m$ be a binary tensor such that $E|_p = 1$ if there are at least two hyperplanes which disagree on the point $p$, and otherwise $E|_p = 0$. For the point $p$ we say that the point is almost-fixed if $E|_p = 0$ but $p$ is contained in some hyperplane $\tau$ such that $r(\tau)|_p \neq M|_p$. Intuitively, a point $p$ is almost-fixed if all hyperplanes containing this point agree on this point but "think" that its value in $M$ ($M|_p$) should be changed (to $r(\tau)|_p$).

We let $\text{ToFix} = \{p = (i_1, i_2, \ldots, i_m) \mid p \text{ is almost-fixed}\}$ and let $\text{NumToFix} = |\text{ToFix}|$. Recall that $\text{wt}(E) = \frac{|E|}{m}$, i.e., $\text{wt}(E)$ is the relative weight of the tensor $E$.

**The Overview of the Rest of the Proof.** We want to argue that $\rho^D(M) \geq \frac{(\delta(C) n^{-1})}{2m^2} \cdot \delta(M, C^m)$. Intuitively, we prove that whenever $\delta(M, C^m)$ is large then so is $\rho^D(M)$, or equivalently, if $\rho^D(M)$ is small then $\delta(M, C^m)$ is small. So, let us assume that $\rho^D(M)$ is

Random Structures and Algorithms DOI 10.1002/rsa
small and to explain how this implies that $\delta(M, C^m)$ is small, i.e., $M$ is close to $C^m$. We will show that $M$ is close to $C^m$ by decoding $M$ to a close codeword of $C^m$.

Obviously, all points in $M$ can be classified into the three categories:

- **Good points**, where $p$ is a good point if for all hyperplanes $\tau$ such that $p \in \tau$ it holds that $M|_p = r(\tau)|_p$. I.e., all hyperplanes agree on them and “think” that they have the right values.
- **Almost-fixed points** (defined before).
- **Error points**, where $p$ is an error point if some hyperplanes disagree on it, i.e., there exist $\tau_1, \tau_2$ such that $p \in \tau_1 \cap \tau_2$ and $r(\tau_1) \neq r(\tau_2)$. Intuitively, it is not clear what are the right values for the error points.

In Proposition 5.1 we show that $\rho^D(M)$ gives an upper bound on the number of error points and on the number of almost-fixed points. That means that the number of error points and almost-fixed points is small.

Let us say that a hyperplane is heavy if it contains many error points (see Definition 5.2). Lemma 5.3 shows that every error point $p$ is contained in some (at least one) heavy hyperplane. Thus, if all heavy hyperplanes are removed from $M$ the resulting sub-tensor will contain no error points. On the other hand, the number of these heavy planes is small since the number of error points is small. Furthermore, after all heavy hyperplanes are removed the only remaining points are good and almost-fixed. I.e., it is sufficient to modify the almost-fixed points to obtain a consistent sub-tensor, i.e., $M|_S$ in $C^m|_S$, where $S = S_1 \times S_2 \times \ldots \times S_m$ and for all $i \in [m]$ we have $S_i \subseteq [n]$. This consistent sub-tensor can be decoded to the codeword of $C^m$ in a straightforward manner. Then Proposition 5.5 claims that the distance of $M$ from the code $C^m$ is upper bounded by the number of heavy planes and almost-fixed points, which is small, since we found a codeword of $C^m$ that agrees with $M$ everywhere except on the heavy hyperplanes and the almost-fixed points.

We turn to state and prove Proposition 5.1.

**Proposition 5.1.** It holds that $\rho^D(M) \geq \frac{w(E)}{m} + \frac{\text{NumToFix}}{n^m}$.

**Proof.** Equation 5.1 says that

$$\rho^D(M) = \mathbb{E}_{\tau \sim D} [\delta(M|_{\tau}, r(\tau))] = \sum_{\tau} \frac{\delta(M|_{\tau}, r(\tau))}{n \cdot m} = \sum_{\tau} \frac{\Delta(M|_{\tau}, r(\tau))}{n^m \cdot m},$$

where we used the fact that there are $n \cdot m$ hyperplanes and every hyperplane contains $n^{m-1}$ points.

Note that for every point $p$ it holds that if $E|_p \neq 0$ then $p \notin \text{ToFix}$. That means for every point $p$, if there exists a hyperplane $\tau$ such that $(M|_{\tau})|_p \neq r(\tau)|_p$ then exactly one of the following two events occur: either $E|_p \neq 0$ or $p \in \text{ToFix}$. I.e., for every hyperplane $\tau$ it holds that

$$\Delta(M|_{\tau}, r(\tau)) = |\{p \in \tau \mid p \notin \text{ToFix}\}| + |\{p \in \tau \mid E|_p \neq 0\}|.$$

Note also that for every point $p \in \text{ToFix}$ and every hyperplane $\tau$ such that $p \in \tau$ we have $(M|_{\tau})|_p \neq r(\tau)|_p$. Now, every point $p$ is contained in $m$ different hyperplanes. Hence
if \(E|_p \neq 0\) then for at least one hyperplane \(\tau\) (of \(m\) hyperplanes containing the point \(p\)) it holds that \(r(\tau)|_p \neq M|_p\). We conclude that \(\sum_{\tau} \Delta(M|_\tau, r(\tau)) \geq |E| + \text{NumToFix} \cdot m\) and

\[
\frac{\sum_{\tau} \Delta(M|_\tau, r(\tau))}{n^m \cdot m} = \frac{|E|}{n^m \cdot m} + \frac{\text{NumToFix}}{n^m} = \frac{\text{wt}(E)}{m} + \frac{\text{NumToFix}}{n^m}.
\]

Next we define an important concept of “heavy hyperplanes” in the inconsistency tensor \(E\). Intuitively, a heavy hyperplane of the tensor \(E\) is a plane which contains many non-zero symbols.

