Anthopoulos1,7

The short exciton diffusion length associated with most classical organic semiconductors used in organic photovoltaics (5-20 nm) imposes severe limits on the maximum size of the donor and acceptor domains within the photoactive layer of the cell. Identifying materials that are able to transport excitons over longer distances can help advancing our understanding and lead to solar cells with higher efficiency. Here, we measure the exciton diffusion length in a wide range of nonfullerene acceptor molecules using two different experimental techniques based on photocurrent and ultrafast spectroscopy measurements. The acceptors exhibit balanced ambipolar charge transport and surprisingly long exciton diffusion lengths in the range of 20 to 47 nm. With the aid of quantum-chemical calculations, we are able to rationalize the exciton dynamics and draw basic chemical design rules, particularly on the importance of the end-group substituent on the crystal packing of nonfullerene acceptors.
After a few years of stagnation in terms of efficiency, organic solar cells (OSCs) are back in the spotlight thanks to the advent of new non-fullerene acceptor (NFA) molecules1–3. NFAs have brought OSCs’ power conversion efficiency (PCE) to new heights with records set between 16–18.2% for single-junction4–11 and 15–17.3% for tandem cells12–16. While recent progress has been impressive, the aforementioned levels of performance are still below the predicted efficiency limit of 20% and 25% for single-junction and tandem cells, respectively17,18. Recent efforts towards increasing the PCE of OSCs have been motivated by research on new materials with improved charge carrier mobility and broader spectral absorption19,20. However, it is important that exciton formation, dissociation, and subsequent charge collection efficiencies are all simultaneously maximized, yielding the highest possible photocurrent.

In OSCs, successful absorption of a photon generates an exciton, a coulombically bound electron–hole pair19. Thermal dissociation of excitons within a low dielectric medium such as an organic semiconductor is highly improbable. To efficiently generate free charges, two semiconductors with suitable energetics, an electron donor and electron acceptor are intermixed, forming a so-called bulk-heterojunction (BHJ) cell. One of the prerequisites for efficient exciton harvesting is the fast exciton diffusion to the donor–acceptor interface, where it dissociates into free charges. The diffusion constant and the exciton lifetime set the optimal size of the donor and acceptor domains within the BHJ. Up until now, most of the work on exciton diffusion length in OSCs has been focused on electron–donor (p-type) materials20 with very few reports on molecular NFA21,22. Recent work has shown that fused-ring acceptors such as indacenodithiophene end-capped with 1,1-dicyanomethylene-3-indanone (IDIC) exhibit long exciton diffusion length with a diffusion constant of at least 0.02 cm²/s21. This is consistent with the large domain sizes of 20–50 nm often reported for high-efficiency NFA-based BHJ cells22,23–26. It is not yet fully understood why the exciton diffusion length in NFAs, such as IDIC, is significantly higher than in amorphous and other polycrystalline organic semiconductors (typically 5–20 nm)20.

Here, we study the exciton diffusion length (L_D) in a wide range of NFAs3,27–31 (chemical names of all materials can be found in “Methods” section) using two independent experimental techniques, one relying on copper(I) thiocyanate (CuSCN)/NFA bilayer OPV measurements and the other on exciton annihilation spectroscopy. We focus on best-in-class acceptor–donor–acceptor (A–D–A) NFAs comprising different end-groups ranging from methyl (IT-M) to chlorine (IT-2Cl) and fluorine (IT-F4), including the current PCE record holder Y6. The measured L_D is found to vary with IT-4F, amongst all NFAs studied, exhibiting the longest diffusion length of 45 nm. This value is >4 times higher than the ≈10 nm reported for the prototypical fullerene-based acceptor PC_61BM. To elucidate the origin of the long L_D, we combine crystallographic data with quantum-chemical calculations for each molecule. The simulations predict distinctly large excitonic couplings due to aligned transition dipole moments in the crystal, relatively small reorganization energies due to the stiff conjugated core, and quadrupolar symmetry of the exciton—i.e. small energetic disorder—the combination of which leads to the large exciton diffusion lengths observed, in good agreement with our simulations. Key relationships between L_D and the chemical structure of the NFA are identified, leading to important design guidelines for future generation NFAs.

