Abstract

We develop two further numerical tests of parton cascade models: the ideal gas equation of state and the collision frequency tests. The equation of state test checks the initial momentum distribution generator and free expansion dynamics in periodic inhomogeneous geometries. The collision rate test is sensitive to spatial inhomogeneities and the collision algorithm. These tests are applied to the recently developed ZPC parton cascade model. The tests helped uncover unphysical correlations induced by one of the commonly used random number generators and showed the necessity of particle subdivisions for convergence to the exact analytic limit.

1 Introduction

Many observables in nuclear collisions are difficult to calculate analytically because the number of particles is neither large enough to justify rigorously the application of statistical mechanics nor small enough to justify impulse approximations. In most cases, numerical simulations of transport equations are required to compare theory with experiment. However, due to the complexity of the algorithms employed and the number of untested dynamical assumptions [1, 2, 3, 4], it is not straightforward to check or even reproduce the numerical results from parton cascade codes. Recently, several analytic tests were proposed to help check the accuracy and identify limitations of such codes. In the context of earlier non-relativistic transport models tests such as comparing with the analytic Krook-Wu model [5] have been useful. In the context of hydrodynamics, numerical hydrodynamic codes have been tested in cases of expansion of baryon free matter into vacuum [6] and “slab-on-slab” collision [7].

To address the new generation of parton cascade, a new Open Standard for Codes and Routines (OSCAR) [8] has been developed to enable objective testing of essential components of algorithms and ensure reproducibility of numerical results. In this context, we have proposed in ref. [9] a dynamical test of the evolution of the transverse energy in 1 + 1 dimensional expansion for cascade models. Another test of the frame and scattering scheme dependence of cascade models was proposed in [10, 11]. In this paper, we propose two further tests for the OSCAR standard: the equation of state and the collision rate test of one-component relativistic classical gases.

The tests provide information about the nature of the code’s initial momentum distribution and check its evolution algorithm in free expansion in periodic spatial inhomogeneities against nontrivial analytic expressions. The transverse to parallel momentum flux ratio tests the evolution of space-time and momentum space correlations. The asymptotic homogeneous equilibrated state tests the equation of state of the model against the expected ideal gas laws. The collision frequency test checks the basic collision algorithm.

We apply these tests to the newly developed ZPC parton cascade model [4]. In order to pass these tests, we uncovered and fixed a problem with one of the random number generators used in ZPC. We discuss that example in detail to illustrate the importance of applying such numerical tests. We
propose to add these tests to the group already in the OSCAR standard. The paper is organized as follows: In section 2, we recall basic statistical mechanics relations of ideal gas and calculate the free streaming evolution of periodic slab initial spatial distribution. In addition the collision rate is discussed. Numerical tests of ZPC are compared to analytical predictions in section 3. We conclude by emphasizing the importance of testing cascade codes.

2 Analytic Tests

2.1 Equation of State

The partition function for an ideal relativistic classical gas with mass $m$ and degeneracy $\gamma$ is given by (\hbar = c = k_B = 1)

$$Z(N, T, V) = \frac{1}{N!} \left( \frac{\gamma V}{2\pi^2} (Tm^2)K_2(m/T)e^{m/T} \right)^N,$$

In the $N \gg 1$ limit, the free energy, $F = -T \log Z$ is well approximated by

$$F(N, T, V) = -N \left( T \log \left( \frac{\gamma V}{2\pi^2} \frac{VTm^2}{N} K_2(m/T) \right) + m + T \right).$$

