(Received 15 July 2021; accepted 18 February 2022; published online 24 March 2022)

The Value-at-Risk (VaR) is a widely used instrument in financial risk management. The question of estimating the VaR of loss return distributions at extreme levels is an important question in financial applications, both from operational and regulatory perspectives; in particular, the dynamic estimation of extreme VaR given the recent past has received substantial attention. We propose here a new two-step bias-reduced estimation methodology for the estimation of one-step ahead dynamic extreme VaR, called GARCH-UGH (Unbiased Gomes-de Haan), whereby financial returns are first filtered using an AR-GARCH model, and then a bias-reduced estimator of extreme quantiles is applied to the standardized residuals. Our results indicate that the GARCH-UGH estimates of the dynamic extreme VaR are more accurate than those obtained either by historical simulation, conventional AR-GARCH filtering with Gaussian or Student-\( t \) innovations, or AR-GARCH filtering with standard extreme value estimates, both from the perspective of in-sample and out-of-sample backtestings of historical daily returns on several financial time series.

Keywords: Bias correction; Extreme value theory (EVT); Financial time series; GARCH model; Hill estimator; Value-at-Risk (VaR)

1. Introduction

A major concern in financial risk management is to quantify the risk associated to high-impact, low-probability extreme losses. The most widely known risk measure is Value-at-Risk (VaR), defined as a quantile of the loss distribution. Even though the Basel Committee on Banking Supervision recommends the use of VaR at high levels (see for example Basel Committee on Banking Supervision 2013), it has been criticized several times in the financial literature for two main reasons. First, the VaR only measures the frequency of observations below or above the predictor and not their magnitude: this means that, while it is known that 100(1 – \( \tau \))% of losses will be higher than the VaR \( q_\tau \) at level \( \tau \), the VaR alone cannot give any further information about the size of these large losses. Second, the VaR is not a coherent risk measure in the sense of Artzner et al. (1999), because it is not sub-additive in general, meaning that it does not abide by the intuitive diversification principle stating that a portfolio built on several financial assets carries less risk than a portfolio solely consisting of one of these assets. These two weaknesses pushed the Basel Committee to also recommend calculating the Expected Shortfall (or Conditional Value-at-Risk) as a complement or alternative to the VaR. In practice, this is hampered by the fact that the Expected Shortfall is not elicitable in the sense of Gneiting (2011), and therefore the development of a simple backtesting methodology for the Expected Shortfall is not clear (see Deng and Qiu 2021 for a very recent comprehensive study of backtesting procedures for the Expected Shortfall).

This is why the accurate estimation of VaR is worth pursuing, and is our focus in this paper. An estimation of the unconditional VaR (that is, of the common distribution of returns over time, assumed to be stationary) is appropriate for the estimation of potential large levels of loss over the long term, for example with the goal of making long-term investment decisions. On the other hand, the conditional VaR is more appropriate for day-to-day and short-term risk management by capturing the dynamics and the key properties of...
financial asset returns such as volatility clustering and leptokurtosis. The estimation of the extreme conditional VaR, on which we focus in this paper, therefore gives a better understanding of the riskiness of the portfolio because this riskiness varies with the changing volatility. Quantifying the risk associated to extreme losses can then be done by estimating an extreme quantile of order \( 1 - p \), where \( p = p(n) \to 0 \) as the available sample size \( n \) of the data tends to infinity.

There are two main classes of methods to estimate the conditional VaR. Nonparametric historical simulation (HS) relies on observed data directly, and uses the empirical distribution of past losses without assuming any specific distribution, see Danielsson (2011) and McNeil et al. (2015). Although HS is easy to implement, the estimation of extreme quantiles using HS is difficult as the extrapolation beyond observed returns is impossible because this method essentially assumes that one of the observed returns is expected to be the next period return. By contrast, the parametric approach generally refers to the use of an econometric model of volatility dynamics such as, among many others, the Generalized Autoregressive Conditional Heteroskedasticity (GARCH) model of Bollerslev (1986). These models estimate VaRs reflecting the conditional heteroskedasticity of financial data. However, GARCH-type models assuming a parametric distribution of the innovation variable tend to underestimate risk at extreme levels because this strong parametric assumption is not well-suited to the accurate estimation of heavy-tailedness in the conditional returns of financial time series.

To overcome the problems of purely nonparametric or parametric estimations of extreme VaR, McNeil and Frey (2000) propose a two-step approach combining a GARCH-type model and Extreme Value Theory (EVT), referred to as GARCH-EVT throughout. EVT focuses only on the tails and allows the extrapolation beyond available data, while traditional econometric models focus on the whole distribution at the expense of consideration of the tails. The key idea of the GARCH-EVT method is to estimate the dynamic extreme VaR by first filtering financial time series with a GARCH-type model to estimate the current volatility, and then by applying the EVT method to the standardized residuals for estimating the tails of the residual distribution. This approach has been widely used to estimate the extreme conditional VaR. For instance Byström (2004) and Fernandez (2005) find GARCH-EVT to give accurate VaR estimates for standard and extreme quantiles compared with GARCH-type models and unconditional EVT methods on stock market data collected across the US, Latin America, Europe and Asia. Being a two-step procedure based on GARCH-type filtering, the accuracy of the GARCH-EVT approach has been debated. Chavez-Demoulin et al. (2005) point out that estimates of the extreme conditional VaR via the GARCH-EVT approach are sensitive to the fitting of a GARCH-type model to the dataset in the first step. On the other hand, Furió and Climent (2013) and Jalal and Rockinger (2008) have concluded that there is no evidence of any difference in the final VaR estimates, regardless of the particular GARCH model selected to filter financial data.

Since the debate on filtering, several modifications of the conventional GARCH-EVT method have been suggested in the literature to provide a more accurate calculation of the residuals before applying the EVT method in the second step. Yi et al. (2014) propose a semiparametric version of GARCH-EVT based on quantile regression. Youssef et al. (2015) adapt the FIGARCH, HYGARCH and FIAPARCH models to estimate extreme conditional VaRs for crude oil and gasoline market. Bee et al. (2016) propose an approach called realized EVT where returns are pre-whitened with a high-frequency based volatility model. Zhao et al. (2019) develop hybrid time-varying long-memory GARCH-EVT models by using a variety of fractional GARCH models. To the best of our knowledge, little work has been carried out on the EVT step itself; Ergen (2015) uses the skewed \( t \)-distribution that is fitted to the standardized residuals from the GARCH step in order to recover a fully parametric specification. In the context of estimation and inference of unconditional extreme VaR, bias correction is a key concern and has an extensive history (see e.g. Cai et al. 2013 for a review). de Haan et al. (2016) develop a semiparametric bias-reduced estimator of extreme unconditional VaR in stationary time series. However, such improvements have not been investigated so far in the specific context of dynamic estimation of extreme quantiles of financial time series.

