(Dated: July 18, 2017)

We present an implementation of time-dependent density functional perturbation theory for spin fluctuations, based on planewaves and pseudopotentials. We compute the dynamic spin susceptibility self-consistently by solving the time-dependent Sternheimer equation, within the adiabatic local density approximation to the exchange and correlation kernel. We demonstrate our implementation by calculating the spin susceptibility of representative elemental transition metals, namely bcc Fe, fcc Ni and bcc Cr. The calculated magnon dispersion relations of Fe and Ni are in agreement with previous work. The calculated spin susceptibility of Cr exhibits a soft-paramagnon instability, indicating the tendency of the Cr spins to condense in a incommensurate spin density wave phase, in agreement with experiment.

I. INTRODUCTION

Spin fluctuations play a central role in magnetic systems.¹ For example they underpin fundamental thermodynamic properties of magnets, such as the Curie temperature and the heat capacity; they have long been discussed as a potential source of pairing in high-temperature superconductivity²–³; and they offer new opportunities in the development of spintronics⁴–⁶ and multiferroics.⁷

In ordered magnets, spin fluctuations manifest themselves in two forms, magnons and Stoner excitations.¹,⁸ In standard textbooks, magnons or ‘spin waves’ are typically illustrated as a collective, wave-like rotation of spins around their direction in the ground-state;⁹ Stoner or ‘spin flip’ excitations correspond instead to electronic transitions from occupied to empty states, whereby the electron spin is reversed; this process can alternatively be described as the creation of an electron-hole singlet pair of spins. When spin waves and spin flip excitations are degenerate, the spin wave is attenuated and sharp magnon excitations cease to exist. This phenomenon is referred to as Landau damping,¹⁰ and a clear discussion for the simplified case of the uniform electron gas can be found in Refs. 1 and 11. Landau damping is usually important in metallic systems,¹² while it is generally weak in insulators, owing to the large energy needed to excite Stoner pairs across the band gap.

The majority of studies on spin waves are currently based on the adiabatic approximation, whereby spin and electronic excitations are decoupled.¹³,¹⁴ In this approach one maps the magnetic degrees of freedom into an array of local spins, and determines the coupling parameters from total energy calculations based on density functional theory (DFT), or from experiments. This approach proved to work well for insulating magnets, but carries some limitations. For example the adiabatic approximation does not admit Stoner excitations, therefore Landau damping is not captured, and the magnon energy renormalization resulting from Stoner excitations is absent.¹¹,¹²,¹⁵ In addition this approach is sensitive to the choice of the discrete spin model and the determination of its parameters. It is clear that a more general approach is desirable in this context, thus motivating the need for a fully **ab initio** approach to spin waves.

The central quantity to describe spin fluctuations is the wave vector- (\(q\)) and energy- (\(\omega\)) dependent spin susceptibility, \(\chi(q, \omega)\) (in the following Hartree atomic units will be assumed). Magnon excitations correspond to the poles of \(\chi(q, \omega)\).¹ A promising approach for calculating \(\chi(q, \omega)\) from first principles is given by time-dependent density functional perturbation theory (TD-DFPT).¹⁶ The main appeal of this method is that it allows one to describe spin waves and Stoner excitations on the same footing, without invoking materials-specific approximations. TD-DFPT for spin fluctuations has already been demonstrated using either all-electron¹⁵,¹⁷ or pseudopotential¹⁸ implementations. Using the adiabatic local density approximation (ALDA) to the exchange and correlation kernel,¹⁶,¹⁹–²¹ it was shown that the formalism can capture the experimental magnon spectra of typical transition metals (Fe, Co, Ni, Cr) with reasonable accuracy,¹⁵,¹⁷,¹⁸ provided the underlying DFT calculations could reproduce measured Stoner splittings.

Given these encouraging results on the use of TD-DFPT for calculating spin fluctuations, it would be desirable to have these techniques available in the context of popular DFT implementations based on planewaves and pseudopotentials. The first implementation of this type was reported not long ago.¹⁸ In this implementation the authors calculated the spin susceptibility using the sum-over-states approach, and dealt with Brillouin zone sampling using maximally-localized Wannier functions.²²

In this work we present a planewaves/pseudopotential implementation of TD-DFPT for spin fluctuations which does not rely on unoccupied electronic states. Our implementation employs the time-dependent Sternheimer
equation, in the spirit of related work in the area of GW calculations.\textsuperscript{23–29} The implementation is based on the linear-response modules of the Quantum ESPRESSO materials simulation suite,\textsuperscript{30} and is currently hosted on our GitHub repository.\textsuperscript{31} We demonstrate this development by calculating the spin fluctuations spectra of bcc iron, fcc nickel and bcc chromium. Our results are in good agreement with previous calculations. The calculated spectra of Fe and Cr are in agreement with experiments, while our results for Ni deviate from experiments owing to the incorrect Stoner splitting in the underlying DFT calculation.

The manuscript is organized as follows. In Sec. II we present the TD-DFT formalism for the spin susceptibility and the time-dependent Sternheimer equation. We also discuss how to treat fractional occupations in metals, and how to perform the symmetry-reduction of the Brillouin zone. At the end of this section we provide some technical details of the implementation. In Sec. III we present calculation results on the elemental transition metals Fe, Ni, and Cr. Here we compare our results to previous calculations as well as experiments. We offer our conclusions in Sec. IV, together with an outlook on future work.