The pressure, $P = -\partial F/\partial V$ is given by the well known ideal gas law

$$P(N, T, V) = \rho T,$$

in terms of the density $\rho = N/V$, and the energy density is given by

$$\epsilon(N, T, V) = \rho m \left( K_1(\beta m)/K_2(\beta m) + 3T/m \right).$$

where $\beta = 1/T$. For fixed $N, V$ an interesting quantity that reflects the softness of the equation of state is

$$\frac{P}{\epsilon} = \frac{1}{3 + \beta m K_1(\beta m)/K_2(\beta m)}.$$

In the $m/T \ll 1$ relativistic limit, $P/\epsilon \approx 1/3$, while in the nonrelativistic limit, $P/\epsilon \approx T/m$. 
In a cascade simulation, these thermodynamic quantities can be measured as a function of time by computing the spatially averaged energy-momentum tensor

\[ < T^{\mu\nu} > = \frac{1}{V} \sum_i p_i^{\mu} p_i^{\nu} \frac{E_i}{E_i}. \] (6)

Then \( \epsilon = \langle T^{00} \rangle \) and \( P = \langle T^{11} \rangle \). In section 3, we will compare the analytic results of the pressure-energy density ratio as a function of \( m/T \), and the energy density as a function of \( T \).

### 2.2 Free Expansion In Slab Geometries

A simple test of equilibration in a periodic box of volume \( V = L^3 \) and fixed particle number is provided by taking the initial spatial distribution to be confined to one half of the box (say with \( x > 0 \)):

\[ f(x, p, 0) = \rho_0 (1 + \frac{4}{\pi} \text{Im} \tanh^{-1}[e^{2\pi i/\sqrt{3}}] f(p)). \] (7)

In the above, \( \rho_0 = N/V \) is the equilibrium particle density, \( L \) is the length of the box, and

\[ f(p) = \frac{\exp(-\beta \sqrt{m^2 + p^2})}{4\pi(m^2/\beta)K_2(\beta m)}. \] (8)

For the free streaming case, \( f(\vec{x}, \vec{p}, t) = f(\vec{x} - \vec{p}t/p_0^0, \vec{p}, 0) \).

For the interesting case of massless partons, the momentum flux component, \( T^{11} \) evolves from its initial value

\[ T^{11}(x, 0) = T^{11}(\infty)(1 + \frac{4}{\pi} \text{Im} \tanh^{-1}[e^{2\pi i/\sqrt{3}}]) \] (9)

to its final value \( T^{11}(\infty) = \rho_0 \int d^3 p \frac{p_x^2}{p_0^0} f(p) \) via

\[ \frac{T^{11}(x, t)}{T^{11}(\infty)} = 1 + \frac{a}{t^3} \sum_{l=0}^{\infty} \frac{\sin(k_n x)}{n^4} ((k_n t)^2 - 2) \sin(k_n t) + 2 k_n t \cos(k_n t)). \] (10)

Here \( a = 3L^3/(2\pi^4) \), \( n = 2l + 1 \), and \( k_n = 2\pi n/L \). The infinite sum can be expressed in terms of the Lerch \( \Phi(z, n, a) \) functions, but in practice the series converges very rapidly. For example the evolution at the “midway” points \( x = (2k + 1)L/4 \) involves damped oscillations with maxima and minima.
occuring at times $t = (2m + 1)L/4$. At $x = L/4$, the “11” momentum flux oscillates within the envelops

$$T^{11}(x = L/4, 0) = T^{11}(\infty) \left( 1 \pm \frac{c}{4} \left( \frac{3L}{t} - \frac{L^3}{t^3} \right) \right)$$

(11)

reaching the envelop at times $t = (2m + 1)L/4$. Note that free streaming in this geometry leads to global homogeneous equilibrium through mixing from neighboring slabs. The deviation of the parton cascade evolution from this result when collisions terms are turned on are of physical interest as tests of collective hydrodynamic behavior.

