Abstract

Interferon alpha (IFN-α) is commonly used for the treatment of chronic hepatitis B (CHB) patients. Many factors including viral genetics may determine the outcome of IFN-α therapy. In this study, we tested whether the expression of IFN-α directly in the liver inhibits HBV gene expression and replication using a HBV hydrodynamic injection (HI) mouse model. Two replication-competent clones from different HBV isolates that belonging to HBV genotype A and B based on a pAAV vector (pAAV-HBV-A and pAAV-HBV-B) were compared for their susceptibility to IFN-α. HBV clones were injected into mice either alone or in combination with a murine (m) IFN-α expression plasmid (pmIFN-α). HBsAg and HBeAg concentrations and HBV DNA levels in mice differed after injection of these two HBV clones. Co-application of pmIFN-α together with the two distinct isolates resulted in markedly different kinetics of decline of HBsAg, HBeAg, and HBV DNA levels in the mice. Immunohistochemical staining of liver sections with anti-HBc showed that mIFN-α expression plasmid completely inhibited the expression of HBcAg in mice inoculated with pAAV-HBV-B, whereas the expression of HBeAg was only reduced in mice with pAAV-HBV-A. Consistently, mice injected with pAAV-HBV-B and pmIFN-α showed higher expression levels of the IFN-stimulated genes (ISGs) ISG15, OAS, PKR as well as proinflammatory cytokine IL-6 in the liver. In addition, expression levels of anti-inflammatory cytokine IL-10 was down-regulated significantly in liver of the mice injected with pAAV-HBV-B and pmIFN-α. Our data demonstrate that IFN-α exerts antiviral activity in HBV mouse model, but different HBV isolates may have diverse susceptibility to IFN-α.

Introduction

Hepatitis B virus (HBV) is a DNA virus causing chronic infections of the human liver [1]. More than 400 million people worldwide have been infected and about one million patients die annually from HBV infection [2]. The genetic analysis of HBV has revealed the existence of ten different genotypes (A–J) [3]. In Asia, HBV infection is highly prevalent and HBV isolates commonly belong to genotypes B and C.

Currently, inhibition of HBV infection can be achieved by suppressing viral replication. IFN-alpha (IFN-α) and nucleoside/nucleotide analogs [4–6] are mainly used for therapies of chronic hepatitis B (CHB). In contrast to nucleoside analogs, IFN-α is able to enhance host immune responses and promote cellular immune responses, mediating inhibition of HBV replication and gene expression [7–8]. IFN-α is an approved and effective treatment for CHB, inducing HBeAg seroconversion and histological remission in about one third of the patients [9]. In addition, several previous studies have suggested that IFN-α therapy may have long-term beneficial effects in terms of viral clearance, prevention of HCC and prolonging survival in patients with CHB [10–11]. Compared to nucleoside/nucleotide analogs, the advantage of IFN-α therapy includes a more durable response, with the benefit of lacking emergence of drug resistant HBV mutants during the course of treatment. Further, HBsAg loss associated with standard IFN-α therapy has been reported in European studies, with the loss of HBsAg within 1 year of treatment in 5-10% of recipients [12]. However, only 30% of the CHB patients showed sustained response to IFN-α treatment, which limits the clinical effect and application of IFN-α [13]. The mechanisms underlying the low response to IFN-α in CHB patients remain unclear. It has been considered that it involves multiple causes including both virus-related and host-specific factors [14–16]. Previous studies showed that the HBV genotype has little impact on the outcome of CHB patients treated with nucleoside/nucleotide analogues [17–18]. However, different genotypes of HBV showed distinct response to IFN-α.
IFN-α treatment [19–20]. Different genotypes of HBV may have distinct virologic characteristics, which may correlate with antiviral curative effects and clinical outcome [21–22]. It has been suggested that IFN-α-based therapies have higher efficacy in patients including HBcAg-positive and HBeAg-negative patients with genotype A versus D, and in HBeAg-positive patients with genotype B versus C [19]. However, it was not yet demonstrated whether the different HBV isolates display various susceptibility to IFN-α, considering that virus genetic alteration during antiviral therapy is an important factor that influenced the antiviral effect.