II. SPIN SUSCEPTIBILITY IN TIME-DEPENDENT DENSITY FUNCTIONAL PERTURBATION THEORY

A. General theory

In this section we summarize the generalization of the TD-DFT formalism\textsuperscript{16} to non-collinear spins, as already discussed in Refs. 15, 17, 18, 32, and 33. In the following we do not consider spin-orbit coupling, and we use the spin $g$-factor $g = 2$. The DFT Kohn-Sham equations for a non-collinear spin system read:

\[
\left[ -\nabla^2 + \hat{V}_{\text{scf}}(\mathbf{r}) \right] \begin{pmatrix} \psi_{\mathbf{k}n}^{\uparrow}(\mathbf{r}) \\ \psi_{\mathbf{k}n}^{\downarrow}(\mathbf{r}) \end{pmatrix} = \epsilon_{\mathbf{k}n} \begin{pmatrix} \psi_{\mathbf{k}n}^{\uparrow}(\mathbf{r}) \\ \psi_{\mathbf{k}n}^{\downarrow}(\mathbf{r}) \end{pmatrix},
\]

where $\hat{I}$ is the $2 \times 2$ identify matrix, and $\hat{V}_{\text{scf}}$ is the Kohn-Sham potential, expressed as the following $2 \times 2$ matrix:

\[
\hat{V}_{\text{scf}}(\mathbf{r}) = \hat{V}_{\text{scf}}(\mathbf{r}) \hat{I} + \hat{\mathbf{B}}_{\text{scf}}(\mathbf{r}).
\]

In this expression $\hat{V}_{\text{scf}}$ is the scalar part of the self-consistent potential, and $\hat{\mathbf{B}}_{\text{scf}}$ is the effective magnetic field arising from external potential as well as exchange and correlation.\textsuperscript{34} The Pauli matrix is given by $\hat{\mathbf{\sigma}} = \sigma^1 \hat{\mathbf{u}}_x + \sigma^2 \hat{\mathbf{u}}_y + \sigma^3 \hat{\mathbf{u}}_z$, with $\sigma^i$ the usual $2 \times 2$ Pauli matrices, and the unit vectors such as $\hat{\mathbf{u}}_x$ denoting Cartesian directions. $\psi_{\mathbf{k}n}$ is a Kohn-Sham two-spinor eigenfunction with wavevector $\mathbf{k}$, band index $n$, and energy $\epsilon_{\mathbf{k}n}$, and corresponds to two scalar functions dependent on the space coordinate $\mathbf{r}$, as follows:

\[
\begin{pmatrix} \psi_{\mathbf{k}n}^{\uparrow}(\mathbf{r}) \\ \psi_{\mathbf{k}n}^{\downarrow}(\mathbf{r}) \end{pmatrix}.
\]

Using this notation, the $2 \times 2$ density matrix becomes:

\[
\rho_{\alpha\beta}(\mathbf{r}) = \frac{1}{N_{\mathbf{k}}} \sum_{\mathbf{k},n \in \text{occ}} \psi_{\mathbf{k}n}^{\alpha*}(\mathbf{r}) \psi_{\mathbf{k}n}^{\beta}(\mathbf{r}), \quad \alpha, \beta = 1, 2,
\]

where $N_{\mathbf{k}}$ is the number of $\mathbf{k}$ points used to discretize the first Brillouin zone (we assume a uniform sampling), and the asterisk denotes complex conjugation. Using the Pauli matrix $\mathbf{\sigma}$, the density matrix can be decomposed as in Eq. (2):

\[
\hat{\rho}(\mathbf{r}) = \frac{1}{2} \left[ n(\mathbf{r}) \hat{I} + \mathbf{\sigma} \cdot \mathbf{m}(\mathbf{r}) \right],
\]

where $n(\mathbf{r})$ is the standard electron charge density, and $\mathbf{m}(\mathbf{r})$ is the electron spin density.

In order to facilitate the algebra it is convenient to introduce an alternative expression for the density matrix, using vector notation:

\[
\delta \rho(\mathbf{r}) = \frac{1}{N_{\mathbf{k}}} \sum_{\mathbf{k},n \in \text{occ}} \overrightarrow{\psi}_{\mathbf{k}n}(\mathbf{r}) \sigma^i \overrightarrow{\psi}_{\mathbf{k}n}(\mathbf{r}), \quad i = 0, \ldots, 3,
\]

where the dagger indicates the Hermitian conjugate.

We now consider a time-dependent external perturbation, which can be either an electric potential or a magnetic field, $\delta V_{\text{ext}}(\mathbf{r}t)$, with:

\[
\delta V^0_{\text{ext}}(\mathbf{r}t) = V_{\text{ext}}(\mathbf{r}t), \quad \delta V^1_{\text{ext}}(\mathbf{r}t) = B_{\text{ext}}^{\mathbf{x}}(\mathbf{r}t),
\]

and similarly for $j = 2, 3$. We neglect diamagnetic effects, so that the magnetic field $\mathbf{B}_{\text{ext}}$ only couples to the spin degrees of freedom. In linear-response theory the variation of the density matrix in response to the external perturbation is written as:

\[
\delta \rho^i(\mathbf{r}t) = \sum_j \int d(\mathbf{r}'t') \chi^{ij}(\mathbf{r}t, \mathbf{r}'t') \delta V_j^{\text{ext}}(\mathbf{r}'t'),
\]

where the sum runs over the components of the four-vector, and $\chi^{ij}(\mathbf{r}t, \mathbf{r}'t')$ is the generalized susceptibility. In TD-DFT the generalized susceptibility is formally obtained via a Dyson’s equation:\textsuperscript{16}

\[
\chi^{ij}(\mathbf{r}t, \mathbf{r}'t') = \chi^{ij}_{\text{KS}}(\mathbf{r}t, \mathbf{r}'t') + \sum_{kl} \int d(\mathbf{r}_1t_1)d(\mathbf{r}_2t_2) \chi^{ik}_{\text{KS}}(\mathbf{r}t, \mathbf{r}_1t_1) f^{kl}_{\text{xc}}(\mathbf{r}_1t_1, \mathbf{r}_2t_2) \frac{2 \delta \rho^0 \delta \rho^l}{|\mathbf{r}_1 - \mathbf{r}_2|} \chi^{jl}(\mathbf{r}_2t_2, \mathbf{r}'t'),
\]

where $f^{kl}_{\text{xc}}$ is the exchange and correlation kernel, and $\chi^{ij}_{\text{KS}}$ is the non-interacting Kohn-Sham susceptibility.

