The Fermi Large Area Telescope (LAT) has observed more than a hundred of gamma-ray pulsars, about one third of which are radio-quiet, i.e. not detected at radio frequencies. The most of radio-loud pulsars are detected by Fermi LAT by using the radio timing models, while the radio-quiet ones are discovered in a blind search. The difference in the techniques introduces an observational selection bias and, consequently, the direct comparison of populations is complicated. In order to produce an unbiased sample, we perform a blind search of gamma-ray pulsations using Fermi-LAT data alone. No radio data or observations at optical or X-ray frequencies are involved in the search process. We produce a gamma-ray selected catalog of 25 non-recycled gamma-ray pulsars found in a blind search, including 16 radio-quiet and 9 radio-loud pulsars. This results in the direct measurement of the fraction of radio-quiet pulsars $\varepsilon_{RQ} = 64 \pm 10\%$, which is in agreement with the existing estimates from the population modeling in the outer magnetosphere model. The Polar cap models are disfavored due to a lower expected fraction and the prediction of age dependence. The age, gamma-ray energy flux, spin-down luminosity and sky location distributions of the radio-loud and radio-quiet pulsars from the catalog do not demonstrate any statistically significant difference. The results indicate that the radio-quiet and radio-loud pulsars belong to one and the same population. The catalog shows no evidence for the radio beam evolution.

Keywords: pulsars: general; gamma rays: stars

I. INTRODUCTION

A new stage of the history of radio-quiet gamma-ray pulsars discovery began with the launch of Fermi satellite on June 11, 2008. Prior to that, the Geminga pulsar stayed, for a long time, as the only identified gamma-ray pulsar without a detectable radio counterpart. The Fermi Large Area Telescopy (LAT) data enabled to discover 34 more gamma-ray pulsars with both time-differencing technique and a novel semi-coherent method. At present, 117 pulsars are identified by Fermi LAT, 82 of which are radio-loud, see for review.

There are two general classes of gamma-ray pulsar models, namely the Polar cap (PC) and the outer magnetosphere (OM) models. The classes are characterized by a location of the origin of high-energy emission. In the PC model the gamma rays are produced by electrons accelerated in the polar cap region near the surface of the neutron star. In the second class of models, electrons are accelerated in outer regions of the pulsar magnetosphere (see also for recent magnetosphere modeling results). A description of radio-quiet pulsars is different in two model classes. In PC models, gamma-ray and radio beams are produced in the same region and co-directed. In these models, pulsars are observed as radio-quiet only if existing radio survey sensitivity is not sufficient to detect radio emission. In the OM gamma-ray and radio beams naturally possess different geometry, which leads to a geometrical explanation of radio-quietness.

There is still an open question whether both radio-quiet and radio-loud pulsars belong to the same population of astronomical objects. It was noted that radio-quiet fraction is higher for young pulsars. This observation may be interpreted as the time evolution of the width of the radio beam. Still the selection effects may be important as the radio-quiet pulsars are identified with a completely different procedure than radio-loud. In order to exclude this possible bias in population studies, we build here the gamma-ray selected catalog of pulsars applying the same blind search procedure to all Fermi-LAT point sources, independently on the information known from radio or optical observation.

The paper is organized as follows. In Section II, the Fermi LAT data analysis is explained. The photon list is build for each of the Fermi-LAT point sources. In Section II we overview the semi-coherent search method used for the blind search of pulsations. Further we estimate the threshold for the value of $H$-test in order to exclude a single false detection with a probability of at least 90%. The gamma-ray selected pulsar catalog and the discussion of the results are presented in Section IV.

II. DATA

We use the Fermi LAT Pass 7 (V6) publicly available weekly all-sky data for the period from 2008 August 4 to 2013 March 6, corresponding to the mission elapsed time (MET) from 239557418 to 384261063 s. We select “SOURCE” class events with energies from 100 MeV to
300 GeV and apply the standard quality cuts using Fermi Science Tools v9r27p1. We require that zenith angle and satellite rocking angle do not exceed 100° and 52° correspondingly.

