Seed germination of Agave species as influenced by substrate water potential

Hugo M Ramírez-Tobías1,2*, Cecilia B Peña-Valdivia3*, Carlos Trejo2, J Rogelio Aguirre R3 and Humberto Vaquera H4

Abstract

Background: Plants of Agave spp. perform Crassulacean acid metabolism (CAM) and are highly drought-tolerant, but little is known concerning seed germination under low water availability. The aim of this study was to assess the effect of substrate water potential ($\Psi_W$) on seed germination and contrast hydrotime parameters of seven valuable and commercially-important Agave species from different geographical distributions and climatic regions of Mexico. Our hypothesis was that seed germination of Agave species is not affected by low water availability independently of seed biomass and the climate of their distribution area.

Results: Seed germination (at 25°C and in the dark) between 85 and 100% for all species occurred within 80–180 h at -0.03 MPa and 250–430 h at -1.0 MPa. Seed germination at -1.5 MPa declined to less than 50% ($p < 0.05$) for A. asperrima and A. cupreata but did not change significantly for A. americana var. marginata, A. lechuguilla and A. striata, although they showed the lowest mean base water potential (-2.01 to -2.64 MPa). Seed germination of 40% Agave species, from arid and semi-arid climates in this study, was not affected by the lower $\Psi_W$.

Conclusion: Germination of seeds of Agave species is moderately affected by low water availability, is partially dependent of their ecological distribution, and is independent of seed mass.

Background

Approximately 74 Agave species and 28 intraspecific taxa have been used in Mexico as human food, fodder, raw material for fermented beverages and to obtain fibers; at least 48 of these species are currently used to produce spirits called “tequila”, “mezcal”, “bacanora” and other distilled with economic importance [1]. The agave plant is described as a monocarpic perennial monocot that produces an inflorescence only once towards the end of its long life cycle. Each plant produces several hundred seeds and it has been demonstrated for a number of Agave species and genotypes that a large proportion of these seeds are viable [1,2]. Agave plants reproduce both sexually and asexually, but they commonly propagate asexually via rhizomes and bulbils in the wild [3]; this propagation favours successful seedling establishment by initial dependence on the mother plant.

Agave species are Crassulacean acid metabolism (CAM) plants distributed throughout a wide variety of environments, although a large number of them are found in mesophyte communities [4]; moreover, they tolerate high heat and dry conditions and efficiently produce a large biomass in these environments [5], where few commercial crops can grow. It has also been shown that after germination under optimal conditions, seedlings of A. salmiana can grow on a substrate with a water potential ($\Psi_W$) of −2.5 MPa [6] and young and adult plants of A. salmiana and A. angustifolia ssp. tequilana maintain active photosynthetic pathway after six months without water, and even throughout the whole dry season [7,8]. It has also been observed that root and leaf growth of young A. salmiana plants is affected by frequent irrigation [8]. In addition, the diversity of Agave species and environments where they are distributed show an array of specific physiological responses associated with the climate where these plants naturally grow. This evidence suggests that agave seed germination, in addition to other physiological processes, might develop properly in conditions which are suboptimal for other species.
Germination is affected by intrinsic (species and seed size) and environmental (temperature and water availability) factors; however, the seed germination of species adapted to dry environments and cultivars selected for drought tolerance are less affected by low substrate $\Psi_W$ than those adapted to wet environments or classified as drought-sensitive [9,10]. The hydrotine model has been used to quantify the effect of substrate $\Psi_W$ on seed germination. The parameters that describe this model allow quantification of the response of a seed germination population to the substrate $\Psi_W$ and its biological variation [11-13] and are also useful in understanding some of the ecological relationships between plant species [9,14,15].

The aim of this study was to assess the effect of substrate $\Psi_W$ on seed germination and contrast hydrotine parameters of seven valuable and commercially-important Agave species, with a long history of human usage and from different geographical distributions and climatic regions of Mexico. Our hypothesis was that seed germination of Agave species is not affected by low water availability independently of seed biomass and the climate of their distribution area.