The exchange-correlation kernel is usually written within the adiabatic local spin-density approximation
(ALSDA) to time-dependent DFT, meaning that one uses the static LSDA kernel at equal times,\textsuperscript{15,16,20,21}

\[
f_{xc}^{ij}(r, r') = \frac{\delta^2 F_{xc}}{\delta \rho_i(r) \delta \rho_j(r')} \delta(r - r') \delta(t - t').
\]  

(11)

We note that this choice carries the additional implicit approximation that the ALSDA kernel is derived by considering an electron gas with collinear spins.

The Kohn-Sham susceptibility appearing in Eq. (10) is defined so as to yield the density-matrix response to a variation of the self-consistent potential, in analogy with Eq. (9):

\[
\delta \rho_i^t(r) = \sum_j \int d(r' t') \chi_{KS}^{ij}(r, r', t') \delta V_{scf}^{ij}(r', t').
\]  

(12)

In view of practical calculations it is more convenient to work in the frequency domain rather than in the time domain. Since the unperturbed Hamiltonian is time-independent, the susceptibility depends only on the time difference \(t - t'\). As a result, the last equation can be rewritten in the frequency domain as follows:

\[
\delta \rho_i^f(r, \omega) = \sum_j \int d(r' \omega) \chi_{KS}^{ij}(r, r', \omega) \delta V_{scf}^{ij}(r', \omega),
\]  

(13)

having defined:

\[
\delta \rho_i^f(r, \omega) = \int dt \delta \rho_i^t(r) e^{-i \omega t},
\]  

(14)

and similarly for \(\delta V_{scf}^f(r, \omega)\) and \(\chi_{KS}^{ij}(r, r', \omega)\). Equations (9)-(11) are transformed into the frequency domain along the same lines. Using standard perturbation theory, the Kohn-Sham susceptibility in the frequency domain can now be written explicitly in terms of unperturbed Kohn-Sham spinors:\textsuperscript{16}

\[
\chi_{KS}^{ij}(r, r', \omega) = \frac{1}{N^2} \sum_{n, n', k, q} \frac{f_{nk} - f_{nk+q}}{\epsilon_{nk} - \epsilon_{nk+q} + \omega} \times \delta \psi_{nk}(r) \sigma^i \delta \psi_{mk+q}(r') \sigma^j \delta \psi_{nk}(r'),
\]  

(15)

where \(f_{nk}\) and \(f_{nk+q}\) are occupation numbers.

This formulation provides a two-step procedure for calculating the generalized susceptibility. First, the Kohn-Sham susceptibility is calculated via Eq. (15), starting from the unperturbed Kohn-Sham spinor wavefunctions. The computed \(\chi_{KS}^{ij}\) is then used inside Eq. (10) (after transforming to the frequency domain), so as to evaluate \(\chi_{KS}^{ij}\) and obtain spin fluctuation spectra.

The main disadvantage of this procedure is that the evaluation of \(\chi_{KS}\) via Eq. (15) relies on the calculation of unoccupied Kohn-Sham states, and the convergence of the results with respect to the number of empty bands is slow. In order to circumvent this bottleneck, here we employ an alternative approach which is based on the Sternheimer equation,\textsuperscript{35,36} and which requires one to compute only occupied Kohn-Sham states.

**B. Calculation of the spin susceptibility using the Sternheimer equation**

The Sternheimer equation in time-dependent perturbation theory reads:\textsuperscript{17}

\[
\left( \hat{H} - i \frac{\partial}{\partial t} \right) \delta \tilde{\psi}_{nk}(r, t) = -(1 - \hat{P}_{occ}) \delta \tilde{V}_{scf}(r, t) \tilde{\psi}_{nk}(r),
\]  

(16)

where \(\hat{H}\) is the unperturbed Kohn-Sham Hamiltonian, corresponding to the term in square brackets in Eq. (1), \(\delta \tilde{V}_{nk}\) is the first-order change of the spinor wavefunction, and \(\delta \tilde{V}_{scf}\) is the first-order variation of the Kohn-Sham potential from Eq. (2). The operator \(\hat{P}_{occ}\) is the projector on the manifold of unoccupied Kohn-Sham states.

Equation (16) is naturally found as an intermediate step of the perturbation theory approach; by expressing \(\delta \tilde{\psi}_{nk}\) in the frequency domain and expanding on a basis of (occupied and empty) Kohn-Sham states, this expression leads immediately to Eq. (15). In order to avoid the computation of unoccupied states, Eq. (16) must be solved directly as a non-homogeneous linear system.

The Sternheimer equation was originally introduced for calculating the static dielectric polarizability of atoms,\textsuperscript{35} and found widespread use in the DFT community to compute phonon dispersion relations using DFPT.\textsuperscript{36–38} The time-dependent version of the Sternheimer equation was used to calculate spin susceptibilities,\textsuperscript{17} dynamic molecular polarizabilities,\textsuperscript{39} and the screened Coulomb interaction in GW calculations.\textsuperscript{25–29,40}

We now consider an external perturbation given by a monochromatic planewave:

\[
\delta V_{ext}^{ij}(r, \omega) = \delta V_{ext}^{ij}(q, \omega) \left[ e^{i(q \cdot r + \omega t)} - \eta \delta V_{scf}^{ij}(r, \omega) + c.c. \right],
\]  

(17)

with \(\eta\) being a positive infinitesimal. This perturbation induces a variation of the density matrix that can be evaluated using Eq. (16). After some lengthy but otherwise straightforward algebra one finds:

\[
\delta \rho_{\eta}^{ij}(r, \omega) = \frac{1}{N_k} \sum_{n \in occ, k} \tilde{u}_{nk}^{\dagger}(r) \sigma^i \delta \tilde{u}_{nk+q}^{\dagger}(r) \sigma^j \tilde{u}_{nk}(r),
\]  