Results

Material properties. Figure 1a illustrates the chemical structures of the acceptor materials studied, while Fig. 1b shows their absorption spectra together with that of the hole-transport layer CuSCN. The latter is a known wide bandgap (>3.4 eV) inorganic p-type semiconductor absorbing only in the ultraviolet region12,13. With the exception of SF-PDI, all other NFAs absorb across the visible (Vis) all the way to the near-infrared, while exhibiting higher absorption coefficients than PC_71BM. Figure 1c depicts the ionization energies (IE) of the acceptors and the carrier-transport layers as determined by photoelectron spectroscopy in air (PESA).

Exciton diffusion length calculation using bilayer CuSCN/acceptor devices. Figure 2a illustrates the structure and energy diagram of a planar CuSCN/acceptor heterojunction solar cell used to study the L_D. The use of CuSCN allows for efficient extraction of the photogenerated holes while simultaneously blocking electrons, effectively acting as exciton quencher for the organic absorber. Efficient exciton quenchers for n-type organic semiconductor, such as NFAs, are scarce and the particular CuSCN/n-type semiconductor platform for exciton diffusion studies has not been reported before. As electron extracting layer, we employed the wide bandgap Phen-NaDPO (DPO) ((2-(1,10-phenanthrolin-3-yl)naphth-6-yl) diphenylphosphine oxide)34. Adjusting the thickness of the organic semiconductor and measuring the OPV performance allows the study of L_D within the organic layer, without the morphology-related complexities encountered in organic BHJs35.

To estimate L_D within the acceptor layer, we used a similar method to that described by Siegmund et al.35. The external quantum efficiency (EQE) of the bilayer cells is measured as a function of acceptor thickness, and then the measured photocurrent is modeled using the exciton diffusion equation:

$$\frac{\partial n}{\partial t} = D \frac{\partial^2 n}{\partial x^2} + G(x, t) - k_{PL} n - k_{FRET} n - \alpha n$$

where n is the singlet exciton density at position x in the absorber film, D is the diffusion coefficient, G(x, t) is the time-dependent exciton generation profile, k_{PL} is the radiative decay rate in absence of quencher sites, a is an exciton–exciton annihilation rate constant, and k_{FRET} denotes the rate of Förster resonance energy transfer (FRET) in the presence of a neighboring material.

To accurately measure L_D of the NFAs with the bilayer cell, it is important to ensure that: (i) the exciton dissociation happens only at a well-defined quencher–acceptor interface36; (ii) the generation of exciton originates only from the acceptor; and (iii) the photocurrent is not limited by the transport properties of the NFA layer.

Figure 2a shows the schematic of the device and a representative cross-sectional transmission electron microscopy (TEM) image of a CuSCN/NFA bilayer cell. Well-defined interfaces are visible across the device ensuring that requirement (i) is satisfied. Figure 2b shows representative J–V curves for the bilayer CuSCN/NFA cells. Devices with IT-4F show a maximum PCE of 2.65% and JSC > 5 mA cm⁻² (Supplementary Table 1). The EQE spectra of the devices (Fig. 2c) reveal that charge generation occurs across the entire acceptors’ absorption range while CuSCN does not contribute to the generation of excitons (Fig. 1b), hence satisfying requirement (ii). The requirement (iii) is also fulfilled as the performance of the bilayer solar cells is not limited by the charge transport of the acceptor materials as evident from the sufficiently high and ambipolar mobility values extracted using thin-film transistors (TFTs) (Supplementary Fig. 2) and time-resolved microwave conductivity (TRMC) measurements (Supplementary Table 2). The sufficiently high mobility is due to the NFAs investigated in this work exhibit a certain degree of crystallinity as shown from
grazing incident wide-angle X-ray scattering (GIWAXS) measurements (Supplementary Fig. 3).

CuSCN is particularly suitable as an exciton quencher for this type of measurement, since FRET from CuSCN to the acceptor layer is negligible due to the very low fluorescence of CuSCN and the small overlap of its absorption with the acceptors’ emission (Supplementary Fig. 4). Exciton–exciton annihilation ($\alpha$) is also negligible at the considered intensities. As a result, the dominant exciton harvesting mechanism within the acceptor layer is exciton diffusion. Hence, Eq. (1) can be simplified under steady-state conditions.