Another interesting probe of the evolution is the transverse-longitudinal momentum flux anisotropy,

$$A^{zx}(x, t) \equiv \frac{\langle T^{33}(x, t) \rangle}{\langle T^{11}(x, t) \rangle}$$

(12)

Initially in the $-L/2 < x < 0$ region we set $A^{zx} = 0$ while in the $0 < x < L/2$ region $A^{zx} = 1$. In the case of free streaming, this anisotropy is given by

$$A^{zx}(x, t) = \frac{1 + \frac{a}{t^3} \sum_{l=0}^{\infty} \frac{\sin(k_n x)}{n^4} \left( \sin(k_n t) - k_n t \cos(k_n t) \right)}{1 + \frac{a}{t^3} \sum_{l=0}^{\infty} \frac{\sin(k_n x)}{n^4} \left( (k_n t)^2 - 2 \sin(k_n t) + 2 k_n t \cos(k_n t) \right)}.$$

(13)

We note that of course other non-equilibrium initial conditions, e.g., homogeneous spatial distribution with anisotropic momentum distribution, can be set up to test dynamical relaxation toward global equilibrium. In this paper we will study only the evolution of spatial inhomogeneous conditions.

### 2.3 Collision rate for an isotropic, homogeneous gas

The collision rate per unit volume $W$ is another quantity that can be easily monitored. It is related to the number of collisions $N_c$ in a period of time $t$ via:

$$W = \frac{N_c}{Vt}.$$  

(14)

We take the integrated parton elastic cross section to be:

$$\sigma_{gg \rightarrow gg} = \frac{\pi}{\mu^2}.$$  

(15)
The total collision rate per unit volume can be calculated from:

\[ W = < \sigma \rho_1 \rho_2 | \vec{v}_1 - \vec{v}_2 | > = \frac{1}{2} \pi \gamma^2 \int \frac{d^3 p_1}{(2\pi)^3} \frac{d^3 p_2}{(2\pi)^3} e^{-\beta(E_1 + E_2)} | \vec{v}_1 - \vec{v}_2 |, \]  

(16)

and it is expected to be independent of the microscopic form of the differential cross section. The 1/2 on the right hand side of equation (16) takes into account the two identical incoming particles. The identity of two incoming gluons has been taken into account in the scattering cross section. In appendix A, we show that the above 6-dimensional integral can be reduced to a 1-dimensional integral:

\[ W = \frac{8T^6}{\pi^3 \mu^2} F(\frac{2m}{T}), \]  

(17)

in which \( F(x) = \int_x^\infty dy y^2(y^2 - x^2)K_1(y). \)

3 Numerical Tests of the ZPC model

For the cascade calculations, we take the temperature \( T = 0.5, 1, 1.5 \) GeV, and set the total number of particles in the periodic box to be \( N = 4000. \) The volume is related to the density of particle at zero-chemical potential,

\[ V = \frac{N}{\rho}. \]

via \( V = N/\rho. \) In ZPC, there are 1000 computation cells of volume \( V/1000. \) We specify the cell size to the cascade code.

To study the mass dependence, we choose 3 different masses: 0, 2.5, and 5 GeV. For the dependence on the scattering cross section, the interaction length \( \sqrt{\sigma/\pi} = 1/\mu \) is set to be 0.5\( \lambda, \) \( \lambda, \) and 1.5\( \lambda. \) In the above \( \lambda \) is a rough estimate for the mean free path,

\[ \lambda = \frac{1}{\rho \sigma}. \]  

(19)

We specify the screening mass \( \mu \) to the cascade code.
The parameters for the cascade measurement are shown in Table (1).

Fig. 1 shows the pressure-energy density ratio $P/\epsilon$ as a function of $m/T$, and Fig. 2 shows the energy density as a function of temperature $T$ for different particle masses. We see very good agreement between the predictions and the cascade results. This indicates that the initial momentum distributions are correctly generated. There is no time dependence of the pressure and energy density over a time period of 6 fm during which each particle has experienced $\sim 10$ collisions on average.

For periodic slab initial conditions, $T^{11}$ evolution at position $L/4$ in the free streaming case is compared with prediction in Fig. 3. Also shown in Fig. 3 is the result (filled circles) with interactions turned on. We see that interactions reduce the rate of collective expansion compared to free streaming and also the oscillations damp faster than in the free streaming case. For the non-interacting free streaming case, good agreement of prediction (dashed line) and cascade results (pluses) is shown for the $T^{11}$ evolution at $L/4$ in Fig. 3 and time evolution of free streaming $T^{11}$ spatial distribution in Fig. 4. Time evolution of free streaming $A^{xx}$ spatial distribution (Fig. 5) also agrees well with the prediction.