(18)

where \(\tilde{u}_{nk}\) is the Bloch-periodic part of the Kohn-Sham wavefunction, i.e., \(\tilde{u}_{nk}(r) = e^{i k \cdot r} \tilde{u}_{nk}(r)\), and similarly for \(\tilde{u}_{nk+q}\). The variation of the Kohn-Sham wavefunctions appearing in the last expression can be found from Eq. (16), following the usual decoupling procedure employed in DFPT for phonons:\textsuperscript{36}

\[
\left( \hat{H}_{k+q} - \epsilon_{nk} + \omega + i\eta \right) \tilde{u}_{nk+q}(r, +\omega) = -(1 - \hat{P}_{occ}^{k+q}) \delta \tilde{V}_{scf}^{ij}(r, +\omega) \tilde{u}_{nk}(r),
\]  

(19)

\[
\left( \hat{H}_{k-q} - \epsilon_{nk} - \omega + i\eta \right) \delta \tilde{u}_{nk-q}(r, -\omega) = -(1 - \hat{P}_{occ}^{k-q}) \delta \tilde{V}_{scf}^{ij}(r, -\omega) \tilde{u}_{nk}(r).\n\]  

(20)
The variation of the self-consistent potential is related to the variation of the charge density as follows:

\[
\delta V_{\text{scf}}^q(r, \omega) = \sigma^j \delta V_{\text{ext}}^j(q, \omega) + \sigma^0 \int \frac{\delta \rho^0_q(r', \omega)}{|r - r'|} e^{-i q (r'-r')} dr' + \sum_{ij} \sigma^i f_{xc}^{ij}[\rho(r), r] \delta \rho^j_q(r, \omega),
\]

(21)

where the integration in the second line is in the unit cell, and the exchange-correlation kernel in the third line is evaluated for the unperturbed density. From Eq. (20) we see that, in addition to \(\delta V_{\text{ext}}^q(r, \omega)\), we also need \(\delta V_{\text{scf}}^q(r, -\omega)\). In order to evaluate this term via Eq. (21) we simply change the signs of \(q\) and \(\omega\), and observe that \(\delta \rho_{\text{scf}}^q(r, -\omega) = \delta \rho_{\text{scf}}^q(r, \omega)\).

Equations (18)-(21) are to be solved self-consistently. The procedure starts from Eq. (21), by setting the initial variation of the Kohn-Sham potential equal to the external perturbation (i.e. by retaining only the first line). Then Eqs. (19) and (20) are solved, and the solutions are used in Eq. (18) to obtain \(\delta \rho_{\text{scf}}^q(r, \omega)\). We emphasize that the presence of an external magnetic field breaks time reversal symmetry, therefore Eqs. (19) and (20) have to be solved separately. This is in contrast to what happens in DFPT for phonons, whereby these two equations become equivalent after taking into account time-reversal symmetry.36

The self-consistent solution of Eqs. (18)-(21) yields the variation \(\delta \rho_{\text{scf}}^q(r, \omega)\) of the density matrix in response to the external perturbation of Eq. (17). By taking the unit-cell average of the density variation, \(\delta \rho^q(r, \omega) = \int \delta \rho^q_{\text{scf}}(r, \omega)\), we can finally calculate the susceptibility as:

\[
\chi^{ij}(q, \omega) = \frac{\delta \rho^j(r, \omega)}{\delta V_{\text{ext}}^i(q, \omega)}.
\]

(22)

This quantity can directly be compared with experiments. For example, in a ferromagnet with the spin density polarized along the z-direction, the transverse component of spin susceptibility, defined as \(\chi^{+-} = \chi^{11} - i \chi^{12}\), yields the inelastic neutron scattering cross section according to the equation:41

\[
\frac{\partial^2 \sum}{\partial q \partial \Omega} \propto \text{Im} \chi^{+-}(q, \omega),
\]

(23)

where \(q\) and \(\omega\) have the meaning of momentum and energy transfer, respectively, and \(\partial \Omega\) is the element of solid angle spanned by \(q\). Sharp peaks of \(\text{Im} \chi^{+-}\) in the \((q, \omega)\) plane correspond to magnon excitations.1

Magnon excitation are expected to be damped in the presence of resonant Stoner spin-flip excitations. The region in the \((q, \omega)\) plane where Stoner excitations are allowed corresponds to energy and momenta for which the non-interacting susceptibility, \(\text{Im} \chi^{+-}_{\text{KS}}(q, \omega)\), is nonzero.1

In fact, by performing a Fourier transform of Eq. (15), we find immediately:

\[
\text{Im} \chi^{+-}_{\text{KS}}(q, \omega) = \frac{\pi}{2} \sum_{nm, k} \left( f_{nk}^2 - f_{mk+q}^2 \right) \times \left| \langle u_{mk+q}^r | \sigma^- | u_{nk}^r \rangle \right|^2 \delta(\epsilon_{nk} - \epsilon_{mk+q} + \omega),
\]

(24)

where \(\sigma^- = \sigma^1 - i \sigma^2\). The r.h.s. of this expression corresponds to the standard transition rate as given by the Fermi golden rule, with respect to an operator which lowers the spin quantum number in a ferromagnet.

C. Fractional occupations

The formalism described in the previous section is applicable to insulators and semiconductors, where the occupied and unoccupied states are separated by a finite energy gap. In principle, the formalism also applies for metals at zero temperature. However, in the case of metals, a very dense sampling of the Brillouin zone would be required to correctly describe the Fermi surface. To avoid this complication in the case of metals, it is common to perform Brillouin zone integrals using the tetrahedron method,37,42,43 or to employ smearing techniques.36,44 In this work we opted for the use of electronic smearing, and in the following we discuss how the formalism introduced in Ref. 44 needs to be adapted to deal with frequency-dependent perturbations and spinor wavefunctions.