Fig. 1 Molecular structure, absorption, and energy levels of the organic acceptors studied. a Chemical structure of the acceptors investigated in this study. Full names are provided in the “Methods” section. b Absorption spectra of the acceptor molecules studied. c The IE values obtained from PESA measurements (see Supplementary Fig. 1) and IE – optical gap ($E_g$), $E_g$ were estimated from the intersection of the UV–Vis absorption spectra and photoluminescence spectra. DPO is a short name for an electron extraction layer of Phen-NaDPO ((2-(1,10-phenanthrolin-3-yl)naphth-6-yl)diphenylphosphine oxide). The IE value of DPO was obtained from our previous work.

Fig. 2 Device performance and EQE spectra of the bilayer CuSCN/acceptor devices. a Schematic of the device architecture and the cross-sectional transmission electron microscopy (TEM) image of a CuSCN/acceptor bilayer solar cell. b Current density–voltage ($J$–$V$) characteristics of OPV cells measured under simulated solar illumination. c Corresponding EQE spectra of the bilayer OPVs shown in b.
conditions with \( k_{F} = D/L_{2D}^{2} \) such as

\[
\left( \frac{\partial^2}{\partial x^2} - \frac{1}{L_{D}^2} \right) n(x) = \frac{G(x)}{D} \tag{2}
\]

which can be solved for any generation assuming that the excitons are fully quenched at the interface \( n(\text{interface}) = 0 \). The EQE can then be calculated considering that the photocurrent is only due to the exciton dissociation at the CuSCN/NFA interface:

\[
\text{EQE} = \frac{J_{\text{photo}}}{J_{\text{inc}}} = \frac{\eta_{c} D}{J_{\text{inc}}} \frac{\partial n(x)}{\partial x} \bigg|_{\text{interface}} \tag{3}
\]

where \( J_{\text{photo}} \) and \( J_{\text{inc}} \) are the generated photocurrent density and the incident light current density, \( \eta_{\text{c}} \) the combination of the exciton dissociation and extraction at the electrode efficiencies.\(^{35}\)

There are four main factors that influence the magnitudes of \( J_{\text{photo}} \) and EQE, namely the absorption coefficient, \( \eta_{\text{c}} \), \( D \) and \( L_{D} \) (Supplementary Fig. 5a, b). The contribution of the absorption is included in the generation profile \( G(x, \lambda_{\text{exc}})^{38} \) evaluated using transfer-matrix modeling.\(^{37}\) However, \( \eta_{\text{c}} \) and \( D \) have no influence on the shape of the EQE vs. thickness curve, only on its absolute value. As a result, we can only obtain the \( D \times \eta_{\text{c}} \) product and as such we will not discuss those values at this point. Instead, we focus on fitting Eqs. (2) and (3) to normalized EQE vs. thickness data, as it is mostly influenced by \( L_{D} \) hence allows reliable estimation of its magnitude.\(^{35}\) The fits assumed that geminate and nongeminate recombination losses are independent of thickness which is valid in our case as confirmed by light-intensity and thickness dependent of the \( J-V \) characteristics of IT-4F devices (Supplementary Fig. 5c, d). We also coupled the results from solving Eq. (2) with drift-diffusion simulation (Supplementary Fig. 5e, f, Supplementary Table 3) to demonstrate that the photocurrent measurement is not limited by the mobility of the NFA or the recombination. However, there could be cases (e.g. extremely thick layers or very low mobility materials) where recombination losses do depend on layer thickness which can lead to incorrect values of the exciton diffusion length.