This is the contribution of the present paper. More precisely, in the context of the estimation of the one-step ahead dynamic extreme VaR, we develop a new methodology called GARCH-UGH (standing for Unbiased Gomes-de Haan, after Gomes et al. 2002, de Haan et al. 2016). The novelty in this methodology is that, instead of applying the Peaks-Over-Threshold (POT) method in the GARCH-EVT approach as in McNeil and Frey (2000), we use an asymptotically unbiased estimator, derived from the work of de Haan et al. (2016), of the extreme quantile applied to the standardized residuals from the GARCH step. We analyze the performance of our approach on four financial time series, which are the Dow Jones, Nasdaq and Nikkei stock indices, and the Japanese Yen/British Pound exchange rate. As we shall illustrate, our results indicate that GARCH-UGH provides substantially more accurate one-step ahead extreme conditional VaRs than either HS, the conventional GARCH-N method (that is, the standard GARCH specification of heteroskedasticity with normal innovations), its GARCH-\( t \)-analog where the innovations are Student-\( t \) distributed, the GARCH-EVT approach, or bias-reduced EVT without filtering, based on the performance of the in-sample and out-of-sample backtests. In addition, our bias-reduction procedure will be designed to be robust to departure from the independence assumption, and as such will be able to handle residual dependence present after filtering in the first step. Our finite-sample results will also illustrate that the GARCH-UGH method leads to one-step ahead extreme conditional VaR estimates that are less sensitive to the choice of sample fraction, and hence mitigates the difficulty in selecting the optimal number of observations for the estimations. Finally, the computational cost of GARCH-UGH is lower than that of conventional GARCH-EVT: the extreme value step in the GARCH-UGH method is semiparametric with an automatic and fast recipe for the estimations of the one-step ahead extreme conditional VaRs, while the GARCH-EVT method is based on a parametric fit of the Generalized Pareto Distribution (GPD) to the residuals using Maximum Likelihood Estimation.
2. The GARCH-UGH method and framework

Let \( p_t \) be a daily-recorded price for a stock, index, or exchange rate, and let \( X_t = -\log(p_t/p_{t-1}) \) be the negative daily log-return on this price. We assume that the dynamics of \( X_t \) are governed by

\[
X_t = \mu_t + \sigma_t Z_t, \tag{1}
\]

where \( \mu_t \in \mathbb{R} \) and \( \sigma_t > 0 \) denote the (conditional) mean and standard deviation, and the innovations \( Z_t \) form a strictly stationary white noise process, that is, they are i.i.d. with zero mean, unit variance and common marginal distribution function \( F_Z \). We assume that for each \( t \), \( \mu_t \) and \( \sigma_t \) are measurable with respect to the \( \sigma \)-algebra \( \mathcal{F}_t \) representing the information about the return process available up to time \( t-1 \).

We are concerned with estimating extreme conditional quantiles of these negative log-returns. Recall that for a probability level \( \tau \in (0,1) \), the \( \tau \)th unconditional quantile of a distribution \( F \) is \( q_{\tau}(F) = \inf\{x \in \mathbb{R} : F(x) \geq \tau \} \). Here we focus on the one-step ahead quantile, that is, the estimation of the conditional extreme quantile of \( X_{t+1} \) given \( \mathcal{F}_t \), whose order \( \tau \) tends to 1 as the available sample size \( n \) goes to infinity. In this case, by location equivariance and positive homogeneity of quantiles, the one-step ahead conditional quantile (or VaR) of \( X_{t+1} \) can be written as

\[
q_{\tau}(X_{t+1} | \mathcal{F}_t) = \mu_{t+1} + \sigma_{t+1} q_{\tau}(Z), \tag{2}
\]

where \( q_{\tau}(Z) \) is the common \( \tau \)th quantile of the marginal distribution of the innovations \( Z_t \). The problem of estimating \( q_{\tau}(Z) \) can then be tackled by estimating the mean and standard deviation components \( \mu_{t+1} \) and \( \sigma_{t+1} \) and the unconditional quantile \( q_{\tau}(Z) \). Given estimates \( \hat{\mu}_{t+1}, \hat{\sigma}_{t+1} \) and \( \hat{q}_{\tau}(Z) \) of these quantities, an estimate of \( q_{\tau}(X_{t+1} | \mathcal{F}_t) \) is

\[
\hat{q}_{\tau}(X_{t+1} | \mathcal{F}_t) = \hat{\mu}_{t+1} + \hat{\sigma}_{t+1} \hat{q}_{\tau}(Z).
\]

In calculating this estimate, there are three main difficulties. First, one has to estimate \( \mu_{t+1} \) and \( \sigma_{t+1} \), which supposes that an appropriate model and estimation method have to be chosen. Second, the innovations \( Z_t \) are unobserved, which means that the estimation of \( q_{\tau}(Z) \) has to be based on residuals following the estimation of \( \mu_{t+1} \) and \( \sigma_{t+1} \). A third difficulty is specific to our context: we wish here to estimate a dynamic extreme VaR, that is, a conditional quantile \( q_{\tau}(X_{t+1} | \mathcal{F}_t) \) with \( \tau \) very close to 1. In such contexts, it is well-known that traditional nonparametric estimators become inconsistent (see for example the monographs by Embrechts et al. 1997, Beirlant et al. 2004), and adapted extrapolation methodologies have to be employed.

Our GARCH-UGH method combines estimation of the mean and standard deviation in a GARCH-type model with a flexible bias-reduced extrapolation methodology for the estimation of \( q_{\tau}(Z) \) \( (\tau \uparrow 1) \) using the residuals obtained after estimation of the model structure. We describe these two steps successively below.

2.1. GARCH step

In order to estimate \( \mu_{t+1} \) and \( \sigma_{t+1} \), one should select a particular model in the class (1). Many different models for volatility dynamics have been used in the literature of GARCH-EVT approach, as we highlighted in our literature review in Section 1. Here we use an AR(1) model for the dynamics of the conditional mean, and a parsimonious but effective GARCH(1,1) model for the volatility, as in the original GARCH-EVT approach; this will allow us to subsequently illustrate how improving the second, EVT-based step can result in more accurate estimates of extreme conditional VaR.