The type I IFNs belong to a multigene family with over 14 IFN-α subtypes in humans [23] and over 10 IFN-α subtypes in mice [24]. There is 80–95% homology at the amino acid level among various IFN-α subtypes [25]. The IFN-α-mediated complex antiviral responses include immune regulation and the induction of cytokines and antiviral proteins. The IFN-α signaling is mediated by the JAK-STAT pathway and leads to the activation of a large number of interferon-stimulating genes (ISGs) [26–28]. These effectors individually may block viral transcription, degrade viral RNA, inhibit translation or modify protein function to inhibit the process of viral replication.

The antiviral activity of IFN-α against HBV could be demonstrated in vitro and in an HBV transgenic mouse model [29–31]. It has shown that IFN-α may destabilize HBV nucleocapsids at a post-transcriptional step [32]. Tian et al. have shown that IFN-α may exert complex antiviral activities in different HBV transgenic mouse strains, depending on the replication status of HBV [33]. Zhang et al. reported that the effectiveness of Peg-IFN-α to suppress HBV replication is dependent on different HBV genotypes in HBV HI mouse model by subcutaneously injection of Peg-IFN-α [34]. However, it was not yet demonstrated whether directly application of IFN-α in the mouse liver displays various antiviral effect between HBV isolates and it was not yet possible to compare genetically different HBV isolates for their susceptibility to IFN-α. In this paper, the antiviral effect of mIFN-α against two different HBV isolates belonging to the genotypes A and B was determined in a hydrodynamic injection (HI) mouse model.

It is worth mentioning that injection of recombinant IFN-α distributes IFN-α in the organism and only a part of IFN-α could reach the liver. It is clear that IFN-α is diluted and the major part will be metabolized in the body. Thus, we attempted to test the application by HI where the plasmids could be delivered into the liver and express IFN-α protein there. In addition, eukaryotic proteins have some post-translational modifications which are required for its biological activities. The hepatocytes will produce fully functional IFN-α with complete post-translational modifications. Therefore, the expression of IFN-α in the liver by HI method may achieve a better therapeutic effect for the treatment of chronic HBV infection.

For this experiment, we chose IFN-α4, as this subtype has similar properties like IFN-β and is able to induce the expression of other subtypes [35]. Co-application of pmIFN-α together with the HBV clones led to rapid but kinetically different decline of HBsAg, HBeAg, and HBV DNA levels in sera of the mice. Interestingly, 3 ISGs ISG15, OAS, PKR and proinflammatory cytokine IL-6 were up-regulated, anti-inflammatory cytokine IL-10 was down-regulated in liver tissue after pmIFN-α injection, but to different degrees for the two HBV isolates.

Ethics Statement

The animal experiments were carried out in concordance with the guidelines and protocols established by the Institutional Animal Care and Use Committee (IACUC Number: 287) at the Huazhong University of Science and Technique and the Tongji Hospital of Tongji Medical College. IACUC at the Huazhong University of Science and Technique and the Tongji Hospital of Tongji Medical College approved this study. All surgeries were performed under sodium pentobarbital anesthesia, and every effort was made to minimize suffering.

Materials and Methods

HBV Genotype B infectious clone and pmIFN-α expression plasmid

A Not-digested and blunted fragment of 1.3 fold genotype B HBV DNA including nt 1038-3215-1984 (GenBank accession number AF220698.1) from pAAV-HBV1.3 [36] was cloned into the SacII/BglII digested and blunted pAAV vector derived from pAAV-HBV1.2 [37] (kindly provided by Prof. Pei-Jer Chen, National Taiwan University). The resulting plasmid named pAAV-HBV-B contains the HBV fragment spanning nucleotides 1038-3215-1984 flanked by inverted terminal repeats of AAV.