**Results**

**Seed water uptake**

Seed water uptake with maximum water availability varied significantly ($p < 0.05$) among species (Figure 1). Imbibition by A. cupreata and A. duranguensis was 20% higher than for A. americana and A. salmiana during first 12 h of germination at $-0.03$ MPa, at $\Psi_W$ lower than $-0.03$ MPa decreased significantly (between 42% and 67%) for all species, and with the exception of A. americana, A. cupreata and A. duranguensis decreased linearly. Also, of these three species, initial seed water uptake at $-1.5$ was not significantly different ($p > 0.05$) than at $-1.0$ MPa (Figure 2A).

Differences and similarities in seed water uptake changed with time and with substrate $\Psi_W$. Maximum seed

![Figure 1 Calculated time-courses of cumulative seed water uptake of Agave spp. at 25°C, in the dark, and in substrate water potentials of -0.03 (A), -1.0 (B) and -1.5 MPa (C). A. americana var. marginata (black line), A. asperrima (red line), A. cupreata (green line), A. duranguensis (gray line), A. lechuguilla (dark blue line), A. salmiana (pink line) and A. striata (light blue line); n = 50.](image)

![Figure 2 Initial seed water uptake (after the first 12 h) (A) and maximum seed water uptake (B) of Agave spp. during germination in different substrate water potentials, in the dark and at 25°C. water uptake of *A. asperrima* and *A. striata* was significantly higher (165%) than for the other five species and strongly contrasted with that for *A. americana* and *A. salmiana*, which had the lowest water uptake (100 and 115%) (p < 0.05) of all seven species at a $\Psi_W$ of −0.03 MPa (Figures 1A and 2B). The initial accelerated water uptake up to maximum germination, was on average 43% lower (p < 0.05) at both low $\Psi_W$ (40 h) than at −0.03 MPa (70 h) (Figure 1A–C). Maximum seed water uptake of all *Agave* species reduced significantly in a non-linear fashion (50% on average) with lower $\Psi_W$ (Figure 2B) and the large differences observed at −0.03 MPa among species almost disappeared at −1.0 and −1.5 MPa (Figure 1A–C). In general, maximum seed water uptake of *A. striata* and *A. asperrima* was among the highest at all three $\Psi_W$, whereas that of *A. americana* was among the lowest. Other differences in seed water uptake were that only *A. asperrima* reached similar (p > 0.05) maximum seed water uptake at −1.0 MPa and −1.5 MPa; and only *A. duranguensis* reached a higher (p < 0.05) maximum seed water uptake at −1.5 MPa than at −1.0 MPa (Figure 2B).

**Radicle emergence**

All seven *Agave* species lacked significant seed dormancy and mean cumulative germination (radicle emergence) at −0.03 MPa was 84–100% in 80 to 180 h, depending

![Figure 3 Time-course of cumulative germination of Agave spp. seeds in substrate at -0.03 MPa (A), -1.0 MPa (B), and -1.5 MPa followed by -0.03 MPa (shaded area; C), in the dark and at 25°C. A. americana var. marginata (crosses), A. asperrima (red triangles), A. cupreata (green triangles), A. duranguensis (gray stars), A. lechuguilla (blue circles), A. salmiana (pink squares) and A. striata (blue diamonds), n = 50.](http://www.biolres.com/content/47/1/11)
on the species (Figure 3A). On average, germination at −0.03 MPa started at 72 h and significantly increased almost each 12 h, up to 120 h. Maximum cumulative germination was similar at \(\Psi_W\) of −1.0 MPa and at −0.03 MPa, but the time taken to reach the maximum increased more than two-fold (Figure 3A-B). On average, germination at −1.0 MPa started after 132 h and significantly rose for 240 h, but the cumulative germination increase was significantly each 12 or 24 h, and was slower than at −0.03 MPa. In contrast, a \(\Psi_W\) of −1.5 MPa reduced on average 50% the maximum cumulative germination of all species in comparison with −0.03 and −1.0 MPa, except for \(A.\) striata and \(A.\) americana (Figure 3C). Germination at −1.5 MPa started after 209 h, but was significantly different from the starting level until 228 h (almost zero), this \(\Psi_W\) caused significantly rise of germination at 12, 24 and 36 h periods, but this rise was slower than at −1.0 and −0.03 MPa.