In the scheme of Ref. 44 each Kohn-Sham energy level is broadened by a smearing function defined by \(\delta_q(\epsilon) = \tilde{\delta}(\epsilon/\gamma)/\gamma\). Here \(\tilde{\delta}(x)\) is a normalized function such that \(\tilde{\delta}(x)\) tends to the Dirac \(\delta\) function when the smearing width \(\gamma\) tends to zero. The simplest smearing function is a Gaussian but there are many practical alternatives.30 From the definition of \(\delta_q\) one naturally obtains a smooth approximation to the step function, \(\theta(x) = \int_{-\infty}^x \tilde{\delta}(x')dx'\).

Following Ref. 44 we define \(\tilde{\theta}_{n,m} = \tilde{\theta}[(\epsilon_n - \epsilon_m)/\gamma]\), and \(\tilde{\theta}_{F,m} = \tilde{\theta}[(\epsilon_F - \epsilon_m)/\gamma]\), with \(\epsilon_F\) the Fermi energy. Using these definitions the smeared density matrix reads:

\[
\rho^i(r) = \frac{1}{N_k} \sum_{nk} \tilde{\theta}_{F,nk} \tilde{u}_{nk}^r \sigma^\dagger \tilde{u}_{nk}^r(r),
\]

(25)

where the sum is over all states \(n\). Since \(\tilde{\theta}\) is a smeared step function, it is sufficient to only calculate all occupied states and a handful of unoccupied states, up to the energy \(\sim \epsilon_F + 10\gamma\). The linear density response to an external monochromatic perturbation as in Eq. (17)
reads:

\[ \delta \rho_{q}^{i}(r, \omega) = \frac{1}{N_{k}} \sum_{nk} \left[ \theta F, n_{k} \right] \delta \overrightarrow{u}_{n_{k}+q}(r) \sigma^{i} \delta \overrightarrow{u}_{n_{k}+q}(r, \omega) + \frac{1}{N_{k}} \sum_{nk} \theta F, n_{k} \delta \overrightarrow{u}_{n_{k}-q}(r, -\omega) \sigma^{i} \overrightarrow{u}_{n_{k}}(r). \] (26)

In this expression we are neglecting the contribution to the density variation arising from a change in the Fermi level, which corresponds formally to the variation of the prefactor \( \theta F, n_{k} \). This contribution is only important for \( q = 0 \), and it vanishes for the perturbations considered in this work.

The linear variation of the spinor wavefunction can be formally written using perturbation theory:

\[ \delta \overrightarrow{u}_{n_{k}+q}(r, \omega) = \sum_{m} \overrightarrow{u}_{m_{k}+q} \langle \overrightarrow{u}_{m_{k}+q} | \delta \overrightarrow{V}_{scf}^{q}(r, \omega) \rangle \overrightarrow{u}_{n_{k}}, \] (27)

and similarly for \( \delta \overrightarrow{u}_{n_{k}-q}(r, -\omega) \). After replacing this expression in Eq. (26) one obtains:

\[ \delta \rho_{q}^{i}(r, \omega) = \frac{1}{N_{k}} \sum_{nm,k} \left( \theta F, n_{k} - \theta F, m_{k}+q \right) \delta \overrightarrow{V}_{scf}^{q}(r, \omega) \delta \overrightarrow{u}_{n_{k}}(r) \times \delta \overrightarrow{u}_{m_{k}+q}(r) \sigma^{i} \overrightarrow{u}_{m_{k}+q}(r) \overrightarrow{u}_{n_{k}}(r) \] (28)

To obtain a more compact expression, in the second line of Eq. (26) we replaced \( k \) by \( k + q \) and \( m \) by \( n \), and we used the identity \( \delta \overrightarrow{V}_{scf}^{q}(r, -\omega) = \delta \overrightarrow{V}_{scf}^{q}(r, \omega) \).

Equation (28) contains a summation over all states, occupied and empty. In order to recast this expression into a sum over occupied states only, we observe that the prefactor \( \theta F, n_{k} - \theta F, m_{k}+q \) vanishes when the states \( n_{k} \) and \( m_{k}+q \) are both occupied or both unoccupied. This observation can be used to bring Eq. (28) into a form similar to Eq. (26), but without the \( \theta \) prefactors. To this aim we note that \( \hat{\theta}(x) + \hat{\theta}(-x) = 1 \), therefore Eq. (28) can be rewritten as:

\[ \delta \rho_{q}^{i}(r, \omega) = \frac{1}{N_{k}} \sum_{nm,k} \left( \theta F, n_{k} - \theta F, m_{k}+q \right) \delta \overrightarrow{V}_{scf}^{q}(r, \omega) \delta \overrightarrow{u}_{n_{k}}(r) \times \delta \overrightarrow{u}_{m_{k}+q}(r) \sigma^{i} \overrightarrow{u}_{m_{k}+q}(r) \overrightarrow{u}_{n_{k}}(r) \] (29)