To estimate \( L_{D} \), we measured the EQE spectra of the bilayer devices with different NFA layer thicknesses, whilst maintaining the thickness of the CuSCN layer to ca. 60 nm. As shown in Fig. 3, the measured EQE (at \( \lambda_{\text{exc}} = 650 \text{ nm} \), see Supplementary Figs. 6–14 for EQE at different \( \lambda_{\text{exc}} \)) reaches a maximum value for acceptor thickness between 60 and 100 nm, which indicates long \( L_{D} \) values. Analysis of the data yields an exciton diffusion length in IT-M and ITIC of \( L_{D} = 25–30 \text{ nm} \). Incorporating electron-deficient elements like F or Cl into the end-capping groups, such as in the case of IT-2Cl and IT-4F acceptors, results in an increase of \( L_{D} \) to 40–45 nm. For the remaining acceptors, the \( L_{D} \) values are summarized in Table 1. For the Y6 acceptor, with recently reported PCE values reaching in the range 15–18.2\% when blended with best-in-class donor polymers,\(^{3,5,7,8,10}\) we calculate an \( L_{D} \) value of 35 nm. Additionally, we obtained \( L_{D} \approx 10 \text{ nm} \) for PC\(_{71}\)BM, which is close to that of C\(_{70}\) (7.4 nm) but significantly smaller than that of C\(_{60}\) (18.5 nm) obtained using a photocurrent method.\(^{16}\) For comparison, the exciton diffusion length of PC\(_{71}\)BM obtained by a different measurement technique, namely PL quenching in blends, was reported to be 3.1 or 4.5 nm.\(^{39,40}\) The constraint of this technique is, however, that the quencher must be intimately mixed with the matrix material, since demixing in the blend does lead to lower diffusion coefficients as the quencher concentration is increased.\(^{20}\)

The fits reproduce well the experimental data (Supplementary Figs. 6–14) and the values of \( L_{D} \) are estimated based on the sensitivity of the fit over a range of thickness between 10 and 150 nm for at least four different excitation wavelengths. The uncertainty of these fits depends on the experimental uncertainties of the EQE, the layer thicknesses, and the values of the complex refractive index. The variation in refractive index may explain the deviation from the fit for thin NFA layers.\(^{35}\) We find that decent fits can be obtained, for most of the NFAs, when varying \( L_{D} \) within a margin of \( \approx 5–10 \text{ nm} \) (Supplementary Figs. 6–14).

**Exciton diffusion length measured via exciton annihilation.** We independently validated the photocurrent-based measurements of \( L_{D} \) using the exciton annihilation method.\(^{32}\) The latter technique uses ultrafast transient absorption (TA) spectroscopy to measure exciton lifetimes as a function of excitation density. The measurement is carried out on bulk films and does not require exciton quenching interfaces. When exciton annihilation occurs in the film, the exciton decay is accelerated with increasing excitation fluence. The excitation fluences used here range from 0.3 to 11 \( \mu \text{ J cm}^{-2} \). The exciton decay can be globally fit to a rate equation accounting for exciton annihilation and first-order recombination of the excitons:\(^{21,41}\)

\[
\frac{dn(t)}{dt} = n(t) \left( 1 - \frac{dn}{2 \alpha n^{2}(t)} \right)
\]

$L_{D}$ obtained using photocurrent and transient absorption (TA) techniques. Diffusion constant ($D$) inferred from the TA measurements and was calculated by assuming the annihilation radius of singlet excitons to be 1 nm.

Fig. 4 Exciton diffusion lengths of various NFAs estimated from singlet-singlet annihilation measurements and non-exhaustive comparison of diffusion length of organic donor and acceptor materials. Singlet-singlet exciton annihilation decay in neat films of: a IT-M (excitation wavelength: 700 nm), b ITIC (700 nm), c IT-2CI (700 nm), d IT-4F (750 nm), and e Y6 (700 nm). Fluence-dependent singlet exciton decays of the neat films fitted to the exciton annihilation model (Eq. (4)). The exciton decays of the NFAs diluted in a polystyrene (PS) matrix are also superimposed in this figure. f Comparison of diffusion lengths reported from 2005 onwards for various types of donor and acceptor materials relevant to organic photovoltaics. Publication details can be found in Supplementary Table 5.

which leads to the following solution:

$$n(t) = \frac{n(0)e^{-\alpha t}}{1 + \frac{2\kappa}{\pi} n(0)[1 - e^{-\alpha t}]}$$  \hspace{1cm} (5)

Here, $\kappa$ is the fluorescence decay rate constant in the absence of any annihilation, $\alpha$ is the singlet–singlet bimolecular exciton annihilation rate constant, $n(t)$ is the singlet exciton density as a function of time after the laser excitation. The measurement requires two sets of films prepared on a quartz glass substrate: (1) neat acceptor film to obtain the $\alpha$ value and (2) dilute acceptor in polystyrene film to extract $\kappa$ (or intrinsic exciton lifetime, $\tau = 1/\kappa$).