The rate of germination at \(\Psi_W\) between −0.03 and −1.5 MPa decreased linearly (\(p < 0.05\)) for all species (on average from 0.26 to 0.06 seeds d\(^{-1}\)), however, the decrease in \(A.\) salmiana was the lowest (0.2 to 0.1 d\(^{-1}\); Figure 4). The hydrotime parameters of \(A.\) salmiana were notable among all species as it had the highest \(\theta_{15}\) and \(\sigma_{\Psi_{b(50)}}\) and the lowest \(\Psi_{b(50)}\). All species showed a relatively similar \(\theta_{15}\) between 140 and 190 (Table 1), except for \(A.\) salmiana.

### Table 1 Parameters of the hydrot ime model for seed germination of seven \(Agave\) species under three substrate water potentials (−0.03, −1.0 and −1.5 MPa)

| Species                      | \(\theta_{15}\) (MPa h) | \(\Psi_{b(50)}\) (MPa) | \(\sigma_{\Psi_{b(50)}}\) (MPa) | \(r^2\) |
|------------------------------|-------------------------|-------------------------|---------------------------------|--------|
| \(A.\) americana var. marginata | 142                     | −2.01                   | 0.44                            | 0.823  |
| \(A.\) asperrima             | 158                     | −1.58                   | 0.37                            | 0.881  |
| \(A.\) cupreata              | 190                     | −1.82                   | 0.46                            | 0.814  |
| \(A.\) duranguensis          | 137                     | −1.68                   | 0.58                            | 0.775  |
| \(A.\) lechuguilla           | 153                     | −1.84                   | 0.36                            | 0.892  |
| \(A.\) salmiana              | 282                     | −2.64                   | 0.81                            | 0.768  |
| \(A.\) striata               | 176                     | −2.02                   | 0.41                            | 0.829  |

\(\theta_{15}\): hydrot ime constant; \(\Psi_{b(50)}\): base water potential; \(\sigma_{\Psi_{b(50)}}\): standard deviation of \(\Psi_{b(50)}\); \(r^2\): determination coefficient.

### Recovery of germination

A large proportion (20-80%) of seeds of several species did not germinate after a relatively long period (732 h) at \(\Psi_W\) of −1.5 MPa. However, germination continued after 12–48 h when these seeds were transferred to a substrate with a \(\Psi_W\) of −0.03 MPa. Thus, \(A.\) cupreata, \(A.\) striata, \(A.\) duranguensis and \(A.\) lechuguilla reached the second final maximum cumulative germination (85-100%) similar to that at −1.0 and −0.03 MPa (\(p > 0.05\)). Likewise, germination of the other three species also increased up to 80% after being transferred to the highly hydrated substrate (Figure 3C). Under these conditions, most \(Agave\) species tolerated slow seed water uptake and survived for more than 30 d with 70% hydration without damage.

### Discussion

#### Seed water uptake

Germination phases I and II for the seven species (Figure 1) were similar to those of dried mature seeds of several \(A.\) salmiana genotypes [2]. Differences of initial seed water uptake in phase I under maximum water availability (Figure 2A) show that \(A.\) cupreata, which originates from a sub-humid climate (838 mm annual mean precipitation; Table 2), imbibed more water than species from arid and semi-arid climates (340–361 mm of precipitation) i.e. \(A.\) lechuguilla, \(A.\) americana and \(A.\) salmiana. However, this response was not common to all \(Agave\) species but was the case for \(A.\) striata, with a high water uptake during phase I of germination under the three substrate \(\Psi_W\), it possibly can happen as an adaptation to arid habitats (287 mm of precipitation).