Also in this case the second line has been rewritten by exchanging \( k \) and \( k - q, n \) and \( m \), and using \( \delta \overrightarrow{V}_{scf}^{q}(r, -\omega) = \delta \overrightarrow{V}_{scf}^{q}(r, \omega) \). By inspecting the terms \( (\theta F, n_{k} - \theta F, m_{k}+q) \delta \overrightarrow{u}_{m_{k}+q,n_{k}} \) we can see that now the summation over \( n \) effectively runs over occupied states, and that over \( m \) runs over unoccupied states. At this point it is a matter of algebra to show that the density matrix variation can be written compactly as follows:

\[ \delta \rho_{q}^{i}(r, \omega) = \frac{1}{N_{k}} \sum_{nk} \overrightarrow{u}_{n_{k}}^{\dagger}(r) \sigma^{i} \delta \overrightarrow{u}_{n_{k}+q}(r, \omega) + \frac{1}{N_{k}} \sum_{nk} \delta \overrightarrow{u}_{n_{k}-q}(r, -\omega) \sigma^{i} \overrightarrow{u}_{n_{k}}(r), \] (30)

where \( \delta \overrightarrow{u}_{n_{k}+q}(r, \omega) \) is the solution of the modified Sternheimer equation:

\[ \left( \hat{H}_{k+q} + \alpha \hat{Q}_{k+q} + \epsilon_{n_{k}} - \omega + i\eta \right) \delta \overrightarrow{u}_{n_{k}+q}(r, +\omega) = \left( \hat{H}_{k+q} + \alpha \hat{Q}_{k+q} + \epsilon_{n_{k}} - \omega + i\eta \right) \delta \overrightarrow{u}_{n_{k}+q}(r, +\omega) \] (31)

In this equation \( \alpha \) is a real parameter to be discussed below, and the projector operators are defined as:

\[ \hat{Q}_{k+q} = \sum_{m} \overrightarrow{u}_{m_{k}+q} \langle \overrightarrow{u}_{m_{k}+q} \rangle, \] (32)

\[ \hat{P}_{n_{k}+q}^{+} = \sum_{m} \beta_{nm,k+q}^{+} \langle \overrightarrow{u}_{m_{k}+q} \rangle \overrightarrow{u}_{n_{k}+q}, \] (33)

with the summation running over the occupied states plus a few empty states, as discussed for Eq. (25). The parameters \( \beta_{nm,k+q}^{+} \) are given by:

\[ \beta_{nm,k+q}^{+} = \hat{H}_{k+q} \hat{P}_{n_{k}+q}^{+} + \alpha \hat{Q}_{k+q} \hat{P}_{n_{k}+q}^{+} \] (34)

An equation analogous to Eq. (31) is obtained for the function \( \delta \overrightarrow{u}_{n_{k}-q}(r, -\omega) \) needed in Eq. (30). In practice one only needs to change the signs of \( q \) and \( \omega \) in Eqs. (31)-(34). In order to derive Eqs. (30)-(34) starting from Eq. (29) it is sufficient to act on the first line of the r.h.s. with the operator \( \epsilon_{n_{k}} - (\hat{H}_{k+q} + \alpha \hat{Q}_{k+q}) + \omega - i\eta \). These equations constitute a straightforward generalization of the treatment of fractional occupations in standard DFPT for phonons.36,44

As in the case of phonon calculations, the parameter \( \alpha \) appearing in Eq. (31) is chosen so as to make the linear operator on the l.h.s. non-singular. When choosing \( \eta = 0 \), the system can become singular if \( \epsilon_{n_{k}+q} \) is in resonance with \( \epsilon_{n_{k}} + \omega \), where \( n \) belongs to the manifold of occupied states. To avoid a singularity it therefore suffices to choose \( \alpha = \epsilon_{F} - \epsilon_{min} + \omega_{max} + 10\gamma \), where \( \epsilon_{min} \) is the smallest eigenvalue of the occupied manifold, and \( \omega_{max} \) is the highest frequency considered in the calcula-
tions. If we set instead $\eta > 0$, the calculation is effectively performed for a complex frequency, and strictly speaking the linear system cannot become singular. However, the use of the projector $\alpha Q_{k+q}$ is still important in order to reduce the condition number of the linear system.

The summation over $k$-points in the Brillouin zone in Eq. (30) can effectively be performed by exploiting crystal symmetry operations. In standard DFPT symmetry is used to reduce the set of $k$-points to a symmetry-irreducible wedge of the Brillouin zone. In the present work we are dealing with DFPT in the presence of spinor wavefunctions, therefore we also need to take into account the effect of symmetry operations on the electron spins. To this aim we make use of spin-space groups (SSG). The action of an element $S$ of the SSG on a spinor wavefunction can be described as:

$$ S: \{R_s|R|f\} \mapsto \psi(r) = R_s\psi(R^{-1}r - f), \quad (35) $$

where $R$ is the spacial rotation, $f$ is the possible fractional translation, and $R_s$ is the matrix that rotates the spins.

Generally speaking one could also consider time-reversal symmetry in order to perform further reductions of the number of required $k$-points. Time-reversal can be combined with operations in the SSG. However, since in our present work we are focusing on perturbations corresponding to magnetic fields, time-reversal symmetry is broken. As a result we can only consider symmetry operations in the SSG which do not involve time-reversal. In practice we perform symmetry-reduction by considering all the symmetry operations $S$ which do not contain time-reversal and which belong to the small group of $q$, where $q$ is the wavevector of the perturbation (the small group is the sub-group of elements which leave $q$ unchanged, $Sq = q$).

In order to minimize fluctuations of the density matrix during the self-consistent iterations, we employed a generalization of the modified Broyden method for charge-density mixing, following Ref. 25. We found that typically 5 iterations are enough to reach convergence in the self-consistent calculation.

In this method we need to solve Eq. (30) both for the $(+q, +\omega)$ channel and the $(-q, -\omega)$ channel. The solutions for each channel are evaluated separately and independently. The parallelization of the algorithm is on the $k$-points within each channel.

In all the calculations reported below we employed a parameter $\alpha = 500$ meV in Eq. (30), which lies above the highest magnon energy calculated in the three examples.

### III. RESULTS

In order to test our implementation we performed calculations on three representative elemental transition metals, namely bcc iron, fcc nickel, and bcc chromium. Ground-state DFT calculations were performed using Quantum ESPRESSO, within the local density approximation for the exchange and correlation and using pseudopotentials from the repository ‘PSlibrary 0.3.1’.