We thus model the conditional mean of the series by \( \mu_t = 0 \times X_{t-1} \), for some \( \phi \in (-1,1) \), and the conditional variance of the mean-adjusted series \( \epsilon_t = X_t - \mu_t \) by \( \sigma_t^2 = \kappa_0 + \kappa_1 \epsilon_t^2 + \kappa_2 \sigma_{t-1}^2 \), where \( \kappa_0, \kappa_1, \kappa_2 > 0 \). Necessary and sufficient conditions for the stationarity of a model following GARCH(1,1) dynamics are given in Chapter 2 of Francq and Zakoïan (2010); the condition \( \kappa_1 + \kappa_2 < 1 \) is a simple sufficient condition guaranteeing stationarity. The model is therefore the AR(1)-GARCH(1,1) model

\[
X_t = \mu_t + \sigma_t Z_t, \quad \text{with } \mu_t = \phi X_{t-1} \text{ and } \sigma_t^2 = \kappa_0 + \kappa_1 (X_{t-1} - \mu_{t-1})^2 + \kappa_2 \sigma_{t-1}^2. \tag{3}
\]

In equation (3), the innovations \( Z_t \) are i.i.d. with zero mean, unit variance.

In order to make one-step ahead predictions at time \( t \), we fix a memory \( n \) so that at the end of time \( t \), the financial data consist of the last \( n \) negative log-returns \( X_{t-j} \), for \( 0 \leq j \leq n-1 \). We then fit the AR(1)-GARCH(1,1) model to the data \( (X_{t-n+1, \ldots, t-1}, X_t) \) using Gaussian Quasi-Maximum Likelihood Estimation (QMLE), that is, by maximizing the likelihood constructed by assuming that the innovations \( Z_t \) are i.i.d. Gaussian with zero mean and unit variance. The R package rugarch (Galanos and Kley 2022) has been used for the estimation. While of course the innovations \( Z_t \) will not be Gaussian in general (and indeed in our UGH step we shall assume that they are heavy-tailed), the QMLE method yields a consistent and asymptotically normal estimator, see for example Francq and Zakoïan (2004) for a theoretical analysis. One may also put a strong heavy-tailed parametric specification on \( Z_t \), such as assuming that they are location-scale Student distributed; this was tried in our analysis of financial log-returns but did not improve results substantially.

Let \( (\phi, \kappa_0, \kappa_1, \kappa_2) \) be the Gaussian QMLE estimates. Choosing sensible starting values for \( \kappa_2^2 - n \) and \( \kappa_2^2 \) (for example, constant values as in Section 7.1 of Francq and Zakoïan 2010), estimates of the conditional mean and the conditional standard
deviation, \((\hat{\mu}_{t-1}, \ldots, \hat{\mu}_t, \hat{\sigma}_t)\) and \((\hat{\sigma}_{t-1}, \ldots, \hat{\sigma}_t)\) respectively, can be calculated from equation (3) recursively. This leads to the residuals
\[
(\hat{Z}_{t-n+1}, \ldots, \hat{Z}_t) = \left( \frac{X_t - \hat{\mu}_t}{\hat{\sigma}_t}, \ldots, \frac{X_t - \hat{\mu}_t}{\hat{\sigma}_t} \right).
\]
We end this step by calculating the estimates of the conditional mean and standard deviation for time \(t + 1\), which are the obvious one-step ahead forecasts, as follows:
\[
\hat{\mu}_{t+1} = \hat{\phi}X_t, \quad \hat{\sigma}_{t+1} = \sqrt{\hat{\kappa}_1 + \hat{\kappa}_1^2 + \hat{\kappa}_2^2},
\]
where \(\hat{\kappa}_i = X_i - \hat{\mu}_t\). In summary, this first GARCH step of the method consists in fitting an AR(1)-GARCH(1,1) model to the negative log-returns at a certain past time horizon \(n\) (not too small so that the method produces reasonable results, and not too large so that the AR-GARCH model is believable over this time period), using a Gaussian QMLE, leading to forecasts \(\hat{\mu}_{t+1}\) and \(\hat{\sigma}_{t+1}\) and standardized residuals \(\hat{Z}_{t-j}\), \(0 \leq j \leq n - 1\).

2.2. UGH step

With standardized residuals at our disposal, we can now discuss the estimation of the extreme quantile \(q_\gamma(Z)\) of the innovations \(Z_{\tau}\) for \(\tau \uparrow 1\). The residuals \(\hat{Z}_{t-j}\), \(0 \leq j \leq n - 1\), approximate the true unobservable \(Z_{t-j}\). Assume that the underlying distribution of these \(Z_{t-j}\) is heavy-tailed, that is (see Theorem 1.2.1 p. 19 and Corollary 1.2.10 p. 23 in de Haan and Ferreira 2006)
\[
\lim_{t \to \infty} \frac{U(tz)}{U(t)} = z^\gamma, \quad \forall z > 0, \text{ where } U(t) = q_{1-t^{-\gamma}}(Z).
\]
(4)

In other words, we assume the tail of the innovations to be approximately Pareto, with the so-called extreme value index \(\gamma\) tuning how heavy the tail is. This assumption is ubiquitous in actuarial and financial risk management (see e.g. p. 9 of Embrechts et al. 1997 and p. 1 of Resnick 2007). It makes it possible to construct extrapolated extreme quantile estimators: the classical Weissman quantile estimator (see Weissman 1978) of a quantile \(q_{\gamma}(Z) = q_{1-p}(Z)\) with \(p = 1 - \alpha\) close to 0 (meaning, in mathematical terms, that \(p = p(n) \to 0\) as \(n \to \infty\)) is then
\[
\hat{\gamma}_{1-p}(Z) = \left( \frac{k}{n}\right) \gamma_{i} Z_{n-k,n}
\]
(5)
where \(Z_{0,n} \leq Z_{1,n} \leq \cdots \leq Z_{n,n}\) are the order statistics from \(Z_{n+1}, \ldots, Z_t\) and \(\gamma_i\) is a consistent estimator of \(\gamma\). The tuning parameter \(k\) denotes the effective sample size for the estimation: this parameter should be chosen not too small, so that the variance of the estimator is reasonable, but also not too large so that the bias coming from the use of the extrapolation relationship (4) does not dominate. The most common estimator \(\gamma_k\) of \(\gamma\) is the Hill estimator (introduced in Hill 1975):
\[
\hat{\gamma}_k = \hat{\gamma}_k = \frac{1}{k} \sum_{i=1}^{k} \log Z_{n-i+1,n} - \log Z_{n-k,n}.
\]
(6)
The Hill and Weissman estimators can be shown to be asymptotically Gaussian under suitable conditions on \(k = k(n)\) (see for example Chapters 3 and 4 in de Haan and Ferreira 2006).