Fig. 6, 7 give scaled collision rate per unit volume as a function of $m/T$. The data points with the same $m/T$, and same $\mu$ overlap. The three data sets at the same $m/T$ correspond to three different screening masses $\mu$. The smaller the screening mass, the lower the collision rate.

The collision rate is the same for the ZPC default Yukawa type scattering differential cross section and the straight line propagation. This indicates the collision number loss is not due to particle shielding.

With small screening mass, the interaction range is large. When the interaction range is much larger than the mean free path, non-causal collisions become more abundant. To process the non-causal collision, we pick up one collision out of several collisions for one particle according to the ordering time (see ref. [11] for details). This process neglects other collisions in the same non-causal collision set. Some of them will not be recovered later. The larger the interaction range, the larger percentage of non-causal collisions. Hence, more collisions are neglected and the collision rate is lower than expected.

In the dilute limit, the percentage of non-causal collisions out of total number of collisions for massless particles is proportional to the number of particles inside the causal sphere in the two colliding particle center of mass.
The radius of the sphere is proportional to the impact parameter. So
\[ \frac{N_{\text{nonc}}}{N_{\text{total}}} \propto \frac{1}{\sigma} \int_0^{\sqrt{\pi}/2} 2\pi b db \frac{4\pi}{3} b^3 \bar{\gamma} \rho = \frac{8}{15} \bar{\gamma} \rho \frac{\sigma^{3/2}}{\sqrt{\pi}}. \]

2\(\pi b_0 db/\sigma\) is the probability of having impact parameter \(b\). Here, \(\bar{\gamma}\) is for the averaged boost factor from lab frame to the two colliding particle center of mass frame. In the case of massless particles, \(\bar{\gamma} \approx 2\). \(4\pi b^3 \bar{\gamma} \rho / 3\) gives the number of particles in the sphere with radius \(b\) in the two colliding particle center of mass frame. The exact radius of the sphere depends on the definition of non-causal collisions [1, 11] and the collision prescription of cascade.

The non-causal to total ratio is closely related to the ratio of interaction length to the mean free path:

\[ \chi = \frac{\sqrt{\sigma / \pi}}{\rho \sigma} = \rho \frac{\sigma^{3/2}}{\sqrt{\pi}}. \]

We see \(N_{\text{nonc}}/N_{\text{total}}\) decreases linearly with \(\chi\) as \(\chi \to 0\). This motivates the algorithm of reducing the non-causal collision percentage [1] by subdividing the particles by a factor \(l\) so that \(\rho \to l \rho\) while decreasing \(\sigma \to \sigma / l\). This preserves the mean free path \(1/\sigma \rho\) while \(\chi \propto 1/\sqrt{l} \to 0\).

The number of non-causal collisions, and total number of collisions for 4000 particles with \(m = 0\), \(T = 0.5\) GeV, and a time period of 6 fm is summarized in table (2). In the table, \(\mu\) is screening mass. \(a\) gives the ratio of interaction length to the estimate of mean free path before rescaling. \(l\) is the scaling parameter, i.e., the total number of particles is increased by a factor of \(l\) and the cross section is decreased by a factor of \(l\) (but the number of collisions is still for 4000 particles). \(\chi_1\) is the ratio of interaction length to the estimate of mean free path including the rescaling, i.e., \(\chi_1 = a / \sqrt{l}\). \(\chi_2\) is the ratio of interaction length to the measured mean free path. The mean free path is measured through the formula, \(\rho / (2W)\), in which \(W\) is the collision rate per unit volume and the particles are moving at the speed of light. The ratio of the number of non-causal collisions to the total number of collisions is also plotted in Fig. 8 against the ratio of interaction length to the mean free path. In Fig. 8, the open circles are data against \(\chi_1\) and the filled circles are against \(\chi_2\). It shows that when the density increases, i.e., when \(\chi\) increases, the difference between \(\chi_2\) and \(\chi_1\) increases. This tells us
that when density is high, the naive formula for the estimate of mean free path, \( \lambda = 1/(\rho \sigma) \), needs to be corrected. Also we see the data deviate from linear formula and has a tendency of saturation when density is large. This is consistent with the fact that the ratio should always be less than 50% from the definition of the non-causal collision.