When performing calculations of spin fluctuations, the ground state calculation and the solution of the Sternheimer equation must be carried out using the same sampling of the Brillouin zone. This is necessary in order to avoid spurious symmetry-breaking leading to the so-called gap error, that is the presence of long-wavelength magnons with finite excitation energy.

In all the following calculations we employed a $50 \times 50 \times 50$ grid of $k$-points for calculating both the ground state and the spin fluctuation spectra.

Below, when comparing with previous work, we only include the most recent theoretical studies. A more detailed comparison between earlier theoretical results can be found in Refs. 18 and 32.

### A. BCC Iron

We performed calculations using a norm conserving pseudopotential, using a planewaves kinetic energy cutoff of 60 Ry. To deal with fractional occupations we used a Gaussian smearing with a width of 10 mRy. We employed the experimental lattice parameter $a = 5.406$ bohr. Our calculations yield a ground-state magnetization of $2.16 \mu_B$ per atom, and the mean Stoner splitting is 2.5 eV. We evaluated the transverse spin susceptibility $\chi_{\perp}(-q, \omega)$ for wavevectors $q$ along the $\Gamma$-$N$ and the $\Gamma$-$H$ high-symmetry lines $[N = (1/2, 1/2, 0)2\pi/a, H = (0, 0, 1)2\pi/a]$. We sampled the frequency axis in the range 0 to 400 meV, with a spacing of 2 meV between consecutive grid points. The broadening parameter was set to $\eta = 0.1 \omega$; this choice was motivated by the observation that a larger broadening is required to obtain...
FIG. 1. (Color online) (a) Calculated $\text{Im} \chi^{\pm+}(q,\omega)$ of Fe along the ΓN and ΓH directions. The susceptibility is given in atomic units, $1/(\text{Ry bohr}^3)$. (b) Calculated $\text{Im} \chi_{KS}^{\pm+}(q,\omega)$ along the ΓN and ΓH directions. We also show the magnon dispersion curves superimposed as dots. (c) Magnon bands of Fe along the ΓN and ΓH directions. We compare our results to the experimental data of Loong et al.,\textsuperscript{53} and the calculations of Rousseau et al.,\textsuperscript{18} and Buczek et al.\textsuperscript{15} (d) Calculated $\text{Im} \chi^{\pm+}(q,\omega)$ of Fe, for selected wavevectors along the ΓN direction. All peaks are normalized to their maximum for clarity, and the wavevectors are given as $q = 2\pi/a(1,1,0)q$.

The calculations are shown in Fig. 1. In particular, Fig. 1(a) shows a two-dimensional plot of $\text{Im} \chi^{\pm+}$ in the $(q,\omega)$-plane. For clarity we also report some cuts for a few selected wavevectors in Fig. 1(d). The maxima of the map in Fig. 1(a) are reported in the form of magnon frequency-wavevector dispersion relations in Fig. 1(c). The map of Fig. 1(a) shows a significant attenuation of the magnon resonances beyond $|q| \sim 0.38 \Gamma N$, nevertheless we can clearly recognize the magnon excitations all the way up to the Brillouin zone edge. Along the ΓH line instead, magnon excitations are so strongly damped beyond $|q| \sim 0.35 \Gamma H$ that no clear curve can be identified in this region. The difference in the magnon damping patterns along the two directions is a direct consequence of the anisotropic nature of the Stoner continuum, as it is seen in Fig. 1(b). Here we see that along ΓH Stoner excitations become possible already around 100 meV, causing the complete suppression of magnons with energies above this threshold.

In Fig. 1(c) we also compare our results with previous experimental and theoretical work. Along the ΓN direction our magnon dispersion curve is in excellent agreement with the results of Ref. 18. This level of agreement was to be expected since also the implementation of Ref. 18 is based on the Quantum ESPRESSO package, although these authors used the method described in Sec. II A instead of the Sternheimer equation. As pointed out in Ref. 18, theoretical results tend to differ significantly beyond $|q| \sim 0.4 \Gamma N$. Notably, our calculations yield a plateau around $|q| \sim 0.5 \Gamma N$, while Ref. 15 reports a monotonic curve. We also observe that the discrepancies lie in the region where Stoner excitations kick in. It is likely that these differences between the various approaches arise from the difference in the underlying ground-state DFT calculations. Along the ΓH direction our results are in agreement with those of Ref. 15, which also find a strong suppression of spin waves in the same range of wavevectors. Our calculations are in reasonable agreement with the low-temperature experimental data of Ref. 53 (taken at 10 K). One aspect which complicates the comparison between theory and experiment is that the measurements were not taken exactly along the ΓN or ΓH lines. Having more information on the precise wavevector path probed in the experiments would be useful to perform a more detailed comparison.
FIG. 2. (Color online) (a) Calculated $\text{Im} \chi^{+-}(q, \omega)$ of Ni along the $\Gamma X$ direction. (b) Calculated $\text{Im} \chi^{+-}_{\text{KS}}(q, \omega)$, with the magnon band superimposed as dots. (c) Calculated magnon dispersion curve of Ni along the $\Gamma X$ direction. Our results are compared with experimental data of Mook et al.,54,55 and with the calculations of Rousseau et al.,18 Buczek et al.,15 and Şanlıoğlu et al.33 (d) Calculated $\text{Im} \chi^{+-}(q, \omega)$ of Ni for selected wavevectors along the $\Gamma X$ direction. The peaks are normalized to their maximum value, and the wavevector is given as $q = 2\pi/a(1,0,0)$.

B. FCC Nickel

In this case we performed calculations using an ultra-soft pseudopotential,47 using a planewaves kinetic energy cutoff of 42 Ry for the wavefunction and a cutoff of 236 Ry for the charge density. We employed Marzari-Vanderbilt smearing56 with a broadening parameter of 10 mRy. We used the experimental lattice parameter $a = 6.65$ bohr. We obtained a ground-state magnetization of 0.61 $\mu_B$ per atom and the mean Stoner splitting of 0.66 eV. We computed $\chi^{+-}(q, \omega)$ along the $\Gamma X$ direction $[X = (0, 0, 1)2\pi/a]$. We sampled frequencies up to 600 meV with a grid spacing of 2 meV and a broadening parameter $\eta = 0.1 \omega$.