**Definition 5.2 (Heavy hyperplanes).** A \((b, i)\)-hyperplane of \(E\) is called heavy if \(\left|E|_{(b,i)}\right| \geq \frac{(\delta(C)m)^{m-1}}{2}\).

Lemma 5.3 is our main observation in the proof of Theorem 4.4. It says that any non-zero element of \(E\) is located in some heavy hyperplane of \(E\). This lemma plays a crucial role since it gives us an understanding of how the inconsistent points of the input tensor are distributed. Again, as was pointed in Remark 4.6, this lemma may be of independent interest due to the plausible connections to [40, 41].

**Lemma 5.3 (Main Lemma).** Let \(p = (i_1, i_2, \ldots, i_m)\) be a point such that \(E|_p \neq 0\). Then \(p\) is contained in some heavy hyperplane of \(E\).

The proof of Lemma 5.3 is postponed to Section 5.2.1. Using Lemma 5.3 it is quite simple to prove Corollary 5.4 which shows that it is sufficient to remove at most \(\frac{2|E|}{(\delta(C)n)^{m-1}} \cdot m\) hyperplanes from \(E\) to get a zero sub-tensor.

**Corollary 5.4.** There exists \(S_1, \ldots, S_m \subseteq [n]\) such that \(n - |S_1| + n - |S_2| + \ldots + n - |S_m| \leq \frac{2|E|}{(\delta(C)n)^{m-1}} \cdot m\) and letting \(S = S_1 \times S_2 \times \ldots \times S_m\) we have \(E|_S = 0\).

**Proof.** Let \(\text{HeavyPlanes} = \{(b, i) \mid (b, i)\text{ is a heavy hyperplane}\}\) be a subset of pairs associated with heavy hyperplanes. For \(b \in [m]\) let \(\overline{S}_b = \{i \in [n] \mid (b, i) \in \text{HeavyPlanes}\}\) and \(S_b = [n]\setminus \overline{S}_b\).

We claim that \(|\text{HeavyPlanes}| \leq \frac{2|E|}{(\delta(C)n)^{m-1}} \cdot m\). This is true since every heavy hyperplane contains at least \(\frac{(\delta(C)n)^{m-1}}{2}\) non-zero elements of \(E\) and the total number of non-zero elements of \(E\) is \(|E|\). Furthermore, every non-zero element of \(E\) is contained in at most \(m\) (heavy) hyperplanes. Thus \(n - |S_1| + n - |S_2| + \ldots + n - |S_m| = \sum_{b \in [m]} |\overline{S}_b| \leq \frac{2|E|}{(\delta(C)n)^{m-1}} \cdot m\).

Now, note that Lemma 5.3 implies that every point \(p = (i_1, i_2, \ldots, i_m)\) such that \(E|_p \neq 0\) is contained in some heavy hyperplane, i.e., in some hyperplane of \(\text{HeavyPlanes}\). Hence if all heavy hyperplanes are removed from \(E\) we obtain a zero sub-tensor. So, it follows that \(E|_S = 0\).

Proposition 5.5 says that if after removing a small fraction of hyperplanes from \(M\) we obtain a sub-tensor that is close to the consistent sub-tensor then \(M\) is close to \(C^m\).

**Proposition 5.5.** Let \(S_1, S_2, \ldots, S_m \subseteq [n]\) be such that \(n - |S_1| + n - |S_2| + \ldots + n - |S_m| \leq \gamma n < \delta(C) \cdot n\) and let \(S = S_1 \times S_2 \times \ldots \times S_m\). Let \(C' = C|_{S_1} \otimes C|_{S_2} \otimes \ldots \otimes C|_{S_m}\). Recall
that $M|_S$ is a sub-tensor of $M$ obtained by removing at most $\gamma \cdot n$ hyperplanes. Assume that $\Delta(M|_S, C') \leq \alpha \cdot n^m$. Then $\delta(M, C^m) \leq \gamma + \alpha$.

**Proof.** Note that for every $i \in [n]$ we have $|S_i| > n - \delta(C) \cdot n$. We now claim that every word in $C'$ has a unique preimage in $C^m$. This simple claim was proven in [12, Proposition 3.1] and we provide its proof for the sake of completeness.

Every codeword $c'$ of $C'$ can be extended to a unique codeword $c$ of $C^m$. To see this note that the projection of $C$ to $C|_S$ is bijective. It is surjective because it is a projection, and it is injective because $|S_i| > n - \Delta(C)$. So, the projection of $C^m$ to $C'$ is bijection, because both codes are of dimension $(\dim(C))^m$. Thus, every word in $C'$ has a unique preimage in $C^m$.

