Abstract We suggest an appealing strategy to probe a large class of scenarios beyond the Standard Model simultaneously explaining the recent CDF II measurement of the $W$ boson mass and predicting first-order phase transitions (FOPT) testable in future gravitational-wave (GW) experiments. Our analysis deploys measurements from the GW channels and high energy particle colliders. We discuss this methodology focusing on the specific example provided by an extension of the Standard Model of particle physics that incorporates an additional SU$(2)_{L}$ Higgs doublet, vector-like fermion SU$(2)_{L}$ triplets, vector-like top partners, leptoquarks, singlet-doublet fermion pairs, scalar SU$(2)_{L}$ triplets and quadruplets, right-handed neutrinos, $Z'$ and extra vector bosons, FIMP dark matter modes, $U(1)_{L_{\mu}-L_{\tau}}$ modes, vectorlike quarks, canonical scotogenic neutrino-dark matter modes, $U(1)_{L_{\mu}-L_{\tau}}$ vector-like leptons – see e.g. Refs. [3–37]. Also a top-down motivated model has been considered, in which extra states come from a D3-brane [38]. Implications for electroweak baryogenesis and Chameleon dark energy have been also considered [39,40], while the relevance of hadronic uncertainty and electroweak precision tests for the correct interpretation of the result and the prospect on new physics has been delved in [41–43].

This large and statistically significant anomaly within the Electro-Weak (EW) sector urges us to question what are its possible implications for our understanding of the EW phase transitions (EWPTs), and more in general whether it can be related to a first-order phase transition (FOPT) in the early Universe. At the first sight, a relation between the $W$ mass anomaly and the order of cosmological phase transitions may appear not so direct and clear. Certainly, the answer would be model-dependent.

In this short letter, we do not pretend to be exhaustive in covering the wealth of phenomenologically allowed models that address this broad research topic. We rather seek to answer questions related to the aforementioned relevant issues, focusing on a specific simplified framework that
relates the parameter space of EWPTs to a possible explanation of the $M_W$-anomaly. Specifically, the model we consider is based on a minimal scalar-triplet extension of the SM scalar sector providing a natural explanation of the anomaly as suggested earlier in Ref. [6]. Even without providing here a detailed scan of the parameter space of the considered minimal model, this simplified approach will nevertheless help us gain intuition on the way our outlined strategy for new physics search can be applied to other theoretical frameworks invoked to explain the measured $M_W$-anomaly.

We will show that, in a large subset of the parameter space of the simplified model, we obtain gravitational-wave (GW) stochastic background signals as echoes of the strong EW FOPT in the early Universe that can be tested in space-based interferometers such as LISA, DECIGO, BBO, TianQing and TAIJI to be deployed in the foreseeable future. We also notice that the considered parameter space of the model does not violate the current LHC constraints. The model can also be tested at future linear or circular lepton colliders such as the FCC, ILC and CEPC, through a measurement of the trilinear Higgs interactions, which receives relatively large corrections due to Higgs interactions with the scalar triplet.

2 Minimal $SU_L(2)$ triplet extension: $M_W$-anomaly and FOPT

The CDF-II measurement of the $W$ boson mass $M_W$ suggests an anomaly in the $\hat{T}$-parameter [28] (in particular, under an assumption of $\hat{U} = 0$), namely

$$\hat{T} \simeq (0.84 \pm 0.14) \times 10^{-3},$$

and hence leading to a positive $\hat{T}$ contribution consistent with the observed shift in the $W$ mass,

$$\hat{T} = \frac{k_\Delta^3 \mu_{\Delta}^2}{M_{\Delta}^2} = 0.84 \times 10^{-3} \left( \frac{k_\Delta}{M_\Delta} \right)^2 \left( \frac{8.5 \text{ TeV}}{M_\Delta} \right)^2.$$

This is a tree-level effect suggesting that the $SU(2)_L$ scalar triplet can be in a multi-TeV mass range. Nonetheless, saturating the perturbativity bound $|k_\Delta|/M_\Delta \leq 4\pi$, the triplet cannot exceed 100 TeV [6].

It is worth to notice that, after integrating out $\Delta$, Eq. (5) generates an additional contribution to the quartic Higgs self-interaction term of the form $(k_\Delta/m_\Delta)^2(H^\dagger H)^2$. The Higgs bare coupling constant $\lambda_{\Delta}$ hence receives a tree-level correction, according to $\lambda = \lambda_{\text{bare}} + (k_\Delta/m_\Delta)^2$. In what follows, we consider the full Higgs quartic coupling $\lambda = m^2/2v^2$ (with $m^2$ being the Higgs mass parameter in the Lagrangian and $v \simeq 246$ GeV – the Higgs vacuum expectation value) rather than $\lambda_{\text{bare}}$, which appears in the SM framework.