A reasonable idea to define an estimator of \(q_{\gamma}(Z)\) in our context is then to use the estimators defined in equations (5) and (6) with the order statistics of the residuals, \(\hat{Z}_{t-j,n}\), in place of the unobservable \(Z_{t-j,n}\).

The choice of the parameter \(k\) requires solving a bias-variance tradeoff for which there is no straightforward approach. Indeed, with a low \(k\), the estimators use observations that are very informative about the extremes, but their low number results in a high variance. With a high \(k\), the variance is reduced, but at the cost of taking into account observations that are further into the bulk of the distribution and thus carry bias. One possible way to make the choice of \(k\) easier is to work on correcting this bias. This can be done under the following so-called second-order condition on \(U\):
\[
\lim_{t \to \infty} \frac{1}{A(t)} \left( \frac{U(tz)}{U(t)} - z^\gamma \right) = z^\gamma \left( \frac{\rho^2 - 1}{\rho} \right), \quad \forall z > 0,
\]
(7)
where \(\rho \leq 0\) is called the second-order parameter and \(A\) is a positive or negative function converging to 0 at infinity, such that \(|A|\) is regularly varying with index \(\rho\). See equation (6.35) p. 341 in Embrechts et al. (1997) and, in our parametrization, Theorem 2.3.9 p. 48 in de Haan and Ferreira (2006). The function \(A\) therefore controls the rate of convergence in equation (4): the larger \(|\rho|\) is, the faster \(|A|\) converges to 0, and the smaller the error in the approximation of the right tail of \(U\) by a Pareto tail is. This makes it possible to precisely quantify the bias of the Hill and Weissman estimators, and to correct for this bias by estimating the function \(A\) and the parameter \(\rho\). This results in bias-corrected Hill and Weissman estimators for which the selection of \(k\) is typically much easier because their performance is much more stable.

Our idea in this second, UGH step is to apply such bias-corrected estimators constructed in de Haan et al. (2016) (and built on second-order parameter estimators of Gomes et al. 2002, hence the name UGH, for Unbiased Gomes-de Haan) to our residuals obtained from the GARCH step. Our estimator of \(\rho\) motivated by Gomes et al. (2002) is
\[
\hat{\rho}_k^{(\alpha)} = \left( s^{(\alpha)} \right)^{-1} \left( S_k^{(\alpha)} \right).
\]
Here \(\alpha \notin \{1/2,1\}\) is a positive tuning parameter, \(s^{(\alpha)}\) denotes the generalized (left-continuous) inverse of the function
\[
s^{(\alpha)}(\rho) = \frac{\rho^2 (1 - (1 - \rho)^{2\alpha} - 2\alpha \rho (1 - \rho)^{2\alpha - 1})}{(1 - (1 - \rho)^{2\alpha + 1} - (\alpha + 1)\rho (1 - \rho)^{2\alpha})^2},
\]
and we set
\[
S_k^{(\alpha)} = \frac{\alpha (\alpha + 1)^2 \Gamma(\alpha)}{4 \Gamma(2\alpha)} \left( \frac{R_{k-k,n}^{(\alpha)}}{(R_{k-k,n}^{(\alpha + 1)})^2} \right).
\]
our residual-based, bias-corrected estimator of unconditional extreme quantiles of \( Z \):

\[
\hat{q}_{1-p}(Z) = \left( \frac{k}{np} \right)^{\frac{1}{4}} \hat{Z}_{n-k,n} \times \left[ 1 - \left\{ \frac{M_k^2(2) - 2(\hat{\gamma}^H)^2}{2\hat{\gamma}^H \hat{\rho}_k} \right\} \left[ 1 - \left( \frac{k}{np} \right)^{\frac{1}{4}} \hat{\rho}_k \right] \right].
\]  

(9)

This corresponds to a slightly different version of the estimator in Section 4.3 of de Haan et al. (2016), given later by Chavez-Demoulin and Guillou (2018), who pointed out a mistake in the analysis of de Haan et al. (2016). The use of \( \hat{\rho}_k \), rather than the Hill estimator in the extrapolation will correct the bias due to the estimation of the extreme value index; the multiplier corrects the bias specifically due to the use of the Pareto distribution for the extrapolation of extreme quantiles. The versions of these estimators for fully observed data work when this data is weakly serially dependent, as shown in Chavez-Demoulin and Guillou (2018). As such, our proposed method will be robust to the presence of residual dependence after filtering and to model misspecification in the sense of Hill (2015). We shall also show that the choice of \( k \) for this estimator is not as crucial in finite samples as for the traditional Hill estimator, because this estimator has reasonably good performance across a large range of values of \( k \).

Note that if the \( Z_{t-j}, 0 \leq j \leq n - 1 \) are independent, then Theorem 4.2 of de Haan et al. (2016) suggests that

\[
\frac{\sqrt{k}}{\log(k/np)} \left( \frac{\hat{q}_{1-p}(Z)}{q_{1-p}(Z)} - 1 \right) \overset{d}{\longrightarrow} N\left( 0, \frac{\gamma^2}{\hat{\rho}^2} (\rho^2 + (1 - \rho)^2) \right).
\]

A standard Gaussian 95% asymptotic confidence interval for the extreme quantile \( q_{1-p}(Z), p \downarrow 0 \) is then given by

\[
\left[ \hat{q}_{1-p}(Z) \left( 1 \pm \frac{1.96}{\sqrt{k/\log(k/np)}} \times \sqrt{\frac{\hat{\gamma}^2_{k,n}}{\hat{\rho}_k} + (1 - \hat{\rho}_k)^2} \right) \right].
\]

This asymptotic Gaussian confidence interval is easy to implement, but of course its validity relies on assuming that the negative log-returns are correctly filtered using the AR-GARCH model.