We turn to prove Proposition 5.5. We know that there exists $M' \in F^{m^m}$ such that $M'|_S \subseteq C'$, $M'$ agrees on $M$ on all points in $[n]^m \setminus S$ and $\delta(M, M') \leq \alpha$. Since $M'|_S$ is obtained from $M'$ by removing at most $\gamma \cdot n$ hyperplanes, it follows that at most $\gamma \cdot n$ hyperplane cover all points outside $M'|_S$. We know that every hyperplane contains only $n^{m-1}$ points. Hence $\gamma \cdot n$ hyperplanes cover at most $\gamma \cdot n^m$ points, which is a $\gamma$-fraction of all points in $M'$. Then, by the claim above, there exists a codeword $X \in C^m$ such that $X|_S = M'|_S$ and $\delta(M', X) \leq \gamma$ since all symbols of $[n]^m \setminus S$ are at most $\gamma$-fraction of $[n]^m$. We conclude that $\delta(M, C^m) \leq \delta(M, M') + \delta(M', X) \leq \alpha + \gamma$.

Now, let us recall and prove Theorem 4.4.

**Theorem 4.4 (restated).** Let $C \subseteq F^n$ be a linear code and $m \geq 3$. Let $D$ be the hyperplane tester for $C^m$. Then $\rho^D(C^m) \geq \frac{(\delta(C)^m}{2m^2}$.

**Proof of Theorem 4.4.** By Proposition 5.1 we have $\rho^D(M) \geq \frac{\wt(E)}{m} + \frac{\NumToFix}{n^m}$. If $\wt(E) \geq \frac{2|E|}{\delta(C)^m}$ then we are done. Otherwise, assume that $\wt(E) < \frac{2|E|}{\delta(C)^m}$.

Corollary 5.4 implies that it is sufficient to remove at most $\frac{2|E|}{(\delta(C)^m-1)} \cdot m < \delta(C) \cdot n$ hyperplanes from $E$ to get a zero sub-tensor $E|_S$. Similarly, the sub-tensor $M|_S$ is obtained from $M$ by removing at most $\frac{2|E|}{(\delta(C)^m-1)} \cdot m < \delta(C) \cdot n$ hyperplanes. The fact that $E|_S = 0$ implies that $\Delta(M|_S, (C^m)|_S) \leq \NumToFix \cdot \frac{n}{m^m}$. Proposition 5.5 implies that $\delta(M, C^m) \leq \frac{2\wt(E)}{\delta(C)^m-1} \cdot m + \frac{\NumToFix}{n^m}$.

Let $\beta = \frac{2\wt(E)}{\delta(C)^m-1} \cdot m$. Then, by Proposition 5.1 we have $\rho^D(M) \cdot \beta \geq \frac{\wt(E)}{m} + \frac{\NumToFix}{n^m} \cdot \beta \geq \delta(M, C^m)$ and $\rho^D(M) \geq \frac{(\delta(C)^m}{2m^2} \cdot \delta(M, C^m)$.

5.2.1. **Proof of Main Lemma 5.3.** In this section we prove Lemma 5.3.

**Proof of Main Lemma 5.3.** By definition of $E$ we know that there are (at least) two hyperplanes that disagree on the point $p$. Assume without loss of generality (symmetry) that the hyperplanes $\tau_1 = (1, i_1)$ and $\tau_2 = (2, i_2)$ disagree on the point $p$. We will prove that either $\tau_1$ is a heavy hyperplane or $\tau_2$ is a heavy hyperplane.

Consider the intersection of $\tau_1$ and $\tau_2$, i.e., $\text{reg} = \tau_1 \cap \tau_2 = \{(i_1, i_2, j_1, j_2, \ldots, j_m) | j_k \in [n]\}$. Note that $p \in \text{reg}$. Let $l$ be a line, which is parallel to the third axis and contains the point $p$ (recall that $m \geq 3$). Then the hyperplanes $\tau_1$ and $\tau_2$ disagree on this line (since they disagree on the point $p$ contained in the line $l$), i.e., $r(\tau_1)|_l \neq r(\tau_2)|_l$. But $r(\tau_1)|_l, r(\tau_2)|_l \in C$ by definition. This implies that $\Delta(r(\tau_1)|_l, r(\tau_2)|_l) \geq \delta(C) \cdot n$, i.e., for at least $\delta(C) \cdot n$ points $p \in l$ it holds that $r(\tau_1)|_p \neq r(\tau_2)|_p$.

*Random Structures and Algorithms DOI 10.1002/rsa*
Let $BadPoints = \{ p \in l | \tau_1$ and $\tau_2$ disagree on $p\}$. Note that $|BadPoints| \geq \delta(C) \cdot n$. Let $BadPlanes = \{(3, i) - \text{hyperplane} | i \in [n], \exists p \in BadPoints \text{ s.t. } p \in (3, i) - \text{hyperplane}\}$. Note that $|BadPlains| \geq \delta(C) \cdot n$.

Observe that for every $\tau \in BadPlanes$ we have that either $\tau$ disagrees with $\tau_1$ on some point $p \in BadPoints$ or with $\tau_2$ on some point $p \in BadPoints$. Hence at least one of $\tau_1, \tau_2$ disagrees with at least $\frac{1}{2} \cdot |BadPlanes| \geq \frac{1}{2} \cdot \delta(C)n$ hyperplanes from $BadPlanes$. Without loss of generality assume that $\tau_1$ disagrees with at least $\frac{1}{2} \cdot \delta(C) \cdot n$ hyperplanes from $BadPlanes$.

Let $BadPlanes_{\tau_1} = \{\tau \in BadPlanes | \tau$ disagrees with $\tau_1\}$. All hyperplanes from $BadPlanes$ are non-intersecting and thus all hyperplanes from $BadPlanes_{\tau_1}$ are non-intersecting. Every hyperplane $\tau \in BadPlanes_{\tau_1}$ disagrees with the hyperplane $\tau_1$ on some point and hence disagree on at least $(\delta(C)n)^{m-2}$ points in their intersection region $(\tau \cap \tau_1)$ since $r(\tau)|_{\tau \cap \tau_1} \neq r(\tau_1)|_{\tau \cap \tau_1} \in C^{m-2}$.