In this paper, pAAV-HBV1.2 was renamed as pAAV-HBV-A to distinguish from pAAV-HBV-B. The detail of construction procedure was shown in supplementary material. The expression plasmid pCMVin-t-mIFN-α (pmIFN-α) contained the full length murine IFN-α4 gene [38].

Preparation of HI mouse model

Adult SPF C57BL/6 mice (male, 6–8 weeks old) were purchased from the breeding colonies of the experimental animal center in Shanghai, China, and maintained in a 12-hour light-dark cycle, and cared for in accordance with national and local regulations. HI experiments were carried out as described previously [37]. 10 μg pAAV-HBV-A or pAAV-HBV-B together with 20 μg pmIFN-α were co-injected into the tail vein of mice in a volume of 0.9% NaCl equivalent to 8% of the mouse body weight. The total volume was delivered within 5–8 s. The mice injected only with pAAV empty vector or 0.9% NaCl were used as negative control and the mice injected only with pAAV-HBV-A, pAAV-HBV-B or pmIFN-α, separately, were used as positive control. Each group included at least 10 mice.

Detection of mIFN-α protein in mouse serum samples

The amount of mIFN-α protein in mouse serum samples were collected at 24 hour post injection (hpi), 1, 10, 20, 30, 50 day post injection (dpi) and determined by commercial enzyme-linked immunosorbent assay (ELISA) kit (BD Biosciences, New Jersey, USA). The serial dilutions of mIFN-α standard samples from 12.5 to 500 pg/ml were used to establish the standard curve. The sera of mice used in this test were 2-fold diluted. The mIFN-α standard samples were measured in duplicates.

Detection of HBsAg and HBeAg in mouse sera

The serum specimens were collected and assayed for HBsAg and HBeAg at 1, 4, 7, 10, 15, 20, 25, 30, 40, 50 and 60 dpi. HBsAg and HBeAg were determined by using commercial enzyme-linked immunosorbent assay (ELISA) kits (Kehua, Shanghai, China). 10-fold diluted serum samples were used for detection.

Isolation and analysis of HBV DNA in mouse sera

The serum HBV DNA were detected at 1, 4, 7, 10, 15, 20, 25, 30, 40, 50 and 60 dpi. HBV DNA was extracted from 10 μl mouse serum sample using the following method : 10 μl mouse serum was added into 40 μl...

Antiviral Effect of IFN-α against Two HBV Isolates

Purification of RNA from mouse liver tissue and Real-Time PCR detection

Total RNA was isolated from collected liver tissue at indicated time points by commercial kits (OMEGA, Norcross, USA). RNA was reverse-transcribed and the product was used for analyzing the copy number of mouse ISG15, OAS, PKR, IL-6, IL-10 and TGF-β cDNA by using real-time quantitative PCR (RT-PCR).

Enzyme-linked immunospot (ELISPOT) assay

ELISPOT assay was carried out using the mIFN-α precoated ELISPOT Kit (Dakewe, Shenzhen, China) according to the manufacturer’s instructions. Briefly, 96-well flat-bottomed microtiter plates were preincubated with the coating antibody (anti-mIFN-α monoclonal antibody) at 4°C overnight and blocked for 2 hr at 37°C. Mouse splenocytes were added to wells at the density of 2×10⁵ cells per well in triplicate with 0.5 μg/ml of full length recombinant HBsAg and HBeAg peptide separately and incubated at 37°C, 5% CO₂ for 24 hr. 5 μg/ml of ConA (Sigma, St. Louis, USA) was used as positive control and 0.5 μg/ml of CMV (prospect) as negative control. Thereafter, cells were removed. Wells were washed ten times with PBS containing 0.05% Tween-20 (PBS-T) and incubated with 100 μl of biotinylated anti-IFN-α antibody for 1 hr. The plates were washed again with PBS-T and incubated with 50 μl HRP-strepto-avidin solution at 37°C for 1 hr. Spot-forming cells were counted and analyzed with an ELISPOT plate reader (BioReader 4000, Biosys, Germany). Results were presented as spot-forming cells per 2×10⁵ cells.