We may now focus on a Lagrangian term of the form

$$\frac{\mu_\Delta^2}{\Lambda^3} \Delta^3 + \text{h.c.},$$

where $\Delta^3 \equiv (\Delta \cdot \sigma)(\Delta \cdot \sigma)(\Delta \cdot \sigma)$. Integrating out $\Delta$-states, Eqs. (5) and (8) generate the following six-dimensional operator

$$\frac{k_\Delta}{\Lambda^2} (H^\dagger H)^3 + \text{h.c.},$$

in terms of the cutoff scale $\Lambda$, where

$$\Lambda \frac{\kappa}{\sqrt{\mu_\Delta^3}} = \frac{\mu_\Delta^2 k_\Delta^3}{3 M_\Delta^6}.$$

The latter recasts as

$$\frac{\Lambda}{\sqrt{\kappa}} = \frac{\sqrt{3} M_\Delta^3}{\sqrt{\mu_\Delta^3 k_\Delta^3/2}},$$

with $\kappa \lesssim 4\pi$ as a perturbativity bound. Note, the six-dimensional operator (9) appears to be a crucial contribution to determine the nature and the strength of the EWPT.

In order to develop a consistent analysis of the EW FOPT, it is convenient to choose the unitary gauge, such that $H = h/\sqrt{2}$. The one-loop finite-temperature effective potential then casts as

$$V_{\text{eff}}(T, h) = V_{\text{tree}}(h) + V_1^{(1)}(h) = \Delta V_T(h, T),$$

where

$$V_{\text{tree}}(h) = \frac{1}{4} m^2 h^2 + \frac{1}{4} h^4 + \frac{\kappa}{8 \Lambda^3} h^6$$

is the tree-level Higgs potential, $V_1^{(1)}(h)$ is the Coleman–Weinberg one-loop potential fixed at the EW scale at zero temperature, and $\Delta V_T(h, T)$ is the thermal contribution.
obtained through the daisy resummation technique [44,45] and the use of dimensional reduction within the context of EWPT thermodynamics [46–49].

At tree-level, the effective Higgs potential acquires a dominant thermal correction to the mass that reads as \( CT^2/2 \), where
\[
C \simeq \frac{1}{16} \left( g^2 + 3g^2 + 4\gamma_1^2 + 4\mu_0^2/m^2 + 36\lambda_1 v^2/\Lambda^2 \right),
\] (14)
and where \( g\), \( g\) are, respectively, the \( U(1)_Y \) and \( SU(2)_L \) gauge couplings, \( \gamma_1 \) is the Yukawa coupling of the top quark providing a leading contribution from the SM fermion sector and \( m_h \) is the Higgs boson mass which, at tree-level, is given by \( m_h^2 = 2\kappa v^2 + 3\lambda_1 k/\Lambda^2 \). In this work, we compute the Coleman–Weinberg contribution and perform the bounce action calculations and the search for FOPTs using the CosmoTransitions package [50].

As it was previously found in [44,45,51], the required condition to induce strong FOPTs in effective extensions of the Higgs sector with dimension-6 operators implies that the \( \Lambda/\sqrt{\kappa} \) energy scale is limited in the range \( 480 \pm 840 \) GeV. In this article a concrete UV realization is considered such that, using relation (11), one can recast this range in terms of the \( \Delta \)-sector parameters as
\[
480 \text{ GeV} \lesssim \sqrt{\frac{\sqrt{3} M_3^2}{\mu_0^2}} \lesssim 840 \text{ GeV},
\] (15)
which will be used as input in our numerical analysis. The FOPT conditions that must be satisfied are \( T_c > 0 \) and \( v(T_c)/T_c > 1 \), in terms of the critical temperature of the phase transition, \( T_c \). These lead to the range in the cutoff scale \( \Lambda_m \leq \Lambda \leq \Lambda_M \), which in turn corresponds to the observed Higgs mass \( m_h = 125 \) GeV. This is found employing the following relations for \( \alpha, \gamma, \) parameters in the Higgs sector:
\[
m^2 = m_{\text{SM}}^2 (1 - \Lambda_3^2/2\Lambda^2) \quad \text{and} \quad \lambda = \lambda_{\text{SM}} (1 - \Lambda_3^2/\Lambda^2),
\]
with \( \Lambda = \sqrt{3} \lambda_3 \Lambda_3 = \sqrt{3} k v^2/m^2 \), and \( m_{\text{SM}}, \lambda_{\text{SM}} \) being the SM counterparts.