Let total $= \{p = (i_1, j_1, \ldots, j_m) | \exists \tau \in BadPlanes_{\tau_1} \text{ s.t. } p \in \tau \cap \tau_1, r(\tau)|_p \neq r(\tau_1)|_p\}$. We have $|\text{total}| \geq (\delta(C)n)^{m-2} \cdot \frac{\binom{n}{2}}{2} = \frac{(\delta(C)n)^{m-1}}{2}$ since every intersection region (as above) contains at least $(\delta(C)n)^{m-2}$ inconsistency points and there are at least $\frac{1}{2} \cdot \delta(C) \cdot n$ such regions. We stress that we do not count any inconsistency point more than once, since the hyperplanes in $BadPlanes_{\tau_1}$ are non-intersecting.

Hence the hyperplane $\tau_1$ disagree with other hyperplanes in at least $\frac{(\delta(C)n)^{m-1}}{2}$ points (on the hyperplane $\tau_1$). Thus $E|_{\tau_1}$ has at least $\frac{(\delta(C)n)^{m-1}}{2}$ non-zero symbols. We conclude that $\tau_1$ is a heavy hyperplane of $E$ and the point $p$ is contained in the hyperplane $\tau_1$.

**Remark 5.6.** We notice that the proof of Lemma 5.3 shows even a stronger claim than it is needed. Namely, it shows that if two different hyperplanes $\tau_1$ and $\tau_2$ disagree on some point then at least one of them disagree with many different non-intersecting hyperplanes, and as a consequence, is heavy. This lemma can be easily reformulated and shown for the low-degree test analysis in [41], and it remains an interesting question whether this could affect the work of [41].

### 6. PROOF OF THEOREM 3.1

First, let us recall Theorem 3.1.

**Theorem 3.1 (restated).** Let $C \subseteq F^n$ be a linear code and $m \geq 3$ be an integer. Then $C^m$ is a $(n, \alpha_m)$-LTC, where $\alpha_m = \frac{1}{2} \cdot \frac{(\delta(C)n)^{m-1}}{18(m+1)m}$. Note that the blocklength of $C^m$ is $n^m$.

We shall use the following proposition appeared in [13].

**Proposition 6.1 ([13]).** Let $C_1 \subseteq F^{n_1}$ and $C_2 \subseteq F^{n_2}$ be linear codes. Let $S_1 \subseteq [n_1]$ and $S_2 \subseteq [n_2]$ be subsets. Assume that $M \in F^{n_2 \times n_1}$ such that every row of $M|_{S_2 \times S_1}$ belongs to $C_1$ and every column of $M|_{S_2 \times S_1}$ belongs to $C_2$. Then $M|_{S_2 \times S_1} \in (R \otimes C)|_{S_2 \times S_1}$.

Now, we state and prove the following folklore claim regarding the second power of a tensor product.

Random Structures and Algorithms DOI 10.1002/tsa
Claim 6.2 (Folklore). If $C \subseteq F^n$ be a linear code then $C^2 \subseteq F^{n^2}$ is a $(n, \frac{1}{2})$-LTC. Note that the blocklength of $C^2$ is $n^2$.

Proof. Let $M \in F^{n^2}$ be a word. We can view this word as a matrix $n \times n$, i.e., $M \in F^{n \times n}$. Consider the following row/column tester (suggested in [12]):

- Flip a coin
- If “heads” pick random $i \in [n]$ and select $M|_{[i] \times [n]}$;
- Else pick random $j \in [n]$ and select $M|_{[n] \times [j]}$.
- Accept iff the selected row (column) belongs to $C$.

Let $bad_r = \{i \in [n] \mid M|_{[i] \times [n]} \notin C\}$ and $bad_c = \{j \in [n] \mid M|_{[n] \times [j]} \notin C\}$. On the one hand, the rejection probability of the tester is (exactly) $\frac{|bad_r| + |bad_c|}{2n}$.

On the other hand, letting $S_1 = [n] \setminus bad_r$ and $S_2 = [n] \setminus bad_c$, Proposition 6.1 says that $M|_{S_1 \times S_2} \in C^2|_{S_1 \times S_2}$. That means there exists $X \in C^2$ such that $M|_{S_1 \times S_2} = X|_{S_1 \times S_2}$. Therefore $\delta(M, C^2) \leq \frac{|bad_r| + |bad_c|}{n}$. Thus the rejection probability of the tester is at least $1/2 \cdot \delta(M, C^2)$.

We proceed to the following simple claim that explains how a “robust” tester can be composed with a “standard” tester.

Claim 6.3. Let $C^m \subseteq F^{nm}$ be a code and assume that $D$ is its tester such that $\rho^D(C) \geq \alpha$ and the query complexity of $D$ is $n^2$. Moreover, assume that every local view of $D$ is a candidate word for $C^2$, i.e., if $M \in C^m$ then every local view of $D$ on $M$ is a codeword of $C^2$. Then $C^m$ is a $(n, \frac{1}{2} \cdot \alpha)$-LTC.

Proof. Let $D'$ be an $n$-query tester for $C^2$ as stated in Claim 6.2.