When we fix \( \mu \) and increase \( l \) from 1 to 5, the total number of collisions goes up from 64700 for \( l = 1 \) to 75400 for \( l = 5 \). For \( l = 10 \), the total number of collisions is 77800. We see clearly the trend toward a constant value of total number of collisions when \( l \) is increased. The collision rate with \( l = 10 \) is shown in Fig. 6 as an open triangle (the \( l = 1 \) data is shown as an open circle). The collision rate with \( l = 10 \) is within 1% of the analytic prediction.

During the preliminary study of the collision rate, we found when \( m/T = 10 \), the collision rate is higher than the predicted rate. By looking more carefully into the code, we found out that it was caused by the larger than statistical fluctuations in the position distribution. When the fugacity \( \lambda \) is not uniform in space, the collision rate per unit volume:

\[
W = \int \frac{d^3x}{V} \lambda^2(x) I, \quad (20)
\]

in which:

\[
I = \frac{\pi \mu^2 \gamma^2}{(2\pi)^3} \int \frac{d^3p_1}{(2\pi)^3} \frac{d^3p_2}{(2\pi)^3} e^{-\beta(E_1+E_2)} |\vec{v}_1 - \vec{v}_2|. \quad (21)
\]

By using the inequality,

\[
\int \frac{d^3x}{V} \lambda^2(x) \geq \left( \int \frac{d^3x}{V} \lambda(x) \right)^2, \quad (22)
\]

and the fact that the system we prepared has zero chemical potential and hence averaged fugacity is one, we arrive at:

\[
W \geq W_0 = \frac{\pi \mu^2 \gamma^2}{(2\pi)^3} \int \frac{d^3p_1}{(2\pi)^3} \frac{d^3p_2}{(2\pi)^3} e^{-\beta(E_1+E_2)} |\vec{v}_1 - \vec{v}_2|. \quad (23)
\]

The equality holds only when the fugacity has no spatial dependence. This shows that when there are space clusters existing for some time period, the collision rate is higher than that expected for the uniform system.
It was found only in $m/T = 10$ and not in other cases because in the $m/T = 10$ case, particles are moving very slowly, and they stay in clusters for much longer time.

We traced the origin of the non-uniform distribution. It was caused by some correlation of random number generators (see Appendix B). When we use ran1 from [17], and generate first the momenta for all the particles and then generate the positions for all the particles, there are no abnormal fluctuations. When we generate momentum and position together, we found abnormal fluctuations. This does not occur when ran3 from [17] is used. We correct the generation by separating the generation of particle momentum and particle position.

4 Conclusions

From the above study, we show that the equation of state and the collision rate can be used to test the initial conditions and collision mechanisms of relativistic parton cascade. For massless particles, when the interaction range is much larger than the mean free path, the cascade collision rate is lower than the theoretical value. Other methods, e.g., particle partition, have to be used to correct the collision rate.

The comparison of free streaming and interacting cascade approach to equilibrium indicate qualitative similarities of the two cases. However, the damping and speed of collective motion are quite different. A detailed comparison of free streaming, ideal hydrodynamics, and cascade approach to global equilibrium in the case of half filled periodic box initial conditions will be addresses in another paper [12].

As discussed in this paper, spatial distribution with larger than statistical fluctuations gives higher than thermal reaction rate. HIJING [13] predicts initial spatial clusters of partons for nucleus-nucleus collisions at collider energies. This implies higher than thermal collision rates [14] and many other interesting physical phenomena beyond the widely used hot gluon scenario [16] predictions.