Seed water uptake is governed by several variables including seed size and biomass [15], seed-soil \(\Psi_W\) difference, seed contact area as affected by vapour or liquid transfer, and conductive properties of the seed for both liquid and vapour phases, among others [12]. In the present study, seeds experienced similar conditions
during germination, except substrate $\Psi_W$. Maximum seed water uptake was high in some species with a low seed biomass, but no general correlation between the two variables was noted. *A. asperrima* and *A. striata* had a low mean seed biomass (2 and 5 mg; Figure 5) and the highest maximum seed water uptake (160%), but *A. americana var. marginata*, with one of the larger mean seed biomass (11 mg), had the lowest maximum seed water uptake (105%) at $-0.03$ MPa (Figures 1A, 2B and 5). Differences in maximum seed water uptake among species (Figure 2B) were partly similar to those found by Peña-Valdivia et al. [2] for three *A. salmiana* genotypes with different seed sizes. We suggest that this result might be evidence for differences in seed water permeability among *Agave* species. Different ways of water entry into the seed and contrasting sequences of seed structure imbition among species and cultivars have been previously documented [21,22]. Furthermore, differences in maximum seed water uptake during phase II of germination are due to changes in volume and reorganisation of seed macromolecules (e.g. polysaccharides and proteins) [23] that promote more places on seed for water absorption [24]. During this process, changes within the seed occur at different

![Figure 5](image-url)  
*Figure 5 Frequency distribution of seed size (mass) of Agave spp. $n = 300$. A, A. americana var. marginata, B, A. asperrima, C, A. cupreata, D, A. duranguensis, E, A. lechuguilla, F, A. salmiana and G, A. striata.*
rates. Thus, low water availability ($\Psi_W$ between $-1.0$ and $-1.5$ MPa) might promote partial hydration and volume increase of macromolecules in *Agave* seeds. Despite controversy regarding the role of seed composition in seed water uptake, heterogeneity in maximum seed water uptake between a barley mutant and a cultivar was explained by differences in seed chemical composition [25]. In this context, Brancalion et al. [26] observed a positive relationship between seed protein content and critical seed water content for germination in five Brazilian tropical woody species.

Differences in maximum seed water uptake during phase II of germination in *Agave* species (Figure 2B) were similar to those for *Festuca rubra* ssp. *litoralis*, *Lolium perenne* and *Poa pratensis* [27]. Results suggest that *Agave* seeds at low substrate $\Psi_W$ reached a hydration threshold for radicle emergence. Therefore, more time is required to reach the hydration threshold at low $\Psi_W$ and radicle emergence will not occur [12]. The seed water uptake threshold in most *Agave* species was approximately half that reached at the highest $\Psi_W$ (Figure 1A-B). This difference was larger than that obtained with seeds of *Lolium perenne* and *P. pratensis*; seed water uptake to germination in these species diminished from 100 and 90% to an asymptotic level of 90 and 80%, respectively, when the $\Psi_W$ changed from zero to $-0.8$ MPa or less [27].

**Radicle emergence**

The lack of dormancy in several *Agave* species and genotypes has been documented [1,2], as well as the high reproductive effort expressed by semelparity and the production of a huge amount of seeds by a single plant [28]. In contrast, most *Agave* species in field conditions predominantly present asexual reproduction [29]. The small seed size, which varied between 2 and 11 mg (Figure 5), in relation to the high plant biomass (200 kg estimated for an *A. salmiana* adult plant), differs from the usual positive correlation found between seed and plant size [30]. However, a lack of dormancy and massive production of small and viable seeds might favour the emergence of a large quantity of seedlings when environmental conditions are favourable, and represent an opportunity for repopulation based on sexual reproduction.

The lowest substrate $\Psi_W$ reduced the maximum accumulated germination of some species (p < 0.05) (Figure 3C). *Agave* germination at such restrictive substrate $\Psi_W$, under laboratory conditions, might partially mirror the response in the natural environmental conditions where each species grows (Table 2). The low percentage of germination of *A. cupreata* (20%) at $-1.5$ MPa (Figure 3C) appears to be related to the sub-humid climate (838 mm mean annual precipitation) where this species is distributed and contrasts with the non-significant effect of this low $\Psi_W$ on germination of *A. striata* (85%), *A. americana* (78%) and *A. lechuguilla* (70%) and the arid and semi-arid climate (280–580 mm mean annual precipitation) within their natural distribution range. Nevertheless, this relationship was not general, as *A. asperrima* reached a very low final cumulative germination (30%) at $\Psi_W$ of $-1.5$ MPa, despite originating from a semi-arid climate region (450 mm mean annual precipitation).