2.3. Summary and output of the GARCH-UGH method

The GARCH-UGH approach may be briefly summarized by the following two successive steps:

(1) GARCH step: based on \( n \) previous observations at time \( t \), fit an AR(1)-GARCH(1,1) model to the negative daily log-returns data using a Gaussian QMLE. Obtain \( \hat{\mu}_{t+1} \) and \( \hat{\sigma}_{t+1} \) using the fitted model and compute standardized residuals. See Section 2.1 for full details on this GARCH step, similar to the first step in McNeil and Frey (2000).
Figure 1. Daily negative log-returns of four financial time series: DJ, NASDAQ, NIKKEI and JPY/GBP. (a) DJ (23/12/1993 to 09/11/2009). (b) NASDAQ (30/08/1993 to 16/07/2009). (c) NIKKEI (14/05/1993 to 12/08/2009) and (d) JPY/GBP (02/01/2000 to 14/12/2010).

(2) UGH step: use these standardized residuals as proxies for the true unobserved innovations $Z_t$, $0 \leq j \leq n - 1$, to construct the asymptotically unbiased tail quantile estimator $\hat{q}_{1-\tau}(Z)$ in (9). See Section 2.2 for full details on this UGH step which is a different, residual-based new version of the procedure of de Haan et al. (2016).

Combining the two steps results in the final GARCH-UGH estimator

$$\hat{q}_{\tau}(X_{t+1} \mid \mathcal{F}_t) = \hat{\mu}_{t+1} + \hat{\sigma}_{t+1} \hat{q}_{\tau}(Z), \quad \tau = 1 - p, \ p \ close \ to \ 0.$$  

The goal of our real data analysis is to examine the finite-sample performance of this estimator for low exceedance probabilities, that is, $\tau$ close to 1.

3. Empirical analysis of four financial time series

We consider historical daily negative log-returns of three financial indices and an exchange rate, all made of $n = 4000$ observations:

- The Dow Jones Industrial Average (DJ) from 23 December 1993 to 9 November 2009;
- The Nasdaq Stock Market Index (NASDAQ) from 30 August 1993 to 16 July 2009;
- The Nikkei 225 (NIKKEI) from 14 May 1993 to 12 August 2009;
- The Japanese Yen-British Pound exchange rate (JPY/GBP) from 2 January 2000 to 14 December 2010.

The data have been taken from the R package qrmdata (Hofert and Hornik 2016) and are represented in figure 1. The graphs show that these negative log-returns are extremely volatile around the 2007–2008 financial crisis, which created a succession of extreme positive and negative returns over short time horizons. A noticeable degree of volatility clustering is also detected from a visual inspection of figure 1, revealing the presence of heteroskedasticity. Including a turbulent period from a financial risk management perspective is crucial in order to examine how dynamic extreme VaR estimators behave. An inspection of more recent financial data collected during the COVID-19 crisis did not reveal a more substantial degree of volatility, so we focus on the well-studied subprime crisis in order to assess the quality of our forecasts.

Descriptive statistics and basic statistical tests applied to the negative log-returns on the four financial time series are reported in table 1. According to the descriptive statistics, the means of the negative log-returns of all series are close to zero, and negative log-returns are leptokurtic. The Jarque-Bera test statistics indicate that the Gaussian distribution is not suitable for any of these series of negative log-returns. All four series pass the augmented Dickey-Fuller (ADF) test, indicating that they can be considered stationary for modeling purposes. The Ljung-Box test statistics applied to the squared negative log-returns, with orders 1 and 10, reject the null hypothesis of no autocorrelation, indicating the presence of substantial conditional heteroskedasticity in all series. This provides justification for our use of GARCH-type models with these data.

We compare six methods in total:

- The nonparametric HS method is based on the observed data, and its VaR is simply the empirical quantile of the series $X_t$ at the desired quantile level.
- The GARCH-N (normal) method uses the same filtering step as explained in Section 2.1, but assumes
Table 1. Summary of descriptive statistics and basic statistical tests for daily negative log-returns on DJ, NASDAQ, NIKKEI and JPY/GBP:

|                | DJ     | NASDAQ | NIKKEI | JPY/GBP |
|----------------|--------|--------|--------|---------|
| Sample size    | 4000   | 4000   | 4000   | 4000    |
| Mean           | −0.000250 | −0.000355 | −0.000169 | −0.000557 |
| Median         | −0.000460 | −0.00123 | −0.000177 | 0       |
| Maximum        | 0.0820  | 0.111  | 0.121  | 0.0600  |
| Minimum        | −0.105  | −0.172 | −0.132  | −0.0640  |
| Standard deviation | 0.0119 | 0.0203 | 0.0155 | 0.00626 |
| Skewness       | 0.117  |        |        |         |
| Kurtosis       | 8.096  | 4.469  | 5.579  | 10.931  |
| J-B test       | 10933*  | 3337.3* | 5207.9* | 2014.6* |
| (Q(1))         | 13.159* | 12.988* | 6.680*  | 128.68*  |
| (Q(5))         | 37.723* | 37.62*  | 14.429* | 146.47*  |
| (Q(10))        | 50.388* | 42.192* | 23.023* | 150.37*  |
| (Q^2(1))       | 131.54* | 207.21* | 248.32* | 275.36*  |
| (Q^2(5))       | (0.000) | (0.000) | (0.000) | (0.000)  |
| (Q^2(10))      | 2613.3* | 1907.5* | 3183.4* | 1650.4*  |
| ADF test       | −15.782** | −14.794** | −15.967** | −16.415** |

Notes: A kurtosis greater than 3 indicates that the dataset has heavier tails than a normal distribution. J-B stands for the Jarque-Bera test, Q(n) and Q^2(n) are the Ljung-Box tests for autocorrelation at lags n in the negative log-return series and squared negative log-returns, respectively. The ADF test is the augmented Dickey-Fuller stationarity test statistic without trend. The p-values are given between brackets. **, * denote significance at 1% and 5% levels, respectively.

in the quantile estimation step also that the innovations Zt are i.i.d. N(0, 1). The extreme conditional VaR is then calculated as \( \hat{q}_t(X_{t+1} | \mathcal{F}_t) = \hat{\mu}_{t+1} + \hat{\sigma}_{t+1} \Phi^{-1}(\tau) \), where \( \Phi \) is the cumulative distribution function of the standard normal distribution.