We emphasize the importance of using analytic tests in debugging numerical simulation codes. The spatial distribution with abnormal fluctuations illustrates well the usefulness of the analytic collision rate test. As more components are added to the cascade code, more tests will be needed to
ensure the consistency of different parts of the cascade code and to enable disentangling of the actual physical assumptions that define the model.

A Reduction of the phase space integral in the collision rate calculation

To calculate the collision rate per unit volume, equation (16), we first replace $|\vec{v}_1 - \vec{v}_2|$ by

$$\frac{\sqrt{s(s - 4m^2)}}{2E_1E_2},$$

and get:

$$W = \frac{12\pi}{2\mu^2} \gamma^2 \int_{4m^2}^{\infty} ds \sqrt{s(s - 4m^2)} \int \frac{d^3p_1}{(2\pi)^3 E_1} \frac{d^3p_2}{(2\pi)^3 2E_2} e^{-\beta(E_1+E_2)} \delta(s - (p_1 + p_2)^2).$$

(24)

The delta function can be used to integrate out one angle by using:

$$\delta(s - (p_1 + p_2)^2) = \frac{1}{2p_1p_2} \delta \left( \cos \theta_2 + \frac{s - 2m^2 - 2E_1E_2}{2p_1p_2} \right).$$

(25)

After carrying out the angular integrals, the collision rate becomes

$$W = \frac{\pi\gamma^2}{4(2\pi)^6 \mu^2} \int_{4m^2}^{\infty} ds \sqrt{s(s - 4m^2)} \frac{d\pi p_1^2 dp_1}{E_1 E_2} \frac{2\pi p_2^2 dp_2}{2p_1p_2} e^{-\beta(E_1+E_2)} \Theta \left( 1 - \frac{s - 2m^2 - 2E_1E_2}{2p_1p_2} \right).$$

(26)
The $\Theta$ function constraint can be written as:

$$(E_1 + E_2)^2 m^2 < s E_1 E_2 + m^2 s - \frac{s^2}{4}.$$

Now we change integration variables from $E_1, E_2$ to $x = E_1 E_2$, and $y = E_1 + E_2$. The collision rate becomes:

$$W = \frac{\pi \gamma^2}{2(2\pi)^4 \mu^2} \int_{4m^2}^\infty ds \sqrt{s(s - 4m^2)} \int dx dy \frac{e^{-y/T}}{\sqrt{y^2 - 4x}} \Theta(x + m^2 - \frac{s}{4} - \frac{y^2 m^2}{s}).$$

(27)

The integration over $x$ can be carried out first. The absolute lower bound of $x = E_1 E_2$ is $m^2$, but $x$ is also restricted by the $\Theta$ function. By noticing $y \geq s$, and hence $y^2 m^2 / s - m^2 + s/4 > m^2$, we see the lower bound should be $y^2 m^2 / s - m^2 + s/4$. The upper bound is determined from the square root in the integrand to be $y^2/4$. The result is:

$$\int_{y^2/4}^{\infty} dx \int_{y^2 m^2 / s - m^2 + s/4}^{\infty} dy \frac{1}{\sqrt{y^2 - 4x}} = \frac{1}{2} \sqrt{(s - 4m^2)(y^2 / s - 1)}. \quad (28)$$

Now the collision rate per unit volume is reduced to a 2-dimensional integral:

$$W = \frac{\pi \gamma^2}{4(2\pi)^4 \mu^2} \int_{4m^2}^\infty ds (s - 4m^2) \int_{\sqrt{s}}^\infty dy e^{-y/T} \sqrt{y^2 - s}. \quad (29)$$

The $y$ integral can be readily carried out to be:

$$\int_{\sqrt{s}}^\infty dy e^{-y/T} \sqrt{y^2 - s} = \sqrt{s} T K_1 \left(\frac{\sqrt{s}}{T}\right). \quad (30)$$

In the above, $K_1(x)$ is the modified Bessel function.

Taking $\gamma = 16$, we arrive at equation (17).