Figure 4a–e shows the TA data for IT-M, ITIC, IT-2CI, IT-4F, and Y6, all of which indicate a clear sign of exciton annihilation, where the exciton decay is substantially accelerated with increasing excitation fluence. The exciton decays for all the films can be fitted with Eq. (5), with the only free parameter being the bimolecular rate constant ($\alpha$). The exciton diffusion length can be calculated as $L_{D} = (D\tau)^{1/2}$, where $D$ is the diffusion constant given by $D = \alpha/(8\pi R)$ (three-dimensional diffusion model), $R$ is the annihilation radius of singlet excitons. The annihilation radius cannot be easily measured and generally assumed to be 1 nm$^{-1}$ [44]. In the case of the small molecule donor DTS(FBTTh)$_2$, $R$ has been measured to be around 1.1 nm [44]. The latter has also been assumed to be equal to the intermolecular distance which can be obtained from x-ray diffraction studies (~1 nm for DPP-based small molecule donors [45] or $d_{100}$ spacing obtained from GIWAXS of neat films (1.7–1.9 nm for BTR and...
analyses (Fig. 4) with those derived from the photocurrent measurements (Table 1), is evident. Notably, the similarity in the exciton diffusion values measured between thin films and bilayer solar cells suggests that the values in Table 1 represent the intrinsic $L_D$ value measured for IT-4F using SSA analyses (Supplementary Fig. 15). The energetic disorder of the exciton $\sigma_D$ value of 45 nm inferred from the photocurrent method (Fig. 3d). The SSA analyses also yield $D = 0.064 \text{ cm}^2 \text{s}^{-1}$, which is two times higher than IT-M and ITIC. The similarity in the exciton $\sigma_D$ parameter measured between thin films and bilayer solar cells suggests that the values in Table 1 represent the intrinsic $L_D$. In Fig. 4f we compare the exciton diffusion values reported in the literature with those extracted here. Evidently, the NFAs studied here exhibit the highest $L_D$ amongst the OSCs materials (details in Supplementary Table 5). Longer $L_D$ values have only been reported for conjugated polymer nanofibers (>200 nm)$^{49,50}$, small molecule J-aggregates (96 nm)$^{48}$, or organic single-crystals (>1 μm)$^{49,50}$.

Energetic disorder and Förster transfer radius. We performed temperature-dependent (150–300 K), steady-state PL measurements on all acceptor materials to probe the energetic disorder (Supplementary Fig. 15). The energetic disorder of the exciton density of states (DOS), $\sigma$, was calculated from the slope of the 0–0 peak position ($E_{0\,0}$) vs. $1/T$ (see Supplementary Table 6) following previous work.$^{20,21}$ The calculation assumes that the exciton relaxes toward tail states of the DOS and eventually settles in the occupied density of states (ODOS) at a mean energy $-\sigma^2/kT$ below the center of the DOS.$^{30}$ For EH-IDTBR, SF-PDI$_2$, ITIC, IT-M, and Y6, two temperature regimes can be identified, one at higher (220–310 K) and one at lower (140–220 K) temperature range (Supplementary Fig. 15). At higher temperatures, $E_{0\,0}$ exhibits a relatively strong dependence on temperature but weakens for $T < 220 \text{ K}$. This is consistent with the activated diffusion model observed in previous works.$^{21,31}$ In contrast, IT-Cl, IT-4F, and IDIC exhibit a single temperature regime (Supplementary Fig. 15) with lower $\sigma$ values of 45, 39, and 34 meV, respectively. Comparable $\sigma$ values in the range of 10–23 meV have recently been reported for IDIC.$^{21}$ Using photothermal deflection spectroscopy (PDS), we found the energetic disorder in IDTA and IDTTA NFA films to be between 24 and 28 meV.$^{14}$ For comparison, a $\sigma$ value of 44 meV was reported for the conjugated polymer MDMO–PPV$^{51}$ and 39 meV for P3HT$^{52}$. A very low disorder width of 15 meV has been observed in structurally rigid molecules such as the ladder-type-conjugated chromophore$^{53}$.