The calculated susceptibility is shown as a two-dimensional $(q, \omega)$-map in Fig. 2(a). Also in this case we show representative cuts at selected wavevectors in Fig. 2(d). From the map we recognize a well-defined magnon band along the $\Gamma X$ line. The excitation spectrum is sharp up to $|q| \sim 0.3\Gamma X$, and becomes broadened upon entering the Stoner continuum beyond this point. This effect is clearly seen in Fig. 2(b), where we superimpose the spin wave dispersion curve to the Stoner spectrum. Our calculated magnon band, as extracted from the maxima of $\text{Im} \chi^{+-}(q, \omega)$, is compared to previous calculations and experiments in Fig. 2(c). Here we observe that theoretical data agree well for small wavevectors, but start deviating significantly from each other near the
FIG. 3. (Color online) (a) Calculated Im$\chi$(q, $\omega$) of Cr along the ΓH direction.  (b) Calculated Re$\chi_{KS}$(q, $\omega$) of Cr along the ΓH direction. To highlight the effect of Fermi-surface nesting, we plot Re$\chi_{KS}$(q, $\omega$) − 0.2 and only show the positive values.

zone boundary. which is also observed in Ref. 18. We tentatively assign these deviations to the different choices employed to describe the ground-state electronic structure.

When comparing with experiment we see that our calculations, as well as previous theoretical data, consistently overestimate the experiments by up to a factor of two. This phenomenon is well understood, and is related to the fact that the Stoner splitting of fcc Ni in standard DFT is approximately twice as large as in experiment (0.66 eV vs. 0.3 eV, respectively).\textsuperscript{33,57,58} It was shown that the experimental magnon spectra can be reasonably reproduced by manually reducing the LSDA exchange splitting by one-half.\textsuperscript{32,33}

C. BCC Chromium

For chromium we used a norm-conserving pseudopotential with a cutoff of 60 Ry, and a Gaussian smearing of 10 mRy. We set the lattice parameter to the experimental value $a = 5.5$ bohr. We evaluated the susceptibility along the ΓH line, and we sampled frequencies using a grid spacing of 20 meV, up to a maximum value of 2 eV. In this case we used a constant broadening parameter $\eta = 100$ meV.

Experiments indicate that the ground-state electronic structure of Cr is a spin-density wave (SDW), with an incommensurate wave vector $q_{SDW} \approx (0, 0, 0.95)2\pi/a$.\textsuperscript{59} This SDW was attributed to the presence of pronounced Fermi-surface nesting in paramagnetic Cr,\textsuperscript{60–62} a scenario which was later confirmed by explicit DFT calculations.\textsuperscript{63}

The calculated spin susceptibility of paramagnetic Cr is shown in Fig. 3(a). Here we see a clear peak for wavevectors around $(0, 0, 0.86)2\pi/a$, extending down to zero excitation energy. The presence of zero-energy excitations at finite wavevector is the signature of a SDW, i.e. a frozen spin-wave, analogous to charge-density waves observed in the presence of soft phonons. The role of Fermi-surface nesting can be investigated by inspecting the nesting function, that is Re$\chi_{KS}$(q, $\omega$), as shown in Fig. 3(b). For $\omega = 0$ the nesting function reaches a maximum at $q_{nest} \sim (0, 0, 0.92)2\pi/a$, which is close to our calculated SDW vector. This result confirms that nesting is at the origin of the SDW in chromium.

Our present results are in good agreement with previous calculations,\textsuperscript{17} although we obtain a slightly shorter SDW vector (0.86–2$\pi/a$ vs. 0.92–2$\pi/a$). We assign this difference to the fact that we used the LDA functional, while in Ref. 17 the PBE functional was employed.\textsuperscript{64}

IV. CONCLUSIONS

In conclusion, we described an implementation of time-dependent density-functional perturbation theory for spin fluctuations, based on plane waves and pseudopotentials, built around the linear response modules of the Quantum ESPRESSO package. In the present approach we calculate the macroscopic spin susceptibility $\chi(q, \omega)$ via a self-consistent solution of the time-dependent Sternheimer equation. The main advantage of this formulation is that it avoids altogether the need for evaluating unoccupied Kohn-Sham states.

We demonstrated the methodology by calculating spin wave spectra of bcc Fe, fcc Ni, and bcc Cr along several high-symmetry directions in the Brillouin zone, and we rationalized the suppression of magnon excitations in terms of Landau damping when the magnon energy resonates with the Stoner continuum. In the case of Fe and Ni, our calculated magnon dispersions relations are in good agreement with previous theoretical results near
the zone center, but we see some significant deviations closer to the zone boundaries. These deviations likely result from the underlying DFT description of the ground-state electronic structure. In the case of Fe, our calculations are in reasonable agreement with experiment, while in the case of Ni the calculated magnon energies are too large by a factor of two. This discrepancy is consistent with previous \textit{ab initio} calculations, and is attributed to the fact that standard DFT yields too large a Stoner splitting for this metal as compared to experiment. In the case of Cr, we demonstrated that the calculation of spin wave spectra on systems with strong magnetic anisotropy, for example multiferroic oxides. Apart from these desirable improvements, we believe that our current implementation provides an important new addition to state-of-the-art techniques for investigating spin fluctuations, magnon dispersions, and spin density waves in several important problems of condensed matter physics, and will serve as a starting point to explore incommensurate magnetic excitations systematically, without performing supercell calculations.

\textbf{Note}. We are aware of a closely related work, where the authors used TD-DFPT to calculate magnon dispersion relations.\textsuperscript{65} The present results are consistent with those of Ref. 65.