**B One example showing the interference of generations of distributions of variables**

The following is the a sample program that generates the particle momentum and position together. ran1 is taken from (17) and declared as real*8 function.
program dist
implicit real*8 (a-h, o-z)
parameter (mul = 40000)
parameter (size = 5.19653401d0)
external ran1
common /para/ xmp
temp = 0.5d0
xmp = 5d0
do i = 1, mul
   call energy(e, temp)
call momentum(px, py, pz, e)
x = 2d0 * ran1(iseed) - 1d0
x = x * 5d0 * size
y = 2d0 * ran1(iseed) - 1d0
y = y * 5d0 * size
z = 2d0 * ran1(iseed) - 1d0
z = z * 5d0 * size
end do
stop
end

subroutine energy(e, temp)
implicit real*8 (a-h, o-z)
external ran1
common /para/ xmp
1000 continue
e = ran1(iseed)
e = e * ran1(iseed)
e = e * ran1(iseed)
if (e .le. 0d0) goto 1000
e = - temp * log(e)
if (ran1(iseed) .gt. 
   exp((e - sqrt(e ** 2 + xmp ** 2))/temp)) then
goto 1000
end if
return
subroutine momentum(px, py, pz, e)
implicit real*8 (a-h,o-z)
external ran1
parameter (pi = 3.14159265358979d0)

  cost = 2d0 * ran1(iseed) - 1d0
  sint = sqrt(1d0 - cost ** 2)
  phi = 2d0 * pi * ran1(iseed)
  px = e * sint * cos(phi)
  py = e * sint * sin(phi)
  pz = e * cost
  return
end

The momentum distribution is shown in Fig. 9 along with that generated
by ran3, and the theory prediction. We see that the momentum distribution
is correctly generated with reasonable fluctuations.

Fig. 10 gives the position \( x \) distribution from the above program using
ran1 and ran3. ran1 result has much larger fluctuations than the expected
statistical fluctuations, while ran3 result is consistent with the expected sta-
tistical fluctuations.

When the generation of momentum and position are separated, the dis-
tributions all have reasonable fluctuations. Another possible (and more ef-
ficient) way to solve the problem is to generate Gaussian momentum distri-
bution for large \( m/T \) values.

Since with the above program, the total number of random number used
is 141931896, while we can easily show the period of ran1 with the given
parameters is beyond 2000000000, it is not clear that the large fluctuations
are due to the period of the random number generator ran1. But this is a
concrete example of ill-generated distribution.

Table 1: Input parameters to ZPC: cell size and screening mass for different temperatures and masses of particles. \( \mu_1, \mu_2, \mu_3 \) correspond to three decreasing screening masses as described in the text.

| \( T = 0.5 \, \text{GeV} \) | \( m = 0 \, \text{GeV} \) | \( m = 2.5 \, \text{GeV} \) | \( m = 5. \, \text{GeV} \) |
|-----------------|-----------------|-----------------|-----------------|
| \( l_c \) (fm)  | 0.53240597      | 1.31503518      | 5.19653401      |
| \( \mu_1 \) (fm\(^{-1}\)) | 5.50178669      | 2.22745682      | 0.56368034      |
| \( \mu_2 \) (fm\(^{-1}\)) | 4.36677096      | 1.76793364      | 0.44739338      |
| \( \mu_3 \) (fm\(^{-1}\)) | 3.46590838      | 1.40320985      | 0.35509636      |

| \( T = 1.0 \, \text{GeV} \) | \( m = 0 \, \text{GeV} \) | \( m = 2.5 \, \text{GeV} \) | \( m = 5. \, \text{GeV} \) |
|-----------------|-----------------|-----------------|-----------------|
| \( l_c \) (fm)  | 0.26620298      | 0.36766446      | 0.65751757      |
| \( \mu_1 \) (fm\(^{-1}\)) | 11.00357361     | 7.96700354      | 4.45491373      |
| \( \mu_2 \) (fm\(^{-1}\)) | 8.73354210      | 6.32341486      | 3.53586735      |
| \( \mu_3 \) (fm\(^{-1}\)) | 6.93181691      | 5.01889767      | 2.80641975      |