The bounds imposed by the FOPT conditions allow for a scalar triplet to be in a multi-TeV mass range. Saturing the perturbative bounds for the triplet mass \( M_\Delta \) as \( |k_\Delta|/M_\Delta \approx 4\pi \) and \( |\mu_\Delta|/M_\Delta \approx 4\pi \), the FOPT bounds in Eq. (15) correspond to \( M_\Delta \approx 5 \times 10^{10} \) TeV.

A strong EW FOPT sources bubble nucleation via quantum tunneling and thermal fluctuations from a metastable false vacuum to the true vacuum. The dynamics of phase transitions are characterized by \( T_s \), \( \alpha \), \( \beta \) parameters. Here, \( T_s \) stands for the percolation temperature, at which the probability of finding a point in the false vacuum is 0.7 [60]. The \( \alpha \) parameter reads \( \alpha \equiv \epsilon(T_s)/\rho_{\text{rad}}(T_s) \), with \( \epsilon(T) \) being the latent heat and \( \rho_{\text{rad}}(T) \) – the primordial plasma thermal energy. The \( \beta \) parameter is the characteristic time scale of the EWPT, and is related to the size \( d \) of the bubble as \( d \approx v_b/\beta \), with \( v_b \) being bubble wall expansion velocity. The key parameters are all controlled by the effective scalar potential according to the following relations:
\[
\alpha = \frac{30}{\pi g_s(T_c)T_c^2} \left[ \frac{T}{4} \frac{dV_{\text{eff}}^{\min}(T, h)}{dT} - \Delta V_{\text{eff}}^{\min}(T, h) \right]_{T=T_c},
\] (16)
\[
\beta = -\frac{dS_{\text{eff}}}{dt} \bigg|_{t=t_s},
\] (17)
where \( S_{\text{eff}}(T) \) denotes the bubble 3D Euclidean action divided by the temperature and \( t_s \) is the cosmological time at which \( T = T_s \), \( g_s(T_s) \) are the relativistic degrees of freedom at \( T = T_s \) and \( \Delta V_{\text{eff}}^{\min}(T, h) \) represents the difference of the effective potential before and after the transition takes place at \( T_s \).

The \( T_s \), \( \alpha \), \( \beta \) parameters introduced above characterize the GW energy spectrum, which receives three main contributions from bubble collisions [52], sound shock waves [53] and turbulence [54,55], all described by well-known semi-analytical formulas. Simulations of FOPTs from a specific field theory provide an input for the semi-analytical formulas, which in turn generate the related characteristics of GW spectra as output. Within this analysis we deploy standard methods in accounting for collision, turbulence and sound-wave contributions – see e.g. Refs. [56,57]).

We have performed a parametric scan by varying \( \Lambda/\sqrt{\kappa} \) in the range \([480, 840]\) GeV using a numerical routine based on CosmoTransitions [50] to calculate the phase transition parameters \( \alpha \) and \( \beta \), as well as the GW’s peak amplitude \( (h^2\Omega_{\text{GW}}^{\text{peak}}) \) and frequency \( (f_{\text{peak}}) \). As shown in Fig. 1 one can notice that strong FOPTs associated to the production of potentially visible GWs at LISA and future interferometers restricts \( \Lambda/\sqrt{\kappa} \) to a narrow region of approximately \([500, 510]\) GeV. Such a result is rather tantalizing, not only because it corresponds to a TeV scale triplet, but, above all, this is indeed the preferred region favoured by the CDF II W mass anomaly. In particular, expressing the parametric scan in term of \( \hat{T} \), which is related by \( \Lambda/\sqrt{\kappa} \) through Eq. (7), we have found that higher values of the parameter \( \hat{T} \), related to lower values of the energy range of \( \Lambda/\sqrt{\kappa} \), correspond to higher intensities of the GWs stochastic background that would be originated, as Figs. 1 and 2 clearly depict. Therefore, to higher values of the parameter \( \hat{T} \) measured by CDF II correspond higher values of the amplitude of the GWs signal and of the related signal-to-noise ratio (SNR).

Varying \( \hat{T} \) within the same range \([0.76, 0.84]\) \times 10^{-3}, we can show in Fig. 2 the SNR that corresponds to points detectable by LISA. In particular, for SNR greater than 20, one obtains \( \hat{T} = 0.844 \times 10^{-3}, \) e.g. the first point in Table 1, which corresponds to \( \Lambda/\sqrt{\kappa} \sim 500 \) GeV.