We present an $n$-query tester $D_{fn}$ for $C^m$. Let $M \in F^{nm}$ be an input word. The distribution $D_{fn}$ over the local views is defined as follows. First, we sample $D$ and obtain a local view $M|_I$, where $I \subseteq [n]^m$ such that $|I| \leq n^2$. Then we sample $D'$ on $M|_I$, obtaining a local view $I' \subseteq [n]^m$ such that $|I'| \leq n$. So, $(M|_I)|_{I'}$ is final local view produced by the tester $D_{fn}$. Note that $D_{fn}$ is a distribution over the subsets of size at most $n$, i.e., the query complexity of the tester $D_{fn}$ is $n$.

Clearly, if $M \in C^m$ then $M|_{I'} \in C$. Assume that $M \notin C^m$. By assumption and Definition 4.1 we have $E_{I \sim D}[\delta(M|_I, C^2)] \geq \alpha \cdot \delta(M, C^m)$. By Claim 6.2 it follows that

$$\Pr_{I \sim D}[M|_{I'} \notin C] = \Pr_{l \sim D,l' \sim D^*(l)}[(M|_I)|_{I'} \notin C] \geq \frac{1}{2} \cdot \Pr_{l \sim D}[\delta(M|_I, C^2)] \geq \frac{1}{2} \cdot \alpha \cdot \delta(M, C^m).$$

We conclude that $C^m$ is a $(n, \frac{1}{2} \cdot \alpha)$-LTC.

We are ready to prove Theorem 3.1 using Claim 6.3.

Proof of Theorem 3.1. For $i \geq 3$ let $D_i$ be the hyperplane tester for the code $C^i$. Note that the tester $D_m$ returns a local view that is a candidate to be in the code $C^{m-1}$. We first explain a simple way to compose the testers and then show how to improve this.

Observe that $D_m$ selects only local views which are candidate words to be in $C^{m-1}$. Hence the tester $D_{m-1}$ can be invoked on any local view of $D_m$. Furthermore, $D_{m-1}$ outputs only local views which are candidate words to be in $C^{m-2}$, etc. Finally, the tester $D_3$ can be
invoked on the output of the tester \( D_4 \), and outputs only local views which are candidate words to be in \( C^2 \). This way the testers \( D_m, D_{m-1}, \ldots, D_3 \) can be composed to result in a tester \( D_{\text{comp}} \) for the code \( C^m \) whose query complexity is \( n^2 \), and moreover, all local views of \( D_{\text{comp}} \) are candidate words to be in \( C^2 \).

The robustness of the composed tester will be \( \rho^{D_{\text{comp}}}(C^m) \geq \rho^{D_m}(C^m) \cdot \rho^{D_{m-1}}(C^{m-1}) \cdot \ldots \cdot \rho^{D_3}(C^3) \). To see this let \( w \in F^n \) be a word such that \( \delta(w, C^m) = \delta \). Then the local view of the tester \( D_m \) is expected to be \( \rho^{D_m}(C^m) \cdot \delta \) far from \( C^{m-1} \). When \( D_{m-1} \) will be invoked, its local view is expected to be \( \rho^{D_{m-1}}(C^{m-1}) \cdot \rho^{D_3}(C^3) \cdot \delta \) far from \( C^{m-2} \), etc. Finally, the local view of \( D_3 \) is expected to be \( (\rho^{D_3}(C^3)) \cdot \delta \) far from \( C^2 \).

Theorem 4.4 says that for every \( m \geq 3 \), we have \( \rho^{D_m}(C^m) \geq \frac{(\delta(C))^m}{2^m m^2} \). Hence, for constant \( m \geq 3 \) it holds that \( \rho^{D_{\text{comp}}}(C^m) > 0 \) is a constant that depends only on \( \delta(C) \) and \( m \). Recall that the query complexity of \( D_{\text{comp}} \) is \( n^2 \). However, we can invoke the row/column tester on the selected local view by \( D_{\text{comp}} \) (Claim 6.2), and conclude by Claim 6.3 that \( C^m \) is a \( (n, \frac{1}{2} \cdot \rho^{D_{\text{comp}}}(C^m)) \)-LTC.

Now, let us show a more efficient way to compose the testers. Without loss of generality let us assume that \( m/3 \) is an integer, otherwise we would use \( \lfloor m/3 \rfloor \) and \( \lceil m/3 \rceil \). Then \( C^m = C^{m/3} \otimes C^{m/3} \otimes C^{m/3} \), i.e., \( C^m \) is a 3-wise tensor product of \( C^{m/3} \) with itself. Hence we can test it using a tester with robustness \( \frac{(\delta(C))^{m}}{2^m m^2} \). The local view produced by this tester will be a candidate to be the codeword of \( C^{m/3} \otimes C^{m/3} = C^{2m/3} \). I.e., we decreased the tensor degree of the underlying code from \( m \) to \( 2m/3 \) in the single step. It follows that after \( \log_{(3/2)} m \) steps we obtain the local view that is a candidate to be the codeword of \( C^2 \) that is entirely read by the composed tester. The robustness of this composed tester is

\[
\frac{(\delta(C))^m}{18} \cdot \frac{(\delta(C))^{2m/3}}{18} \cdot \frac{(\delta(C))^{4m/9}}{18} \cdot \ldots \cdot \frac{(\delta(C))^{2m}}{18^{\log_{(3/2)} m}}.
\]

Again, using Claim 6.3 we conclude that \( C^m \) is a \( (n, \frac{1}{2} \cdot \frac{(\delta(C))^{3m}}{18^{\log_{(3/2)} m}}) \)-LTC.