Statistics

Experimental data were reported as means±standard deviations. The t-test was applied to comparisons between different groups; a P value <0.05 was considered statistically significant. Statistical analysis was performed using SPSS (SPSS, Inc., Chicago, IL).

Results

Identification of pAAV-HBV-B

To compare the susceptibility of different HBV isolates to IFN-α in the HI mouse model, a new replication-competent clone belonging to HBV genotype B named pAAV-HBV-B containing 1.3 fold genome of HBV genotype B was constructed. The construction procedure and identification results were shown in Fig. S1A and B separately. We confirmed that the pAAV-HBV-B was constructed correctly.

Expression of mIFN-α in mouse sera after HI

The presence of mIFN-α in sera of mice after HI of pmIFN-α was measured with commercial ELISA kit. Fig. 1A shows that the expression level of mIFN-α at 24 hpi after HI was above 1000 pg/ml, indicating effective expression of mIFN-α in mice after HI of pmIFN-α. We also determined the expression of mIFN-α in the mice over time up to 30 dpi (Fig. 1B). The result has shown that the concentrations of mIFN-α in mice declined with time but remained to be detectable more than 10 days. It is worth pointing out that the peak mIFN-α concentration and the decline was identical if pAAV-HBV-A and pAAV-HBV-B infection clones were co-applied.

Kinetics of HBsAg, HBeAg and HBV DNA in sera of the mice after HI of HBV clones and pmIFN-α

To compare the inhibitory effects of mIFN-α on the replication of different HBV isolates in mice, the kinetics of serum HBsAg, HBeAg and HBV DNA in mice were determined after HI. As shown in Fig. 2, the mice injected with pAAV-HBV-B had the higher HBsAg and HBeAg expression levels during the first two weeks than that with pAAV-HBV-A. However, the serum HBsAg level in the mice injected with pAAV-HBV-B and pmIFN-α significantly declined from 4 dpi on compared to the control group injected with pAAV-HBV-B alone. On 15 dpi, the HBsAg was cleared in all mice of this group. In contrast, serum HBsAg in the mice injected with pAAV-HBV-A and pmIFN-α began to decline at 15 dpi, compared with the control mice injected with pAAV-HBV-A only (Fig. 2A). HBsAg clearance occurred later at day 25 dpi. The HBeAg level decreased from 1 dpi by injecting either pAAV-HBV-B combined with pmIFN-α or pAAV-HBV-A together with pmIFN-α, whereas the HBeAg in the pAAV-HBV-B and pmIFN-α co-injected mice decreased markedly compared with the pAAV-HBV-A and pmIFN-α co-injected mice (Fig. 2A).

Real-time PCR analysis showed that the peak HBV DNA level in sera from mice injected with pAAV-HBV-B was 1 order higher than that of pAAV-HBV-A (Fig. 2B). After co-injection with pmIFN-α, the serum HBV DNA levels declined in both pAAV-HBV-B and pAAV-HBV-A injected mice. Interestingly, after pmIFN-α treatment, HBV DNA in the pAAV-HBV-B injected mice became undetectable after 7 dpi, while HBV DNA was cleared after 25 dpi in the pAAV-HBV-A injected mice (Fig. 2B). Our results suggest that pAAV-HBV-B had higher replication competence than pAAV-HBV-A and led to higher HBsAg and HBeAg expression and HBV DNA levels in mouse sera. Further, the antiviral effect of mIFN-α was more pronounced against pAAV-HBV-B than pAAV-HBV-A, confirming the presumption that different HBV isolates may have different susceptibilities to IFN-α.
Figure. 1. Detection of mIFN-α in serum samples from the mice after HI. Mice received HI with 10 μg of either HBV clones or pmIFN-α alone or combination of HBV clones with pmIFN-α. Mouse sera were collected at the indicated time points. The concentrations of mIFN-α protein were detected by mIFN-α ELISA kit. (A) Expression of mIFN-α in mice at 24 hpi. (B) Kinetics of mIFN-α expression in mice after HI. At least three serum specimens of the mice per group were analysed at the indicated time points.