| \( T = 1.5 \, \text{GeV} \) | \( m = 0 \, \text{GeV} \) | \( m = 2.5 \, \text{GeV} \) | \( m = 5. \, \text{GeV} \) |
|-----------------|-----------------|-----------------|-----------------|
| \( l_c \) (fm)  | 0.17746865      | 0.20981078      | 0.29320839      |
| \( \mu_1 \) (fm\(^{-1}\)) | 16.50536062     | 13.96107515     | 9.99011002      |
| \( \mu_2 \) (fm\(^{-1}\)) | 13.10031331     | 11.08091261     | 7.92915553      |
| \( \mu_3 \) (fm\(^{-1}\)) | 10.39772550     | 8.79492611      | 6.29337487      |

Table 2: Measurement of non-causal collision number and total collision number.

| \( \mu \) (fm\(^{-1}\)) | \( a \) | \( l \) | \( \chi_1 \) | \( \chi_2 \) | \( N_{\text{none}} \) | \( N_{\text{total}} \) | \( R \) |
|-----------------|--------|--------|--------|--------|-----------------|-----------------|------|
| 5.50178669      | 0.5    | 1      | 0.5    | 0.48   | 3240            | 31400           | 10.3%|
| 4.36677096      | 1      | 1      | 1      | 0.88   | 8250            | 46100           | 17.9%|
| 3.46590838      | 2      | 1      | 2      | 1.56   | 19000          | 64700           | 29.4%|
| 3.46590838      | 2      | 5      | 0.89   | 0.81   | 12500          | 75400           | 16.6%|
| 3.46590838      | 2      | 10     | 0.63   | 0.59   | 9700           | 77800           | 12.5%|
Figure 1: Pressure-energy density ratio $P/\epsilon$ as function of $m/T$. The dotted curve is the analytic prediction, and the filled black dots are cascade data.
Figure 2: Energy density $\epsilon$ as a function of temperature $T$ for different masses. The curves are predictions, and the dots are cascade data.
Figure 3: Evolution of the longitudinal momentum flux. $T^{11}$ is in units of $T^{11}(\infty)$. The size of the box is determined by the asymptotic temperature $T = 1.5$ GeV, and the screening mass is set to be 16.5 fm$^{-1}$ for the interacting case.
Figure 4: Evolution of $T_{11}$ spatial distribution. The predictions are drawn with solid and dashed lines alternatively with numbers indicating the times in fm. The cascade data are drawn in filled circles and pluses alternatively for different times. Asymptotic temperature $T = 1.5$ GeV.
Figure 5: Evolution of $A^{xx}$ spatial distribution. The predictions are drawn with solid and dashed lines alternatively with numbers indicating the times in fm. The cascade data are drawn in filled circles and pluses alternatively for different times. Asymptotic temperature $T = 1.5$ GeV.
Figure 6: Collision rate per unit volume $W$ as a function of $m/T$. The curve is prediction, and the pluses are cascade data. The open circle corresponds to the rate at $m/T = 0$ with $\mu = 3.46590838$ fm$^{-1}$. The result from scaling the cross section down by a factor of 10 and increasing the particle density by a factor of 10 is shown as the open triangle.
Figure 7: Collision rate per unit volume $W$ as a function of $m/T$. The curve is prediction, and the pluses are cascade data.
Figure 8: The number of non-causal collisions over the total number of collisions as a function of the ratio of interaction length to the mean free path. The dashed curve is the estimate when the radius of causal sphere is taken to be the interaction range. Open(filled) circles are data plotted against $\chi_1(\chi_2)$ in table (2).
Figure 9: Momentum distribution for $m = 5$ GeV, $T = 0.5$ GeV with 40000 particles. The dotted line is the prediction, the open circles come from code using ran1, and the filled circles are ran3 results.
Figure 10: Number of particles per bin as a function of position $x$ for $m = 5$ GeV, $T = 0.5$ GeV with 40000 particles. The dotted curve is ran1 result, while the solid curve is for ran3.