**APPENDIX: PROOFS OF AUXILIARIES CLAIMS AND PROPOSITIONS**

**Claim A.1.** Let \( m \geq 1 \) be a constant. If \( C \subseteq F^n \) is a linear-time encodable linear code then \( C^m \) is linear-time encodable.

**Proof of Claim A.1.** Let \( k = \dim(C) \). Let \( E_C \) be an encoder for the code \( C \), which receives a message \( x \in F^k \) and outputs a codeword \( E_C(x) \in C \) such that \( C = \{ E_C(x) \mid x \in F^k \} \).

Assume that \( E_C \) has running time \( T = O(k) \). Note that this implies that \( n \leq T = O(k) \) since the blocklength can not exceed the running time of the encoder.

For every \( i \geq 1 \) we define \( E_{C^i} \) to be the encoder for \( C^i \), i.e., \( C^i = \{ E_C(x) \mid x \in F^k \} \). We will argue that the running time of \( E_{C^i} \) is \( i \cdot n^{i-1} \cdot T \). Since \( n \leq T = O(k) \) we will conclude that for any constant \( i \geq 1 \) the running time of \( E_{C^i} \) is linear (in \( k^i \)).

We prove the claim by induction on \( i \). The encoder \( E_{C^1} = E_C \) was defined and its running time is \( T = 1 \cdot n^0 \cdot T \). Clearly, this encoder is injective and maps every message \( x \in F^k \) to a codeword of \( C \). Assume that we defined the encoder \( E_{C^{i-1}} \) for the code \( C^{i-1} \) and its running time is \( (i - 1) \cdot n^{i-1} \cdot T \). Moreover, assume that \( E_{C^{i-1}} \) is injective and maps every message \( x \in F^{k^{i-1}} \) to a codeword of \( C^{i-1} \).

*Random Structures and Algorithms DOI 10.1002/rsa*
Let us define the encoder $E_{C_i}$ for the code $C$. Note that the code $C$ has message length $k^j$ and its blocklength is $n^j$. Hence the message $x \in \mathbb{F}^{k^j}$ can be viewed as a matrix $k \times k^j$. So, we assume that $x \in \mathbb{F}^{k^j \times k^j}$. Note that every row of $x$ belongs to $F^{k^j}$.

The encoder $E_{C_i}$ will first encode (by the encoder $E_{C_{i-1}}$) every row of the matrix $x$, obtaining the matrix $x' \in \mathbb{F}^{k \times n^{i-2} T}$. Then $E_{C_i}$ will encode (by the encoder $E_{C_1}$) every column of the obtained matrix $x'$ to get a codeword of $C'$, and the runtime of this step is $n^{i-1} T$.

Hence the runtime of the encoder $E_{C_i}$ is $k \cdot ((i-1) \cdot n^{i-2} T) + n^{i-1} T \leq ((i-1) \cdot n^{i-1} T) + n^{i-1} T = i \cdot n^{i-1} \cdot T$, where we used the fact that $k \leq n$.

We claim that $E_{C_i}$ is injective. To see this, assume $x_1, x_2 \in \mathbb{F}^{k \times k^j}$ such that $x_1 \neq x_2$. By assumption, we know that $E_{C_1}$ and $E_{C_{i-1}}$ are injective decoders. Thus, in the first stage of the encoding, when every row of $x_1$ and $x_2$ are encoded by $E_{C_{i-1}}$ we will obtain different matrices $x'_1 \neq x'_2 \in \mathbb{F}^{k \times n^{i-2} T}$. In particular, $x'_1$ and $x'_2$ are different in at least one column. So, in the second stage of the encoding, when every column of $x'_1$ and $x'_2$ are encoded we will obtain different matrices of $\mathbb{F}^{k \times n^{i-1} T}$. This proves that $E_{C_i}$ is injective.

Finally, we argue that $E_{C_i}$ maps every message $x \in \mathbb{F}^{k \times k^j}$ to a codeword of $C^m$. Let $x \in \mathbb{F}^{k \times k^j}$. In the first stage of encoding, every row of $x$ is encoded by $E_{C_{i-1}}$ to a codeword of $C^{i-1}$. So, we get $x' \in \mathbb{F}^{k \times n^{i-1} T}$ such that every row of $x'$ is a codeword of $C^{i-1}$. In the second stage of the encoding, every column of $x'$ is encoded by $E_{C_1}$, resulting in $x'' \in \mathbb{F}^{n \times d^{i-1}}$. By construction, every column of $x''$ belongs to $C$. Furthermore, since the code $C$ is linear and $E_{C_i}$ is its encoder, it holds that every row of $x''$ is obtained by a linear combination of rows of $x'$ (which are codewords of $C^{i-1}$). Thus, every row of $x''$ belongs to $C$. We conclude that $x'' \in C^{i-1} \otimes C = C^j$. This completes the induction and the proof of the claim.

**Proposition A.2.** Assume $C \subseteq \mathbb{F}^n$ is a linear code that is linear-time decodable from $\alpha \cdot n$ errors. Let $m \geq 1$ be a fixed constant. Then $C^m$ is a linear code that is linear-time decodable from $\alpha^m \cdot n^m$ errors.

**Proof.** Recall that $C^m = C^{m-1} \otimes C$. It is sufficient to prove by induction on $j = 1, \ldots, m$ that $C'$ is linear-time decodable from $\alpha^j n^j$ errors. For $j = 1$ the claim holds since $C^1 = C$. Let $Dec_C$ be a linear-time decoder for the code $C$ that can correct any $\alpha \cdot n$ errors. Assume that $C^{j-1}$ is linear-time decodable from $\alpha^j n^{j-1}$ errors and let $Dec_{C^{j-1}}$ be its decoder.