We use all 1861 point sources from the Fermi LAT Second Source Catalog (2FGL) [17] as the candidates for the search. No preselection of the sources based on the known type and properties is performed. We use coordinates of the sources from 2FGL, although for many sources the position is known better from other observations. This is a price we pay for the blindness of the search to all data, except gamma-ray radiation. We note, however, that the efficiency of the pulsar search grows substantially if one includes the scan over the sky location [4].

The position variation requires more computational resources and therefore the search in this paper is limited to fixed positions.

For each source we build a source model which includes 2FGL sources in a 8° radius circle, galactic and isotropic diffuse emission components (version P7V6). We fit Fermi LAT events in a circle of 8° with a model by gtlike tool using unbinned likelihood analysis. The probability for each photon to be originated from the source under consideration is obtained by gtsrepro tool. This probability is used in the following analysis as a weight of the event. For each source we keep 12000 events with the highest weights. The barycentric corrections to photon arrival times are applied with gtbbary tool.

### III. METHOD

The search for pulsations is performed with the semi-coherent method proposed by Pletsch et al. [4]. We scan over pulsar frequency \( f \) and spin-down rate \( \dot{f} \) using the set of photon barycentric arrival times \( t_a \) and corresponding weights \( w_a \). The observation time range is split into \( M = 277 \) intervals of length \( T = 2^{19} \) s, where the last interval is padded with zero flux up to the length \( T \). First, the arrival times, measured in MET seconds, are corrected with

\[
\tilde{t} = t + \frac{\gamma}{2}(t - t_0)^2,
\]

where \( \gamma = \dot{f}/f \) and \( t_0 = 286416002 \) s (MJD 55225) is a reference epoch. We further bin each time interval into \( N = 2^{25} \) bins and define \( w_{j(m)} \) as the sum of photon weights in the \( j \)-th bin for the \( m \)-th time interval. Then, the spectrum \( F_j^{(m)} \) in the \( m \)-th interval is obtained with a discrete Fourier transform

\[
F_j^{(m)} = \sum_m w_j^{(m)} e^{2\pi i f_k t_j},
\]

where \( f_k = k/T \) and the Nyquist frequency is \( N/2T = 32 \) Hz. The Fourier transform is performed with the open-source Fast Fourier transform library fftw [18]. Finally, semi-coherent power spectral density is defined as a sum of squares of Fourier densities over \( M \) time intervals

\[
P_k = \sum_{m=1}^{M} \left| F_k^{(m)} \right|^2.
\]

We scan over the parameter \( \gamma \) from 0 to \(-1 \times 10^{-12}\) with a step equal to \(-2 \times 10^{-15}\). The range corresponds to the pulsar characteristic age greater than 16 kyr. The values of \( f \) and \( \dot{f} \) corresponding to the highest \( P_k \) are then fine-adjusted by finding a local maximum of the weighted \( H \)-test statistic [19]. The latter is defined coherently on the whole time-interval as follows:

\[
H = \max_{1 \leq L \leq 20} \left[ \sum_{L=1}^{L} \left| \alpha_l \right|^2 - 4(L - 1) \right],
\]

where \( \alpha_l \) is a Fourier amplitude of the \( l \)-th harmonic,

\[
\alpha_l = \frac{1}{\mathcal{N}} \sum_a w_a \exp(-2\pi ilf t_a),
\]

\[
\mathcal{N} = \frac{1}{2} \sum_a w_a^2.
\]

We define the detection threshold \( H_{th} \) in such a way that the probability to have a single false candidate in the whole set does not exceed 10%. As the distribution of \( H \)-test statistic for non-pulsating objects is not known a priori, we construct an estimate for the particular procedure of our scan. We exclude all known gamma-ray pulsars (117 sources) from the 2FGL list and produce a distribution of \( H \)-test for remaining 1744 sources, see Fig. 1. The tail of the distribution is approximated with an exponential function and then the value \( H_{th} = 87 \)
IV. RESULTS