A lack of germination after 732 h, at $-1.5$ MPa, suggests that some *Agave* seeds lack some stimulus for germination, despite the inhibition of a similar amount of water as those seeds already germinating at this specific $\Psi_W$ (Figures 1 and 2). The lack of germination under optimal conditions has been considered as dormancy [12,31], and occurs by a variation of the critical seed $\Psi_W$ to germinate among individual seeds within the same population. Therefore, whereas the seed $\Psi_W$ remains at a partially limiting level, the cumulative germination remains as an asymptote. Inhibition and the absence of germination for some *Agave* species at $-1.0$ and $-1.5$ MPa (Figure 3B-C) might be evidence of their tolerance to low substrate $\Psi_W$. We recognised $-1.5$ MPa as an adequate substrate $\Psi_W$ to identify the effects of water availability on seed germination of *Agave* spp. and as a stress factor for germination of these species.

The hydrot ime model indicates that seeds do not germinate below a $\Psi_W$ threshold, but up to this value, seeds germinate because of $\theta_H$ accumulation. Each seed in a population varies in the threshold level of accumulated $\theta_H$ necessary to germinate, but $\theta_H$ is constant for the population as a whole [11-13]. Repeated measures analysis indicated that accumulation of $\theta_H$ was delayed by the low $\Psi_W$. Also it indicated that germination at $-1.5$ MPa significantly increased at 12, 24 and 36 h intervals; whereas at $-0.03$ and $-1.0$ MPa significant increase was observed every 12 or 24 h. Then the $\Psi_W$ threshold was lower than $-1.0$ MPa for the seven species, but even lower for some of them, as *A. striata* and *A. americana* (Figure 3C).

The huge difference in minimum water availability necessary for germination among *Agave* species was demonstrated by the variation in $\theta_H$ from 137 MPa h for *A. duranguensis* to 282 MPa h for *A. salmiana* (Table 1). According to Bradford [12], $\theta_H$ is an indicator of seed vigour and physiological quality; results suggested that there was a gradient of vigour among *Agave* species (Table 1). In general, the hydrot ime model adequately fitted data for the germination of *Agave* spp. (mean $r^2 = 0.83$). However, individual $r^2$ values indicated that the hydrot ime model better explained seed germination of *A. asperrima* and *A. lechuguilla* than that of *A. duranguensis* and *A. salmiana* (Table 1).

The linear relationship between the rate of *Agave* seed germination and substrate $\Psi_W$ (Figure 4) was similar to that observed for sugar beet [11] and *Eurotia lanata*
The rate of *Agave* seed germination correlated positively with maximum seed water uptake \((r = 0.74, \ p < 0.05)\); although seeds absorbed more water when water was abundant than when it was restrictive, each seed had a seed water uptake threshold \(\Psi_{bg}\) to initiate germination [13]. The \(\Psi_{bg(50)}\) of *Agave* species (Table 1) was relatively similar to that of *Solanum lycopersicum* seeds when they were exposed to a low substrate \(\Psi_{W}\), which promoted their germination [33] and was also similar to that of a group of 14 coloniser species [15]. In contrast, higher variation in each seed had a seed water uptake threshold \(\Psi_{bg}\) when water was abundant than when it was restrictive, \(r = 0.74, \ p < 0.05\); although seeds absorbed more water correlated positively with maximum seed water uptake under low water availability increases. Germination responses of *Agave* species can maintain low seed water uptake for several weeks and germinate rapidly when water availability increases. Seed biomass do not appears to be a distinctive characteristic for responses to water availability during germination.

### Methods

#### Plant material

Seven Mexican *Agave* species were studied, which all had ancestral or current economic importance and belonged to different geographical distributions with different climates, and had sexual or asexual (or both) reproduction strategies or diverse systematic positions (Table 2). Fruits from vigorous healthy plants were harvested and dried under laboratory conditions (25°C and low relative humidity). To standardise seed water content, seeds of each species were placed in a cheesecloth-like bag inside a glass jar three months prior to experimentation and maintained at 4 ± 1°C. Subsequently, four replicates, each with five seed, were used to measure seed water content, which was 7.62 ± 0.52%.

#### Seed biomass stratification

Seed biomass was obtained from a sample of 300 seeds from each species (Figure 5). Because variation in seed biomass within a species might affect germination, only seeds within one standard deviation of the mean seed
biomass for each species were used [1]. *Agave duranguesis* showed a bimodal seed size distribution; a preliminary assay of germination showed little or no germination of lighter seeds, therefore, heavier seeds of this species were used for this study.