We attempted to rationalize the exciton diffusion length using a FRET model. The rate $k_F$ of FRET between chromophores is given by$^{20}$

$$k_F(d) = \frac{1}{\tau_0} \left( \frac{R_0}{d} \right)^6$$

where $\tau_0$ is the intrinsic exciton lifetime that is not limited by diffusion quenching at defects, $d$ is the distance between chromophores, and $R_0$ is the Förster radius written as$^{20}$

$$R_0 = \frac{9\kappa^2\varphi_{PL} J}{128\pi^2 N_A n^2}$$

Here $\varphi_{PL}$ is photoluminescence (PL) quantum yield, $\kappa$ is the dipole–dipole orientation factor and here we use $\kappa^2 = 0.476$ corresponding to static and randomly oriented dipoles$^{45,54}$, $n$ is the refractive index, $N_A$ is Avogadro number, and $J$ is the spectral overlap for energy transfer between chromophores ($J = \int \varepsilon(\lambda_j) f(\lambda_j) \lambda_j^{-4} d\lambda_j$). The integral $J$ over wavelength, $\lambda$, quantifies the spectral overlap between the area-normalized PL spectrum of donor ($f(\lambda_j)$) and the absorption spectrum of acceptor expressed in terms of molar-absorptivity ($\varepsilon(\lambda_j)$).

Supplementary Fig. 16 shows the absorption and PL spectra of all acceptor molecules studied. All A–D–A NFAs exhibit high

Fig. 5 Quantum chemical calculations of reorganization energy and the exciton transfer rate of NFAs. a The correlation of the measured diffusion length and the reorganization energy, with a fixed intramolecular excitonic coupling. The dashed line corresponds to the Marcus rate. b Featured dimer structures and the corresponding exciton coupling parameters of IDTBR, IT-2CI, and IT-4F. c Correlation between the measured exciton diffusion length and calculated square root of exciton transfer rate. The line is the guide to the eye.
absorption coefficients and large overlap with the PL spectra resulting in a $J$ value in the range of $1 \times 4 \times 10^{-16}$ nm$^4$ M$^{-1}$ cm$^{-1}$ (Table 1). The large overlap between absorption and emission indicates small intramolecular reorganization (i.e. small barrier for the exciton transfer between chromophores) and yields Förster transfer radius between 2.6 and 3.2 nm (Table 1). This is in agreement with the previous report on IDIC, where facile exciton diffusion results from many FRET parameters being optimized for long-range transport$^{21}$. In comparison, PC$_7$BM shows one order of magnitude lower spectral overlap integral $J$ ($1.5 \times 10^{13}$ nm$^4$ M$^{-1}$ cm$^{-1}$) that gives $R_0 = 1.3$ nm. On the other hand, $R_0$ for perylene diimide-based NFA (SF-PDI$_1$) is large (2.6 nm) despite the very low spectral overlap ($2 \times 10^{14}$ nm$^4$ M$^{-1}$ cm$^{-1}$), due to the much higher $\Phi_d$ (Supplementary Table 6). While the difference in $R_0$ explains the difference in diffusion length between PC$_7$BM and the NFAs, it cannot explain the variation between the NFAs (Supplementary Fig. 17).

**Quantum chemical calculations.** Therefore, we turn to quantum chemical calculations to correlate the main chemical structure and the end-group substituents with the exciton diffusion length and diffusion coefficient. Based on Fermi’s Golden rule, the energy transfer rate can be written as $\nu = \frac{\pi}{\hbar} V^2 J$, where $V$ is the electronic coupling element, and $J$ is the Franck–Condon weighted DOS which is normally approximated by the spectral overlap of the donor emission and of the acceptor absorption$^{55}$. Instead of explicitly calculating the spectral overall of Franck–Condon factors, we assume that it is related to the molecular reorganization energy, $\lambda$, i.e., adapt a harmonic approximation for the promoting mode. In this case $\nu = \frac{V^2}{\hbar} \sqrt{\frac{\alpha}{\pi}} \exp\left(-\frac{\lambda}{\alpha}\right)$ is given by the classical Marcus rate which, despite all imperfections, can be used for qualitative analysis of exciton transport$^{36}$.