We apply the procedure of Section III to all 1861 point sources of the 2FGL catalog. As a result, 25 objects are found with the value of $H$-test above the threshold $H_{th}$, see Table I. It appears that all of the pulsation detections correspond to known gamma-ray pulsars, 16 of which are radio-quiet and 9 are radio-loud, see last six columns of Table I. This allows us to estimate directly the fraction of radio-quiet pulsars

$$\varepsilon_{RQ} \equiv \frac{N_{RQ}}{N_{RQ} + N_{RL}} = 0.64 \pm 0.10 \ (68\% \ CL),$$

where $N_{RQ}$ and $N_{RL}$ are numbers of radio-quiet and radio-loud non-recycled gamma-ray pulsars. It should be mentioned that the radio-quietness is determined according to the present-day sensitivity of radio surveys. It is possible that faint radio emission will be detected in the future from some of todays radio-quiet pulsars.

The fraction above confirms the domination of radio-quiet pulsars and is perfectly consistent with the predictions of population synthesis with OM model which gives a value of 0.65 \cite{13}. The PC model with inverse Compton gamma-ray production estimates the fraction as 0.25 \cite{11} which is excluded by the observation. A curvature radiation version of the PC model leads to the fraction value of 0.49-0.53 \cite{12} which is slightly disfavored. Moreover, the model \cite{12} is further disfavored due to its prediction of the decrease of radio-quiet fraction with age. Considering pulsars older than 100 kyr the model expectation of radio-quiet fraction 0.36 should be compared with 0.62 \pm 0.13 in our catalog.

The comparison of distributions over galactic coordinates, gamma-ray energy flux and spin-down luminosity indicate that both radio-loud and radio-quiet pulsars are compatible with the Kolmogorov-Smirnov (KS) probability 54%, see Fig. 3. Therefore there is no indication for the radio beam evolution. We note, however, that the pulsars younger that $\sim 16$ kyrs are outside of the search range of the present Paper.

Pulsars younger than 100 kyr the model expectation of radio-quiet fraction 0.36 should be compared with 0.62 \pm 0.13 in our catalog.

The $P-\dot{P}$ plot for the pulsars from our catalog is shown in Fig. 2. The comparison of distributions over galactic coordinates, gamma-ray energy flux and spin-down luminosity indicate that both radio-loud and radio-quiet pulsars belong to the same population, see Table I. The agreement of the parameter distributions is an additional argument in favor of the geometrical origin of radio-quietness and therefore OM pulsar models are preferable. On the contrary, the PC models unavoidably result in a strong age dependence of the fraction of radio-quiet pulsars.

Given that Fermi LAT has by now observed 82 radio-loud pulsars, we expect according to our value of $\varepsilon_{RQ}$ that there are about 145 radio-quiet pulsars among the Fermi-LAT sources. The pulsed emission is discovered for only 35 of them leaving more than a hundred sources as a challenge for the future pulsation searches. In accord with our result, the machine-learning classification of Fermi-LAT unidentified sources points to more than 50 gamma-pulsar candidates \cite{27}.

follows from the requirement that the integral of extrapolated distribution above $H_{th}$ is equal to 0.1. The above background estimation technique is based on the complete scan procedure and therefore naturally accounts for data-selection and scans. The procedure is conservative as any unidentified pulsars existing in the set lead to an increase of estimated $H_{th}$. Note that the threshold determination required us to involve the sources identification information, but this does not impact detection uniformity as $H_{th}$ is a constant for all sources in the search.

---

FIG. 2. $P-\dot{P}$ plot for 25 pulsars found with a blind search in the present Paper. $P = \frac{1}{f}$ is a rotation period.

FIG. 3. Distributions of characteristic age $\tau_c = \frac{1}{2f}$ for radio-loud and radio-quiet pulsars. The two distributions are compatible with KS probability 54%.
TABLE I. A catalog of gamma-ray pulsars found in a blind search. Frequency $f$ and spin-down rate $\dot{f}$ of gamma-ray pulsations correspond to the epoch MJD 55225. Age is estimated as $-f/2\dot{f}$. The last six columns contain the object information from the literature: pulsar name, galactic coordinates, Fermi LAT energy flux for $E > 100$ MeV [17], type (Q - radio-quiet, L - radio-loud) and a reference to the first identification of gamma-ray pulsations. The improved pulsar positions from [20] are shown for the objects they are available.