**Substrate water potential and experimental conditions**

Vermiculite was rinsed in tap water and then dried at 100°C to constant weight. Three different vermiculite $\Psi_W$ (−0.03, -1.0 and −1.5 MPa) were obtained by mixing 100 g dry vermiculite with 170, 16 or 11 mL distilled water (w/v) in polyethylene bags. These were sealed for 48 h before the start of the assay, according to Peña-Valdivia and Sánchez-Urdaneta [6], after which time a vermiculite sample was incubated in a psychrometric chamber (Wescor C-52, Inc, Utha, USA) for 4 h, and its $\Psi_W$ was subsequently determined by connecting the chambers to a microvoltmeter (Wescor HR-33 T, Inc, Utha, USA) operated in the dew-point mode.

Individual seeds were sown at 1 cm depth in cylindrical polyvinyl chloride (PVC) containers (40 mm diameter, 50 mm depth). Containers were filled with vermiculite at each $\Psi_W$ and sealed with a piece of black polyethylene, which was fixed with an elastic band to keep constant $\Psi_W$ and were kept in the dark at 25 ± 2°C.

**Data recording and analysis**

Seed water uptake (expressed as a percentage of initial seed biomass) and seed germination were recorded every 12 h or daily up to maximum values. Germination was considered to have occurred when the emerging root was at least 5 mm long and maximum germination in each treatment was determined when no additional seeds germinated after 3–4 days. Vermiculite from each experimental unit was renewed every 72 h to maintain a constant substrate $\Psi_W$. When treatments at −1.5 MPa had reached maximum germination, non-germinated seeds were transferred to vermiculite at −0.03 MPa and kept until germination occurred or seed damage appeared.

Germination attributes were analysed using the hydrotime model. According to this model [11–13], seed germination can be described using the following equation:

$$\Psi_{bg} = \Psi_W^{-\left(\theta_H / t_g\right)}$$

where $\Psi_{bg}$ was the base water potential (MPa) at which the g seed sample germinates, $\Psi_W$ was the substrate water potential (MPa), $\theta_H$ was the hydrotime constant, or the accumulated water-time required to germinate a one g sample of a seed population (MPa h), and $t_g$ was the time from water uptake until germination of the g fraction (h or d). It was assumed that $\Psi_{bg}$ was normally distributed within a seed population, and that $\theta_H$ was constant for all seed fractions [13]. Apart from seed $\Psi_{bg}$, the median population $\Psi_{bg}$ can be estimated ($\Psi_{bg(50)}$) and was defined as the base or minimum $\Psi_W$ necessary to achieve 50% germination. At this level of germination, it was possible to quantify the time taken for 50% germination ($t_{g(50)}$) or the rate of germination ($1/t_{g(50)}$). The standard deviation ($\sigma_{\Psi_{bg}}$) of $\Psi_{bg(50)}$ was the parameter of $\Psi_{bg}$ variability. The hydrotime parameters were calculated as described by Allen et al. [9].

**Experimental design and statistical analysis**

This study was conducted using a completely randomized design, with a factorial (7 × 3) arrangement of treatments and five experimental units; each unit was a group of 10 PVC containers. Factors were species (*A. americana var. marginata*, *A. asperrima*, *A. cupreata*, *A. duranguesis*, *A. lechuguilla*, *A. salmiana* and *A. striata*) and substrate $\Psi_W$ (−0.03, -1.0 and −1.5 MPa). The normality test was performed based on graphic residual analysis and the Shapiro-Wilk’s test for data for initial and maximum seed water uptake, rate of germination ($1/t_{g(50)}$) and the maximum accumulated percentage of germination at every time. Data were transformed when normality suposition failed. Variables were analysed using the GLM procedure of SAS software, 9.17 version (SAS Institute, NC, USA) and significant differences among treatment means were established using Tukey’s honest significant difference (HSD) test with $\alpha = 0.05$.

A repeated measurements test was performed in order to analyse variation of cumulative germination along the time. For this analysis Statistica Ver. 6 software was used.