We prove that $C' = C^{j-1} \otimes C$ is linear-time decodable from $\alpha^j n^j$ errors. We define the linear-time decoder $Dec_{C'}$ for the code $C'$ that will correct any $\alpha^j \cdot n^j$ errors. Let $M \in \mathbb{F}^{n \times d^{j-1}}$ be an input word such that $\delta(M, C') \leq \alpha^j$. The decoder $Dec_{C'}$ decodes every row of $M$ (using $Dec_{C^{j-1}}$) to obtain the matrix $X_1 \in \mathbb{F}^{n \times d^{j-1}}$. Then $Dec_{C^{j-1}}$ decodes every column of $X_1$ (using $Dec_C$) to obtain the matrix $X_2 \in \mathbb{F}^{n \times d^{j-1}}$. Finally, the decoder outputs $X_2$.

Clearly, the runtime of $Dec_{C'}$ is $O(n^j)$, i.e., linear to the blocklength of $C'$. Assume $X \in C'$ is the closest codeword, i.e., $\delta(M, X) \leq \alpha^j$. We argue that $X_2 = X$, i.e., the decoder outputs the closest codeword.

---

We can view the matrix $M \in \mathbb{F}^n$ as a matrix in $\mathbb{F}^{n \times d^{j-1}}$.
In this section we restate and prove Proposition 3.15.

\[
\text{Proof of Proposition 3.15.} \quad \text{Let } C \subseteq F^n \text{ be a code. If } C \text{ is a } (q, \epsilon, \delta)\text{-LCC then } C^2 = C \otimes C \text{ is a } (q^2, (q + 1) \cdot \epsilon, \delta^2)\text{-LCC. In particular, } C^{2 \ell} \subseteq F^{n^{2 \ell}} \text{ is a } (q^{2 \ell}, (\Pi_{j=1}^{j=\ell} (q^{2^j-1} + 1)) \epsilon, \delta^{2^\ell})\text{-LCC (which is non-trivial when } (\Pi_{j=1}^{j=\ell} (q^{2^j-1} + 1)) \epsilon < \frac{F-1}{F}).
\]

\[
\text{Proof of Proposition 3.15.} \quad \text{Let } \mathcal{SC} \text{ be the self-corrector for the code } C \text{ and assume without loss of generality that } \mathcal{SC} \text{ always queries exactly } q \text{ queries. Let } M \in F^{n \times n} \text{ be an input word (we view } M \text{ as a matrix } n \times n) \text{ and let } (i,j) \in [n] \times [n] \text{ be an input entry coordinate, the local-corrector for } C^2 \text{ should retrieve. Assume that } \delta(M, C^2) \leq \delta^2 \text{ and let } X \in C^2 \text{ be the closest codeword, i.e., } \delta(M, X) \leq \delta^2.
\]

We turn to describe the self-corrector for the code } C^2 \text{ and recall that the inputs are the matrix } M \text{ and the coordinate } (i,j).

1. Invoke } \mathcal{SC} \text{ on the row } i \text{ of } M, \text{i.e., } M_{i|n} \times [n] \text{ to retrieve the entry } (i,j). \text{ Call this the first invocation of } \mathcal{SC} \text{ and let } j_1, j_2, \ldots, j_q \text{ be the queries of this invocation.
2. For each query } j_k \text{ of the first invocation, let } b_k \text{ be the output of the self-corrector } \mathcal{SC} \text{ when invoked on the } j_k \text{-th column of } M.
3. Return the output of the self-corrector } \mathcal{SC} \text{ would have returned on the first invocation if the query } j_k \text{ would have been answered with } b_k \text{ for every for every } k \in [q].

Clearly, the self-corrector for } C^2 \text{ queries at most } q^2 \text{ entries. In the rest of the proof we prove that with probability at least } 1 - (q + 1) \cdot \epsilon \text{ the self-corrector for } C^2 \text{ outputs } X_{(i,j)}.

Assume that the first invocation of } \mathcal{SC} \text{ queried the coordinates } (i,j_1), (i,j_2), \ldots, (i,j_q). \text{ Note that these coordinates are on the row } i \text{ of } M.

We turn to analyze the error probability of retrieving the entry } (i,j). \text{ Let us call the column } k \text{ of } M \text{ bad if } \delta(M_{i|n \times |k|}, X_{|n| \times |k|}) > \delta, \text{i.e., the column } k \text{ of } M \text{ has more than } \delta\text{-fraction of noise. Since } \delta(M, X) \leq \delta^2 \text{ the number of bad columns is upper-bounded by } [\delta n]. \text{ Let } f = [\delta n] \text{ and assume without loss of generality that columns indexed by } \{1,2,\ldots,f\} \text{ are bad, while all other columns of } M \text{ are good.}
Now, let $x$ be the $i$-th row of $X$ and note that $x \in C$. Recall that a word $\hat{x} \in \mathbb{F}^n$, $SC^i(j)$ denotes the output of the self-corrector $SC$ when invoked on the word $\hat{x}$ and the coordinate $j$. Since $C$ is a $(q, \epsilon, \delta)$-LCC and $SC$ is the self-corrector for the code $C$, it holds that for every $\hat{x} \in \mathbb{F}^n$ such that $\text{supp}(x - \hat{x}) \subseteq [f]$ we have that

$$\Pr[SC^i(j) \neq x_j] \leq \epsilon,$$

i.e., the error probability of $SC$ to retrieve correctly $j$-th entry of $\hat{x}$ is at most $\epsilon$.