doi:10.1371/journal.pone.0090977.g002
Effect of mIFN-α on the HBcAg expression in liver of the mice injected with HBV clones and pmIFN-α

Immunohistochemical staining was performed to determine the expression of HBcAg in the liver sections of the mice at 1, 10, 20, 30 and 50 dpi. As shown in Fig. 3, the control mice injected with either pAAV-HBV-A or pAAV-HBV-B presented comparable HBcAg expression levels in the liver. The number of HBcAg positive cells was only decreased in liver of the mice injected with pAAV-HBV-A and pmIFN-α after 10 dpi whereas HBcAg positive cells were undetectable in the liver of mice injected with pAAV-HBV-B and pmIFN-α during the whole observation period (Fig. 3A and B).

These data indicate that mIFN-α could completely inhibit the expression of HBcAg in liver tissue of the mice injected with pAAV-HBV-B but only partly inhibited the expression of HBcAg in liver of the mice injected with pAAV-HBV-A. Overall, the data of the HBcAg expression in the liver of different mouse groups were well consistent with the data of HBsAg, HBeAg, and HBV DNA detection in mouse sera.

Detection of IL-6, IL-10 and TGF-β in liver tissue of the mice after application of pmIFN-α

To know the expression levels of proinflammatory and anti-inflammatory cytokine in mice liver were influenced by injection of pmIFN-α. mRNA levels of IL-6, IL-10 and TGF-β were detected by RT PCR. The copy numbers of IL-6, IL-10 and TGF-β mRNAs were normalized against those of beta-actin. As shown in Fig. 5, the application of pmIFN-α led to an up-regulation of the mRNA levels of all 3 ISGs but with significantly different kinetics. While ISG15 and OAS were already induced by the application of pmIFN-α at 1 dpi and had the peak expression levels at 4 dpi in the liver of mice. The PKR mRNA level was low at 1 dpi and up-regulated only weakly at 4 dpi and 10 dpi. When co-applied with HBV clones, pmIFN-α induced ISGs expression in the liver of mice (Fig. 4). Though mIFN-α was produced in mice at comparable levels with and without HBV clones (Fig. 1), the kinetics of ISGs induction was changed in the presence of HBV clones. First, the induction of ISG15 (Fig. 4A), OAS (Fig. 4B) and PKR (Fig. 4C) by pmIFN-α were generally reduced in mice with HBV clones compared with that in mice with pmIFN-α alone. The ISGs expression in mice injected with pAAV-HBV-A and pmIFN-α remained lower at 4 dpi and 10 dpi compared with the control mice injected with pmIFN-α alone, consistent with the fact that HBV continued to replicate at this time point. In contrast, ISGs expression in the liver of the mice receiving pAAV-HBV-B was strongly up-regulated at 4 dpi, associated with the early HBV clearance at 7 dpi. Taken together, HBV might inhibit the induction of ISGs by mIFN-α.

HBV-specific CD8+ T cells responses in spleen of the mice after HI

IFN-α may enhance HBV-specific adaptive responses. To investigate the function of specific T-cells, HBV-specific T cell responses were detected at 10 dpi by ELISPOT assay detecting mIFN-γ producing cells. In both control and pmIFN-α treated mice, the mIFN-γ producing cells stimulated with recombinant HBcAg and HBsAg were detectable at 10 dpi (Fig. 6). There was no significant difference in the numbers of mIFN-γ producing cells in mice receiving HBV clones alone and with pmIFN-α together. Apparently, HBV-specific T cell responses were not promoted by mIFN-α within 10 dpi and therefore not primarily responsible for the rapid clearance of HBV from mice, as in mice injected with pAAV-HBV-B (Fig. 6B).