- The GARCH methods again use the filtering step of Section 2.1, but assumes in the quantile estimation step that the standardized residuals from the GARCH step are Student-t distributed. This corresponds to the two-step estimation method discussed on p. 1017 of Ergen (2015).

- The bias-reduced UGH method without filtering: this method applies the UGH step directly to the series \( X_t \).

- The conventional GARCH-EVT method as described in McNeil and Frey (2000). This consists, first, in the same filtering step as described in Section 2.1. Standardized residuals are then recorded and a Generalized Pareto distribution is fitted using a maximum likelihood estimator, thus producing a VaR estimate \( \hat{q}_t(Z) \). This method therefore differs from ours as far as the extreme value step is concerned.

- The proposed GARCH-UGH method.

A comparison with the basic estimation methods (HS, GARCH-N and GARCH-t) indicates the importance of extreme value methods in the estimation of the dynamic extreme VaR. Besides, a comparison with the UGH method (without filtering) allows us to see how effective filtering is, and a comparison with the GARCH-EVT method (not featuring bias reduction) will illustrate the benefit of bias reduction at the extreme value step after filtering. In Section 3.1, we explain how we carry out backtesting of the performance of one-step ahead extreme conditional VaR estimators provided by each approach. This is then followed by in-sample and out-of-sample evaluations of one-step ahead conditional VaR estimates at different \( \tau \) levels and choices of \( k \) in Sections 3.2 and 3.3, respectively: in-sample estimation investigates the fit of the approaches to high volatile returns, while out-of-sample estimation tests how well the method predicts extreme VaR.

### 3.1. Statistical framework for VaR backtesting

Backtesting is carried out to examine the accuracy of the one-step ahead conditional VaR estimates. It compares the ex-ante VaR estimates \( \hat{q}_t(X_{t+1} | \mathcal{F}_t) \) with the ex-post realized negative log-returns in a time window \( W_T \), with a VaR violation at time \( t \) said to occur whenever \( x_t > \hat{q}_t(X_{t+1} | \mathcal{F}_t) \). Define a hit sequence of VaR violations as \( l_t = 1(x_t > \hat{q}_t(X_{t+1} | \mathcal{F}_t)) \). If a VaR estimation method is accurate, then the sequence \( (l_t) \) should be approximately an independent sequence of Bernoulli variables with success probability \( p = 1 - \tau \). Both the distributional and independence properties are equally important. A VaR estimation method with too few VaR violations will tend to overestimate risk and therefore to be excessively conservative in financial terms, while too many VaR violations mean that risk is underestimated, leading to insufficient provision of capital and therefore potential insolvency in case of large losses. Besides, a violation of the independence property typically arises when there is a clustering of VaR violations, which indicates a model that does not represent volatility clustering well enough.

In order to test the distributional assumption, we use the unconditional likelihood ratio coverage test proposed by Kupiec (1995), also known as the Kupiec test or POP test, for Proportion Of Failures. To test the independence property, we use another likelihood ratio test called the conditional coverage test, proposed in Christoffersen (1998) and also known as the Christoffersen test, based on testing for first-order Markov dependence. Strictly speaking the conditional coverage test only assesses departure from either independence or stationarity, but in fact the test statistic is the sum of the unconditional coverage test statistic \( LR_{uc} \) and a likelihood ratio test statistic of independence \( LR_{ind} \), so checking stationarity and independence via the pair of test statistics \( (LR_{uc}, LR_{ind}) \) is exactly equivalent to checking them via the unconditional and conditional coverage tests. We therefore use below both the unconditional and conditional coverage tests to assess the performance of our dynamic extreme VaR estimators. This constitutes a backtesting approach in the spirit of the one suggested by the Basel Committee on Banking Supervision.

### 3.2. In-sample dynamic extreme VaR estimation and backtesting

We start by estimating in-sample one-step ahead conditional extreme VaRs \( q_t(X_{t+1} | \mathcal{F}_t) \) for \( \tau \in \{0.99, 0.995, 0.999\} \). For
Table 2. In-sample evaluations of one-step ahead conditional VaR estimates from 8 December 1997 to 9 November 2009 at different quantile levels for the negative log-returns of DJ index by means of the number of VaR violations, unconditional and conditional coverage tests.

these in-sample evaluations, all methods (HS, GARCH-N and GARCH-t, UGH without filtering, GARCH-EVT without bias reduction, and our proposed GARCH-UGH method) are implemented on a fixed in-sample testing window $W_T$, which consists of 3000 observations; this follows advice by Danielsson (2011) which suggests that this testing window $W_T$ should cover at least 4 years of data, or approximately 1000 observations, for a reliable statistical analysis. Specifically, we use:

- The time period from 8 December 1997 to 9 November 2009 for the Dow Jones,
- The time period from 13 August 1997 to 16 July 2009 for the Nasdaq,
- The time period from 29 May 1997 to 12 August 2009 for the Nikkei,
- The time period from 28 September 2002 to 14 December 2010 for the JPY/GBP exchange rate.

This allows us to focus on extreme VaR estimation around the 2007–2008 financial crisis, of which a consequence was a succession of extremely large negative log-returns in a very short timeframe. This should be considered a challenging problem.

In each case, we implement the three methods on these 3000 observations. The HS and UGH method work directly on the series $X_t$, without filtering, the estimate then being $\hat{q}_T(X_{t+1} \mid \mathcal{F}_t) = \hat{q}_T(X)$, where $\hat{q}_T(X)$ is the empirical $\tau$th quantile of the data for the HS method and, for the UGH method, $\hat{q}_T(X) = \hat{q}_T(X)$ is obtained as in Section 2.2 with the $X_t$ in place of the $\hat{Z}_t$. By contrast, the GARCH-N, GARCH-t, GARCH-EVT and GARCH-UGH methods filter the data using an AR(1)-GARCH(1,1) model $X_t = \mu_t + \sigma_t Z_t$ with a Gaussian QMLE, and then estimate $q_T(Z)$ on the basis of the residuals obtained from this filtering with an approach specific to each method, before obtaining the final extreme VaR estimate by combining the AR(1)-GARCH(1,1) estimates and the estimate of $q_T(Z)$. In these four methods, the difference lies in how $q_T(Z)$ is estimated. In addition, we calculate another version of the GARCH-UGH estimate where the estimator $\hat{\rho}_k$ is replaced throughout by the constant $-1$, as mentioned in Section 2.2. If this other version has a number of VaR violations closer to the expected number of violations (which is
Table 6. In-sample evaluations of one-step ahead conditional VaR estimates at different quantile levels for the negative log-returns of DJ, NASDAQ, NIKKEI indices and JPY/GBP exchange rate (time period given in Section 3.2) by means of the number of VaR violations, unconditional and conditional coverage tests.

| **Notes:** The closest number of VaR violations to the theoretically expected number is highlighted in bold, excluding historical simulation (HS), see Section 3.2. The number of VaR violations for GARCH-UGH is reported when the optimal sample fraction is selected according to tables 2–5. The p-values for the unconditional coverage test by Kupiec (1995) and conditional coverage test by Christoffersen (1998) are given in brackets in order.

known and equal to 3000\((1 − \tau)\) where \(\tau\) is the VaR level), we retain this version.