Now we describe a randomized algorithm which outputs $x_j$ (i.e., the right value) with probability less or equal than the self-corrector for $C^2$, defined above. Then, we prove that the probability that this randomized algorithm outputs a value different from $x_j$ is at most $q \cdot \epsilon + \epsilon$.

- Let $\hat{x} \in \mathbb{F}^n$ be obtained such that $\hat{x}|_{[n] \setminus [f]} = x|_{[n] \setminus [f]}$ and for every $k \in [f]$ set
  $$\hat{x}|_k := SC([M]|_{[n]} \times k)[i],$$
  i.e., $\hat{x}|_k$ is assigned to the output of $SC$ on the $k$-th column of $M$ and the index $i$.
- Let $err \in \mathbb{F}$ be such that $err \neq x_j$.
- Pick $r \in \{1, 2\}$ such that with probability $q \cdot \epsilon$ we have $r = 1$ and with probability $(1 - q \cdot \epsilon)$ we have $r = 2$.
- If $r = 1$ output $err$.
- Otherwise, invoke $SC^i[j]$ and return its output.

Let the error probability of the algorithm (the self-corrector for $C^2$) to denote the probability that this randomized algorithm (the self-corrector for $C^2$) outputs a value different from $x_j$.

On the one hand, the error probability of the algorithm is at most $q \cdot \epsilon + \epsilon$. Too see this, observe that by construction $\text{supp}(x - \hat{x}) \subseteq [f]$ and thus $\Pr[SC^i(j) \neq x_j] \leq \epsilon$. Moreover, the algorithm outputs $err$ in the 4-th bullet with probability $q \cdot \epsilon$.

On the other hand, the self-corrector for $C^2$ “works” with $q$ columns, which can be bad or good. Notice that instead of invocation of $SC$ on $k$-th column of $M$ each time the self-corrector for $C^2$ queries the entry $k \in [f]$, we can invoke a priori $SC$ on each column $k \in [f]$. In this case, whenever the self-corrector for $C^2$ asks an entry $k \in [f]$ we return it a corresponding previously obtained value. Thus the “treatment” of bad columns is identical in this randomized algorithm and in the self-corrector for $C^2$. Recall that the probability that for $k \in [n] \setminus [f]$ the invocation $SC^{M|[n] \times k}[k]$ will output a value different from $X|_{(i, k)}$ is at most $\epsilon$. Since the self-corrector for $C^2$ “works” with at most $q$ columns, the probability that it will receive a “wrong” value on at least one good column is upper-bounded by $q \cdot \epsilon$. Moreover, given the event that the self-corrector for $C^2$ receives the right values on the queried good columns (happens with probability at least $1 - q \cdot \epsilon$), its error probability is equal to $\Pr[SC^i[j] \neq x_j]$. Hence the error-probability of the self-corrector for $C^2$ is at most the error probability of this randomized algorithm.

Thus the self-corrector for $C^2$ outputs a wrong value with probability at most $q \cdot \epsilon + \epsilon$. This completes the proof of the Proposition.

**Proof of Corollary 3.9**

**Proof of Corollary 3.9.** Let $\epsilon > 0$ and $m = \lceil \frac{2}{\epsilon} \rceil$. 

*Random Structures and Algorithms* DOI 10.1002/tsa
For the first bullet corollary, let $C' \subseteq \mathbb{F}_2^n$ be a code from Theorem 3.7 such that rate($C'$) = $\Omega(1)$, $\delta(C') = \Omega(1)$ and $C'$ is linear-time encodable and decodable from the constant fraction of errors. Let $C = (C')^m$ and note that the blocklength of $C$ is $N = n^m$. It follows that rate($C$) = (rate($C'$))$^m = \Omega_m(1)$ and $\delta(C) = (\delta(C'))^m = \Omega_m(1)$. Moreover, Claim A.1 and Proposition A.2 imply that $C$ is encodable in linear time and decodable from the constant fraction ($\Omega_\epsilon(1)$) of errors in linear time. By Theorem 3.1 it holds that $C$ is a $(N^\epsilon, \alpha)$-LTC, where $\alpha$ is a constant that depends on $\epsilon$.

For the second bullet corollary, let $C' \subseteq \mathbb{F}_2^n$ be a code from Theorem 3.8 such that rate($C'$) $\geq (1 - \epsilon)^{1/m}$, and recall that $\delta(C') = \Omega_\epsilon(1)$, $C'$ is linear-time encodable and decodable from the constant fraction of errors. Let $C = (C')^m$ and note that the blocklength of $C$ is $N = n^m$. It follows that rate($C$) = (rate($C'$))$^m$ $\geq 1 - \epsilon$ and $\delta(C) = (\delta(C'))^m = \Omega_\epsilon(1)$. Moreover, Claim A.1 and Proposition A.2 imply that $C$ is encodable in linear time and decodable from the constant fraction of errors in linear time. By Theorem 3.1 it holds that $C$ is a $(N^\epsilon, \alpha)$-LTC, where $\alpha$ is a constant that depends on $\epsilon$.

ACKNOWLEDGMENTS

The author thanks Eli Ben-Sasson for many invaluable discussions about the “robustness” concept and the possible connections to the work [41], mentioned in Remark 4.6. We would like to thank Or Meir for helpful discussions. The author thanks Ronny Roth for pointers to the literature. We thank the anonymous referees for valuable comments on an earlier version of this article.