Induction of ISGs ISG15, OAS and PKR in liver tissue of the mice after application of pmIFN-α

To analyze the induction of ISGs expression by application of pmIFN-α and its association with the inhibition of HBV replication in mice, the total RNAs were extracted from the liver tissue of mice at the indicated time points after HI and subjected to real-time RT-PCR for the quantification of the three ISGs ISG15, OAS and PKR. The copy numbers of ISG mRNAs were normalized in contrast to those of beta-actin. As shown in Fig. 4, the application of pmIFN-α led to a significant up-regulation of the mRNA levels of all 3 ISGs but with significantly different kinetics. While ISG15 and OAS were already induced by the application of pmIFN-α at 1 dpi and had the peak expression levels at 4 dpi in the liver of mice. The PKR mRNA level was low at 1 dpi and up-regulated only weakly at 4 dpi and 10 dpi. When co-applied with HBV clones, pmIFN-α induced ISGs expression in the liver of mice (Fig. 4). Though mIFN-α was produced in mice at comparable levels with and without HBV clones (Fig. 1), the kinetics of ISGs induction was changed in the presence of HBV clones. First, the induction of ISG15 (Fig. 4A), OAS (Fig. 4B) and PKR (Fig. 4C) by pmIFN-α were generally reduced in mice with HBV clones compared with that in mice with pmIFN-α alone. The ISGs expression in mice injected with pAAV-HBV-A and pmIFN-α remained lower at 4 dpi and 10 dpi compared with the control mice injected with pmIFN-α alone, consistent with the fact that HBV continued to replicate at this time point. In contrast, ISGs expression in the liver of the mice receiving pAAV-HBV-B was strongly up-regulated at 4 dpi, associated with the early HBV clearance at 7 dpi. Taken together, HBV might inhibit the induction of ISGs by mIFN-α.

Detection of IL-6, IL-10 and TGF-β in liver tissue of the mice after application of pmIFN-α

To know the expression levels of proinflammatory and anti-inflammatory cytokine in mice liver were influenced by injection of pmIFN-α. mRNA levels of IL-6, IL-10 and TGF-β were detected by RT PCR. The copy numbers of IL-6, IL-10 and TGF-β mRNAs were normalized against those of beta-actin. As shown in Fig. 5, the application of pmIFN-α led to an up-regulation of the mRNA levels of all 3 ISGs but with significantly different kinetics. While ISG15 and OAS were already induced by the application of pmIFN-α at 1 dpi and had the peak expression levels at 4 dpi in the liver of mice. The PKR mRNA level was low at 1 dpi and up-regulated only weakly at 4 dpi and 10 dpi. When co-applied with HBV clones, pmIFN-α induced ISGs expression in the liver of mice (Fig. 4). Though mIFN-α was produced in mice at comparable levels with and without HBV clones (Fig. 1), the kinetics of ISGs induction was changed in the presence of HBV clones. First, the induction of ISG15 (Fig. 4A), OAS (Fig. 4B) and PKR (Fig. 4C) by pmIFN-α were generally reduced in mice with HBV clones compared with that in mice with pmIFN-α alone. The ISGs expression in mice injected with pAAV-HBV-A and pmIFN-α remained lower at 4 dpi and 10 dpi compared with the control mice injected with pmIFN-α alone, consistent with the fact that HBV continued to replicate at this time point. In contrast, ISGs expression in the liver of the mice receiving pAAV-HBV-B was strongly up-regulated at 4 dpi, associated with the early HBV clearance at 7 dpi. Taken together, HBV might inhibit the induction of ISGs by mIFN-α.
Discussion

In the present study, we showed that HI with mIFN-α expression plasmid could induce IFN-α production in mice, trigger the ISGs expression in the mouse liver, and effectively suppressed HBV replication in HBV HI mouse model. Our major finding in the present study is that genetically distinct HBV isolates may have significantly different susceptibility to mIFN-α in vivo. The methodology established in this study will be useful to dissect the viral determinants for IFN-α susceptibility.