Results from tables 2–5 indicate that, on the basis of in-sample validation and compared to the other two methods geared towards extreme value estimation (GARCH-EVT and UGH), the proposed GARCH-UGH approach is the most successful for estimating one-step ahead extreme VaRs that satisfy both unconditional and conditional coverage properties. Across all samples and in terms of number of VaR violations only, in 46 out of 60 cases our GARCH-UGH approach is closest to the mark. In addition, although the unfiltered UGH estimate is somewhat reasonable in terms of number of VaR violations, it is not appropriate because it lacks responsiveness to the time-varying volatility and volatility clustering: figure 2(a) illustrates that the non-dynamic nature of the UGH estimate leaves it unable to respond immediately to high volatility, and VaR violations tend to cluster. By contrast, the conditional VaR estimates obtained by our GARCH-UGH approach (figure 2(b)) clearly respond to the changing volatility with no clustering of VaR violations, while bias reduction results in closer numbers of VaR violations to the expected numbers than with the conventional GARCH-EVT. Numerically, the GARCH-UGH method never fails either the Kupiec or Christoffersen tests, whereas the GARCH-EVT method fails 7 and 5 times out of 60 cases, respectively. The bias correction at the extreme value step appears to be very effective for the accurate estimation of one-step ahead dynamic extreme VaRs. It leads to results that seem less sensitive to the choice of sample fraction \(k\) than the conventional GARCH-EVT method: see tables 2–5, where results appear to be consistently good across a large range of values of \(k\).

In addition, table 6 shows the superiority of the GARCH-UGH approach when it is compared with the basic estimation methods (HS, GARCH-N and GARCH-\(t\)) that are commonly used by practitioners in financial risk management. Note that the number of VaR violations for GARCH-UGH shown in table 6 corresponds to when the optimal (according to tables 2–5) sample fraction is chosen from 5% to 25% for the estimation of dynamic extreme VaR. For all cases, HS provides the same number of VaR violations as theoretically expected. This is because the nonparametric HS method gives the (length of testing window \(\times (1 − \tau)\))th ordered value in the sample as the VaR at quantile level \(\tau\) from the non-updated ordered observations, which always ends up producing the same number of VaR violations as theoretically expected. Hence, in-sample HS is trivial and we exclude it.
Table 7. Out-of-sample evaluations of one-step ahead conditional VaR estimates from 8 December 1997 to 9 November 2009 at different quantile levels for the negative log-returns of DJ index by means of the number of VaR violations, unconditional and conditional coverage tests.

Notes: The closest number of VaR violations to the theoretically expected number is highlighted in bold. The number of VaR violations for GARCH-UGH is when the optimal sample fraction is selected according to tables 7–10. The p-values for the unconditional coverage test by Kupiec (1995) and conditional coverage test by Christoffersen (1998) are given in brackets in order.

from the comparison for in-sample estimation; we will see in the out-of-sample backtestings that HS performs worse out of all estimation methods. Across all samples, in 11 out of 12 cases our GARCH-UGH approach is closest to the mark and never fails any tests, with the GARCH-N approach performing worse since it cannot capture heavy tails. The GARCH-N and GARCH-t methods are not reliable approaches for the estimation of dynamic extreme VaR because GARCH-N fails to pass the Kupiec and Christoffersen tests 6 and 5 times out of 12 cases, and GARCH-t fails 4 and 3 times respectively.

3.3. Out-of-sample dynamic extreme VaR estimation and backtesting

We now focus on the out-of-sample estimation (that is, prediction) of one-step ahead VaR via the same six approaches, again at level τ ∈ {0.99, 0.995, 0.999}. We consider the following samples of data:

- The time period from 23 December 1993 to 9 November 2009 for the Dow Jones,
- The time period from 30 August 1993 to 16 July 2009 for the Nasdaq,
- The time period from 14 May 1993 to 12 August 2009 for the Nikkei,
- The time period from 2 January 2000 to 14 December 2010 for the JPY/GBP exchange rate.

In order to carry out this out-of-sample backtest, we adopt a rolling window estimation approach. Specifically, we first fix a testing window WT in each case, which corresponds to the periods of time considered in our in-sample evaluation (8 December 1997 to 9 November 2009 for the Dow Jones, 13 August 1997 to 16 July 2009 for the Nasdaq, 29 May 1997 to 12 August 2009 for the Nikkei, 28 September 2002 to 14 December 2010 for the JPY/GBP exchange rate). At each time t in this testing window WT, we use a window of length WE of prior information in order to predict the conditional VaR on time t + 1 (with parameter estimates updated when the estimation window changes), which is then compared to the observed log-return on day t + 1. Various choices of WE have been made in the literature: here we choose WE = 1000 as in McNeil and Frey (2000), corresponding to approximately four years of model calibration for each prediction with stock market data, and three years with exchange rate data. Regarding the use of the GARCH-UGH method specifically, we retain the implementation suggested by the results.
GARCH-UGH: a bias-reduced approach for dynamic extreme Value-at-Risk estimation in financial time series

Figures 3 and 4. Out-of-sample backtesting of the DJ index from 8 December 1997 to 9 November 2009, and 99.9%-VaR estimates calculated using rolling estimation windows made of 1000 observations, with $k$ corresponding to the top 15% of observations from this window. GARCH-UGH (blue line), GARCH-EVT (red line) and UGH (dark green line) estimates are superimposed on the negative log-returns (black line).