Reorganization energies were calculated at the m06-2x/6-311g (d,p) level using the Gaussian16 package$^{57}$ and are listed, together with the oscillator strengths at the optimized ground state and the end-group substituents with the exciton diffusion length, see Supplementary Table 7. Reorganization energies for materials with crystal structures available thanks to the conjugated A molecule, from IDTBR to ITIC, to Y6, which reduces the stiffness of the conjugated core; (ii) engineer the end-group substituents for favorable crystal packing; and (iii) increase the exciton coupling element, and $J$ is the Franck–Condon weighted DOS which is normally approximated by the spectral overlap of the donor emission and of the acceptor absorption$^{59}$. Methods

**Materials.** IT-2Cl (3,9-bis(2-methylene-((3-(1,1-dicyanomethylene)-chloro)-indaceno[1,2-b:5,6-b]-dithiophene)-5,5,11,11-tetrakis(4-hexylphenyl)-dithieno[2,3-d:2,3-d']-s-indaceno[1,2-b:5,6-b'-dithiophene]), IT-4F, (3,9-bis(2-methylene-((3-(1,1-dicyanomethylene)-6,7-difluoro)-indaceno)-5,5,11,11-tetrakis(4-hexylphenyl)-dithieno[(2,3-d:2,3-d')]s-indaceno[1,2-b:5,6-b'-dithiophene]), and Y6 (12.00-22.20 Z) (12.13-bis(2-ethylhexyl)-3,9-diundecyl-12,13-dihydro-[1,2,5]-thiadiazolo[3,4-e]thiophene, [2,3,3',5'-5]-thieno[20,30:4,5]pyrrolo[3,2-g]thieno[2030:4,5]-[3,2-b]indole[2-10-diy]bis(methanylefide)1]bis(5,6-difluoro-3-oxo-2,3,4,5-dihydro-1H-indene-2,1-diyliide)1]dimalononitrile)) were purchased from Solarmer Materials Inc. (Beijing). IT-4M (3,9-bis(2-methylene-((3-(1,1-dicyanomethylene)-6,7-methyl)-indaceno))-5,5,11,11-tetrakis(4-hexylphenyl)-dithieno[(2,3-d:2,3-d')]s-indaceno[1,2-b:5,6-b'-dithiophene], ITIC (3,9-bis(2-methylene-((3-(1,1-dicyanomethylene)-indaceno))-5,5,11,11-tetrakis(4-hexylphenyl)-dithieno[2,3-d:2,3-d']s-indaceno[1,2-b:5,6-b'-dithiophene]), and Phen-NaDPO (DPO34 ((2-1,10-phenanthrolin-3-yl)methyl)-6-diphenylphosphine oxide) were purchased from 1-Material Inc. PC$_7$BM ((6,6)-Phenyl-C71-butric acid methyl ester) was obtained from Solenne BV. EH-IDTB (2-ethylhexyl rhodamine-benzothiazole-coupled indocyanine green) was synthesized at KAUT. All materials above were used as received. PES measurements were recorded using a Riken Keiki PESA spectrometer (Model AC-2) with a power setting of 10 nW and a power number of 0.3. Samples for PESA were prepared on glass substrates.
Thin-film preparation and solar cell fabrication. Indium tin oxide (ITO)-coated glass substrates (Kintec Company, 10 12/34) were cleaned by sequential ultrasonication in dilute 300 ml detergent solution, deionized water, acetonitrile, and isopropyl alcohol for 20 min each. These substrates were then cleaned by UV-ozone treatment for 20 min. Copper (I) thiocyanate (CuSCN) (25 mg/ml (Sigma–Aldrich)) was dissolved in diethyl sulfoxide (DES) (Sigma–Aldrich) at 60 °C for 1 h and then filtered. The CuSCN solution was then spin-cast at 2500 rpm for 30 s, followed by annealing at 105 °C for 10 min.