The production of mIFN-α in mice was detected over a period of more than 10 dpi. This finding is useful to achieve prolonged IFN-α expression in vivo for mechanistic studies. Previously, polyinosinic-polycytidylic acid (polyIC) was used to induce IFN-α/β expression to influence HBV replication [33,44]. In our experience, polyIC induced only a short term expression of IFN-α/β and was not active after 4 dpi (Wu et al., unpublished results). Thus, HI application of pmlIFN-α plasmid triggers a kinetically different mIFN-α expression than polyIC and led to long lasting upregulation of ISGs at least up to 30 days in some mice (Fig. 4). The peak levels of ISGs expression were detected at 4 dpi, though the highest level of mIFN-α production was measured at 1 dpi. Thus, the continuous mIFN-α stimulation over days may be important to achieve a high level expression of ISGs and HBV clearance. In addition, to know whether application of pmlIFN-α influenced the inflammatory reaction in liver of the mice, mRNA levels of IL-6, IL-10 and TGF-β were detected. We found that proinflammatory cytokine IL-6 was up-regulated and anti-inflammatory cytokine IL-10 was down-regulated significantly at 10 dpi in liver tissue of the mice co-injected with HBV and pmlIFN-α compared with the mice injected only with HBV clones.

HI of pmlIFN-α was effective to clear HBV from mice. The suppressive effect of mIFN-α on HBV was already pronounced at 1 dpi. Though HBsAg expression was not significantly inhibited at 1 dpi, serum HBeAg and HBV DNA levels were strongly reduced. Dependent on HBV isolates, HBV markers were completely cleared on 7 or 25 dpi. Consistent with previous publications about HBV transgenic mice, HBV is highly sensitive to the
antiviral activity of mIFN-α. However, HBV replication rebounded in HBV transgenic mice as the antiviral activity of mIFNs ceased [30,32]. Here, we could show that HBV could be completely eliminated if the HBV genome is not integrated in the host genome. Strikingly, HBcAg detection by immunostaining was strongly reduced at the very beginning in mice with pAAV-HBV-B which appeared to be very sensitive to mIFN-α. This finding is consistent with the assumption that IFN-α may prevent the formation of HBV nucleocapsid. We also detected HBV-specific CD8+ T cells responses in the spleen of the mice after HI. HBV-specific T cell responses were not promoted by the application of mIFN-α plasmids within 10 dpi and therefore not primarily responsible for the rapid clearance of HBV in these mice. Moreover, we also detected mRNA levels of mIFN-γ in the liver of mice at different time points and found there were no significant difference between the HBV injected group and mIFN-α treated group (data not shown). In addition, we performed HI with pAAV-HBV and injected the mIFN-α plasmids 14 days later.

The results obtained in this experiment showed that HBsAg, HBeAg and HBV DNA levels in mice declined after the injection of the mIFN-α plasmids with kinetics similar to the co-injection experiment (data not shown).

In the natural infection, the IFN-α response in patients was found to be low. The genomic analysis of the gene expression profile in HBV-infected chimpanzees showed nearly no IFN-α response during the acute phase and through the whole infection [45]. The absence of IFN-α may be a result of low induction of IFN-α/b system by HBV but partly of HBV-mediated inhibition of IFN-α/β signaling. Recently, Chen et al. demonstrated that HBV polymerase is able to block IFN-α signaling by inhibition of STAT1 phosphorylation by PKC-δ and importin-mediated nuclear translocation of STAT1/STAT2 complex [46]. These mechanisms were also active in the mouse model, explaining our observation that ISGs expression was reduced in the presence of HBV replication (Fig. 4). Nevertheless, IFN-α is able to finally clear HBV. For acute HCV infection, early IFN-α therapy is