We have fixed \( \mu_\Delta = 7.33 \) PeV, which corresponds to the value \( \Lambda/\sqrt{\kappa} = 500 \) GeV that maximizes the amplitude of the GWs and for which the related SNR is greater than 20, having used the experimental result for \( \hat{T} \) specified by Eq. (1).
In Table 1, we have listed three scenarios corresponding to the generation of EWPT in the model under scrutiny. We show that these FOPT branches can be promisely tested in space-based interferometers (see Fig. 3). As we expected, for the three cases corresponding to the benchmarks in Table 1, we find that non-runaway bubble solutions and sound shock wave and turbulence contributions are predominant with respect to bubbles’ collision ones. We decided to focus on these three examples, since not only they evade LHC bounds on direct searches and trilinear Higgs coupling, but they can also be tested at CEPC. Indeed, in the model we are considering the Higgs trilinear coupling \( \lambda_{3h} \) is expressed by

\[
\lambda_{3h} = -(1 + \delta_h) \frac{A h^3}{6},
\]

where \( A = 3m_h^2/\nu \) and \( \delta_h = 2\Delta m/\Lambda \). Here \( \delta_h \) varies within the range 0.66 \( \div \) 2, the values of which can be compared with the \( hZ \) cross section data \( \sigma_{hZ} \), with precision \( \delta_{\sigma_{hZ}} = \delta\sigma_{hZ}/\sigma_{hZ} \). CEPC can achieve the precision \( \delta_{\sigma_{hZ}} \simeq 1.6\% \) at \( \sqrt{s} = 240 \text{ GeV} \) collision energy, corresponding to \( \delta_h (\kappa = 1) = 0.25 \) for integrated luminosity of \( 10 ab^{-1} \) – see e.g. Refs. [51,58]. Thus CEPC can directly probe the model we considered testing both EWPT and \( M_W \)-anomaly from heavy scalar triplet – see Figs. 3 and 4.

Note that the measurement of the triple Higgs coupling can achieve the statistical significance of 4.5\( \sigma \) at a potential high-energy 27 TeV LHC (HE-LHC) upgrade [59]. This, together with the observed \( W \)-mass anomaly and a possible primordial GWs detection, offers a striking opportunity for probing the considered triplet extension of the SM in a not too distant future.

### Table 1 Benchmark FOPT solutions that can be detected in future GW space-based interferometers

| \( T_* \) (GeV) | \( \alpha \) | \( \beta/H_* \) | \( \hat{T} \) | \( \delta_{\sigma_{hZ}} \) (%) |
|----------------|-------------|-------------|----------|------------------|
| 43.8           | 0.30        | 36.37       | 0.844 \( \times \) 10\(^{-3} \) | 3.02             |
| 55.6           | 0.12        | 180.94      | 0.835 \( \times \) 10\(^{-3} \) | 2.97             |
| 64.2           | 0.07        | 394.14      | 0.822 \( \times \) 10\(^{-3} \) | 2.90             |

In this Letter, we have explored an interplay between the recently observed anomaly detected in the \( W \)-mass measurement by the CDF-II Collaboration and the dynamics of the
strong first-order Electro-Weak (EW) phase transitions. For
this purpose, we have considered an insightful example of a
model for new physics containing a scalar SU(2)_L triplet
with only three adjustable free parameters on top of those of
the Standard Model (SM): a triplet mass term and its trilin-
ear self-coupling as well as a trilinear coupling to the Higgs
boson. We have found that even in this simplified framework
one can naturally explain the observed new physics correction
to the W mass while sourcing a strong first-order EW
phase transition that potentially generates observable primor-
dial gravitational wave (GW) signatures in cosmology.

The considered minimal SU(2)_L triplet extension of the
SM is an important example of more extended Beyond SM
scenarios that predict a sizeable dimension-6 (H H H) operator
in the Higgs sector above the EW scale leading to first-
order phase transitions in the EW sector. Such a heavy triplet
emerges, for instance, in the context of SU(5) Grand-unified
field theory [28,62–64], as a scalar adjoint representation of
dimension 24. Our analysis shows that the existence of poten-
tially observable GW signatures implies the triplet mass scale to be TeV-ish, which in turn is close to the value preferred by the W mass anomaly. With this example, our analysis explicit-
y demonstrates that a class of models featuring a SU(2)_L
triplet scalar state can be probed by future GWs interferome-
ters such as LISA, DECIGO, TianQin and TAIJI, around the
mHz frequency scale, as well as from measurements of the
trilinear Higgs coupling in future linear or circular colliders.