For bilayer CuSCN/acceptor devices, the acceptors were dissolved in chlorobenzene (CB) at different concentration (7–30 mg/ml) for EH-IDTBR, IT-M, ITIC, IT-2Cl, IT-4F, and PC70BM; or in chloroform (CF, 5–20 mg/ml) for Y6, IDIC, PC71BM, and PTCDI-C12. The donor layers were spun on CuSCN layer at different speeds for 30 s to obtain acceptor film with different thicknesses (5–150 nm, film thicknesses were measured by using the Tencor surface profiler). A layer of 5 nm of Phen-NaDPO (DPO) as electron transport layer (ETL) and exciton blocking layer (EBL) was spun from methanol solution (0.5 mg/ml) on top of the acceptor layer. Next, the samples were placed in a thermal evaporator for evaporation of a 100-nm-thick layer of aluminum evaporated at 5 Å s−1; the pressure of <2 × 10−9 Torr. Effective area of the tested solar cells is 0.1 cm². This effective area was determined from the layout of ITO substrate and top contact mask.

Next, the samples were prepared for optical measurements (UV–vis, PL, ellipsometry, TA) were prepared from either CB (20 mg/ml) or CF (10 mg/ml) and spin-coated onto quartz substrates (or Si/SiO2 substrates for GIWAXS, and ellipsometry measurements) in glovebox at 2000 rpm. To measure the intrinsic monomolecular decay constant from the dilute acceptors using TA, the blend film of acceptor with polyisoprene was prepared from CF solution (2 mg/ml) and polyisoprene (56 mg/ml) and mixed in 1:1 ratio.

Solar cells characteristics and analysis. J–V measurements of solar cells were performed in a nitrogen-filled glove box using a Keithley 2400 source meter and an Oriel Sol3A Class AAA solar simulator calibrated to 1 sun, AM1.5 G, with a KG-5 meter analyzer.

Further details can be found elsewhere.64 The nonfullerene acceptor (NFA) films were excited at different wavelengths: IDIC (600 nm), Y6 (700 nm), IT-M (700 nm), IT-4F (750 nm), IT-2CI (700 nm), and ITIC (700 nm).

Computational details. We extracted closely arranged dimer geometries of IDTBR, IT-4F, and IT-2CI from their crystal structures. For ITIC and IT-M, where the crystal structures are not available but their molecular formulas are similar to IT-4F, we formed their dimer structures by using IT-4F dimer structure and substitute F atoms with H atoms and CH2 groups, respectively. To simplify the calculations, we substituted all side alkyl chains of the dimers with CH3 groups. The positions of H atoms and CH2 groups were optimized at the m062x/cc-pVTZ level, while other backbone atoms were kept frozen in order to retain the relative position between the two monomers.

Excited state and the follow-up diabatization calculations were performed with the time-dependent density-functional theory (DFT) method at the m062x/cc-pVTZ level. For diabatization calculations, we define each molecule as a domain, and used up to eight excited states for constructing diabatic states. The coupling matrix of each dimer system consists of at least two local excitations (LEs) and two charge transfer (CT) states, respectively, which ensures a qualitatively correct coupling picture.

Data availability
The source data are available online at https://doi.org/10.6084/m9.figshare.12871736. Extra data are available from the corresponding authors upon request.

Code availability
The codes or algorithms used to analyze the data reported in this study are available from the corresponding authors upon reasonable request.

Author contributions
Y.F., V.M.L.C., I.J.A.K., and T.D.A. conceived the idea, designed the experiments, and wrote the first draft of the paper. Y.F. prepared bilayer devices and characterized their performance. V.M.L.C. conducted the photocurrent data analysis and interpretation. Y.F. prepared thin films for steady-state and transient absorption characterizations. S.K. performed transient absorption measurements and conducted the relevant data analysis. W.L. and A.M. performed quantum-chemical calculations of nonfullerene acceptor dimers. W.L., S.K., and F.L. supervised the optical spectroscopy experiments.

The authors declare no competing interests.