Figure 5. Expression levels of IL-6, IL-10 and TGF-β in the mouse liver after HI. Mice received HI with 10 μg of HBV clones or pmlIFN-α alone or combination of HBV clones and pmlIFN-α. The mice injected with 0.9% NaCl or pAAV vector, were used as control. Total RNA was extracted form liver tissue of the mice at the indicated time points after HI and the levels of IL-6 (A), IL-10 (B) and TGF-β (C) mRNA were determined by quantitative real-time RT PCR. The β-actin mRNAs were quantified for normalization. Each sample was run in duplicate and at least three mouse liver specimens per group were analyzed (n≥3). Differences between the groups were analyzed by using the t test: * means p<0.05 and # means p<0.01. doi:10.1371/journal.pone.0090977.g005
recommended. It is not clinically evaluated whether acute HBV infection could be treated with IFN-α.

An interesting finding in our study is the different susceptibility of HBV isolates to IFN-α. The clinical data suggested a significant role of HBV genetics for the success rate of IFN-α therapy. Using our established system, it will be possible to analyze the HBV genetic determinants for IFN-α susceptibility/resistance by HI pmIFN-α directly into mouse liver. Until now, the role of HBV variants in IFN-α therapy is not well understood.

In HBeAg positive patients treated with conventional IFN-α, a higher rate of HBsAg loss [12] and HBeAg clearance was observed for genotype A compared with non-A genotypes, not only as a result of IFN-α based therapy but also spontaneously [47]. However, we got an opposite result that HBV genotype B isolate was more sensitive to IFN-α treatment than HBV genotype A isolate. We speculated that this is probably associated with the presence of genotype-dependent mutations located within the basic core promoter (BCP) region of the HBV genome [48–49].

Viral genetic factors have been poorly investigated for their effect on the outcome of IFN-α therapy. G1896A mutation, converting a tryptophane (TGG) into a translational stop codon (TAG), has been reported to be associated with a bad prognosis and a poor response to IFN-α therapy. Mutations in the polymerase gene play an important role for resistance to nucleoside analogues, but do not seem to have an effect on the outcome of IFN-α therapy. As yet the relevance of mutations of the HBV core promoter region for responsiveness to IFN-α has not been evaluated.

BCP contains cis-acting elements that independently direct the transcription of pre-C RNA and pgRNA [50]. Double mutant A1762T/G1764A within BCP domain has decreased HBeAg expression and increased HBV replication in vitro [51–52]. The same result was observed in our study. Because HBeAg can inhibit HBV replication [53–54], the reduced expression of HBeAg could be a reason for increased viral replication. The increase of the viral replication is likely the reason why this double mutation often becomes the major quasispecies during chronic infection. Moreover, A1762T/G1764A is non-synonymous mutant and could affect the structure of the X protein, which functions as a transcriptional trans-activator of viral and cellular genes and is required for the establishment of hepadnaviral infection in animals [55–56]. It has been speculated that the immune reaction against infected hepatocytes may be increased as a result of a reduced HBeAg expression and that an enhanced viral replication may even show a cytopathic effect to infected liver. Nevertheless, the precise role of the A1762T/G1764A and the potential impact on viral replication and immune response must be elucidated in future.

**Supporting Information**

**Fig. S1** The construction procedure for pAAV-HBV-B is shown. pAAV-HBV-B was verified by restriction enzyme digestion with BamHI or HindIII, respectively. When pAAV-HBV-B was digested by BamHI, two bands at the sizes of 3215 bp (full-length HBV fragment) and a fragment corresponding to the cloning vector were visible (A). The plasmid pAAV-HBV-B was digested by HindIII that cuts the only at a single site (B).

**Acknowledgments**

We are grateful to Dr. Pei-Jer Chen for providing the vector pAAV-HBV1.2.

**Author Contributions**

Conceived and designed the experiments: JS DY ML . Performed the experiments: JS SL YZ . Analyzed the data: JS DY ML UD . Contributed reagents/materials/analysis tools: BW XZ JW KG . Wrote the paper: JS DY ML UD.