Tables 7–10 gather the numerical results for the comparison between the GARCH-EVT, GARCH-UGH and UGH methods. It can be seen that again, the suggested GARCH-UGH approach appears to be best overall. In 47 out of 60 cases, the GARCH-UGH approach yields the closest number of VaR violations to the theoretically expected numbers, while the unfiltered UGH method fares worst. Based on the Kupiec test, the GARCH-UGH approach fails twice, whereas the GARCH-EVT and UGH fail 6 and 49 times out of 60 cases, respectively. On one occasion GARCH-UGH fails the Christoffersen test, while the GARCH-EVT and UGH methods fail 0 and 43 times out of 60 cases. GARCH-UGH typically performs better than other approaches except possibly when the top 5% and 10% of observations are used (for the choice of $k$); this is because the bias is not the dominating term in the bias-variance tradeoff when $k$ is small. Table 11 also supports the use of the GARCH-UGH approach for the estimation of dynamic extreme VaR because it outperforms the basic HS, GARCH-N and GARCH-$t$ estimation methods.

In 12 out of 12 cases our GARCH-UGH approach (with optimal sample fraction according to tables 7–10) is closest to the mark. It also never fails either of the Kupiec and Christoffersen tests, while HS fails 8 and 7 times, GARCH-N fails 10 and 10 times, and GARCH-$t$ fails 3 and 2 times out of 12 cases, respectively. The corresponding plots of out-of-sample backtesting are shown in figures 3–6 with the corresponding 95% asymptotic Gaussian confidence intervals corresponding to the GARCH-UGH estimation method in figure 7: the confidence interval is given by

$$
\left[ \hat{\mu}_{t+1} + \hat{\sigma}_{t+1} q_1-p(Z) \left( 1 \pm \frac{1.96}{\sqrt{k/\log(n/p)}} \right) \right. \\
\left. \times \left( \frac{\hat{\gamma}_k^2}{\hat{\rho}_k^2} (\hat{\rho}_k^2 + (1-\hat{\rho}_k^2)^2) \right) \right].
$$

It is clearly seen that the GARCH-UGH and GARCH-EVT estimates have the same dynamics, with the bias correction shifting the estimate upwards or downwards depending on the rolling estimation window.
Figure 5. Out-of-sample backtesting of the NIKKEI index from 29 May 1997 to 12 August 2009, and 99.9%-VaR estimates calculated using rolling estimation windows made of 1000 observations, with $k$ corresponding to the top 10% of observations from this window. GARCH-UGH (blue line), GARCH-EVT (red line) and UGH (dark green line) estimates are superimposed on the negative log-returns (black line).

Figure 6. Out-of-sample backtesting of the JPY/GBP exchange rate from 28 September 2002 to 14 December 2010, and 99.9%-VaR estimates calculated using rolling estimation windows made of 1000 observations, with $k$ corresponding to the top 10% of observations from this window. GARCH-UGH (blue line), GARCH-EVT (red line) and UGH (dark green line) estimates are superimposed on the negative log-returns (black line).

Figure 7. Out-of-sample backtesting of the DJ index from 8 December 1997 to 9 November 2009, and 99.9%-VaR estimates calculated using rolling estimation windows made of 1000 observations, with $k$ corresponding to the top 15% observations from this window. GARCH-UGH (blue solid line) estimates are superimposed on the negative log-returns (black line) with the 95% asymptotic Gaussian confidence intervals (blue dashed line).
4. Discussion

In this paper we introduce an extension of the two-step GARCH-EVT approach from McNeil and Frey (2000) for extreme VaR estimation, based on a semiparametric bias-reduced extreme quantile estimator from Chavez-Demoulin and Guillou (2018) and de Haan et al. (2016). This differs from the other papers published in the econometric literature by introducing a finite-sample improvement at the extreme value step, rather than using a more complicated filter than the AR(1)-GARCH(1,1) filter. We conclude from our empirical analysis that the proposed GARCH-UGH approach provides better one-step ahead dynamic extreme VaR estimates for financial time series than the benchmark conventional GARCH-EVT approach of McNeil and Frey (2000) and the other basic estimation approaches we have tested based on historical simulation or traditional fully parametric models. This can be seen from both the in-sample and the out-of-sample estimations at several quantile levels \( \tau \), including the very high \( \tau = 0.999 \) corresponding to a 99.9% VaR, and a large range of sample fractions \( k \), due to the effect of the bias correction. Let us also point out that the GARCH-UGH method is carried out using an automatic recipe for the estimation of the extreme value index and extreme quantile, making it computationally cheap.

We highlight three possible directions for further investigations. The first one is that one could replace the AR(1)-GARCH(1,1) filter by a more sophisticated filter. Which filter should be used is not obvious: one could think about replacing the AR(1) part by an ARMA\((p, q)\) part, or the GARCH\((1,1)\) part by a GARCH\((p, q)\) part (or a more complicated asymmetric version), or both. This may make it possible to even better account for the volatility dynamics, whose accurate estimation and prediction are key. The second one is the extension of our GARCH-UGH approach to the estimation of the multiple-step ahead conditional extreme VaR. This is important, because certain regulations such as those advocated by Basel Committee on Banking Supervision (2009) require the estimation of the 10-day ahead VaR at the 99% confidence level, rather than merely the one-step ahead VaR. This is a challenging problem: McNeil and Frey (2000) tackle this question using a bootstrap methodology, but bootstrapping with heavy tails is known to be very difficult to calibrate, especially in the extreme value setup we consider here. The development of an adaptation of the GARCH-UGH method to the multiple-step ahead setup which stays computationally manageable and accurate is well beyond the scope of the current paper. The third and final perspective is the estimation of alternative dynamic risk measures as a way of solving the two drawbacks of VaR that we highlighted in the previous paragraph. One candidate will be the expectile risk measure (see Newey and Powell 1987 for the original definition of expectiles in a regression context), which takes into account both the frequency of extreme observations and their magnitude, and is also shown to be a coherent and elicitable risk measure in Ziegel (2016). The use of expectiles has recently received substantial attention from the perspective of risk management as an alternative tool for quantifying tail risk (see for example Daouia et al. 2018, 2020, but the case of dynamic estimation of extreme expectiles in a financial time series context has not been considered yet. Of course, there exists no universally preferred risk measure: the expectile only has an implicit formulation in general, and is more difficult to interpret than the VaR. The development of a GARCH-UGH-based method for the estimation of dynamic extreme expectiles will thus be an interesting complement to the present paper.

Acknowledgments

The authors thank the Editors and an anonymous referee for their valuable suggestions and comments which led to an improved version of this paper.
