Abstract: The seabed is usually non-homogeneous in the real marine environment, and its response to the dynamic wave loading is of great concern to coastal engineers. Previous studies on the simulation of a non-homogeneous seabed response have mostly adopted a vertically layered seabed, in which homogeneous soil properties are assumed in the governing equations for one specified layer. This neglects the distribution gradient terms of soil property, thus leading to an inaccurate evaluation of the dynamic response of a non-homogeneous seabed. In this study, a numerical model for a wave-induced 3D non-homogeneous seabed response is developed, and the effects of the soil property distribution gradient on the wave-induced response of a non-homogeneous seabed are numerically investigated. The numerical model is validated, and the results of the present simulation agree well with those of previous studies. The validated model is applied to simulate an ideal two-dimensional (2D) vertical non-homogeneous seabed. The model is further applied to model the practical wave-induced dynamic response of a three-dimensional (3D) non-homogeneous seabed around a mono-pile. The difference in pore pressure and soil effective stresses due to the soil distribution gradient is investigated. The effects of the soil distribution gradient on liquefaction are also examined. Results of this numerical study indicate that (1) pore pressure decreases while soil effective stresses increase (the maximum difference of the effective stresses can reach 68.9% of $p_0$) with a non-homogeneous seabed if the distribution gradient terms of soil properties are neglected; (2) the effect of the soil property distribution gradient terms on the pore pressure becomes more significant at the upper seabed, while this effect on the soil effective stresses is enhanced at the lower seabed; (3) the effect of the soil distribution gradient on the seabed response is greatly affected by the wave reflection and diffraction around the pile foundation; and (4) the soil distribution gradient terms can be neglected in the evaluation of seabed liquefaction depth in engineering practice.

Keywords: wave loading; pore pressure; soil effective stresses; non-homogeneous soil; properties; distribution gradient

1. Introduction

A marine structure usually suffers from complex coastal environmental loadings, such as winds, waves, currents, etc. [1–3], and studying its stability has attracted lots of attention from coastal engineers. The wave-induced seabed response is of significant importance to the construction of marine structures because it can lead to seabed instability around a structure’s foundation [4]. Excess pore pressures can occur as a result of the dynamic wave pressure at the seabed surface. When excess pore pressure exceeds the overburden pressure, the effective stresses of the soil skeleton vanish, and the soil behaves like a liquid. This phenomenon is referred to as liquefaction, and it can lead to the collapse...
of the marine structure [5,6]. Smith and Gordon [7] reported that the failure of marine structures was predominantly caused by wave-induced seabed instability rather than structural deficiencies. Therefore, it is important to investigate the seabed dynamic response to wave loading in order to evaluate seabed instability.

On the basis of Biot’s consolidation theory, Yamamoto et al. [8] were among the first to study the wave-induced seabed response. In their study, analytical solutions for the seabed dynamic response were given for pore pressures, soil effective stresses, and soil displacements. Using a similar approach, Madsen [9] analytically investigated the seabed response with an isotropic soil property. Jeng and Hsu [10] extended the above analytical solutions to the seabed with finite depth and studied the seabed dynamic response using the 3D short-crested wave loading. These investigations adopted Q-S (Quasi-Static) equations, which neglect the inertial terms of pore pressure and the soil skeleton [11]. To consider the inertial term of soil, Jeng and Rahman [12] used a PD model (partial dynamic) to analytically investigate the wave-induced seabed response. They found a 17% difference in pore pressure between the Q-S and P-D models for the same case. Ülker and Rahman [13] used a similar approach to investigate the seabed response and clarified the application range of the QS, PD, and FD (fully dynamic) models. Liao et al. [14] and Tong et al. [15] considered the effect of currents on the wave-induced seabed response, and Chen et al. [16] studied the nonlinear wave-induced response of an anisotropic seabed. Similar studies have been conducted to investigate the seabed response around marine structures, such as pipelines [17], composite breakwaters [18–22], and mono-piles [23,24].

All these studies have assumed a homogeneous seabed that adopts constant soil parameters in space. Because consolidation occurs over a long time, the seabed, in reality, is usually non-homogeneous in the vertical direction [25]. Yamamoto [26] analytically investigated the wave-induced response of a vertically layered seabed at the Mississippi Delta. He found that a seabed with a vertical depth of 1/5 wavelength was the most unstable that and landslides could occur during a storm. Rahman et al. [27] presented a semi-analytical solution for the multi-layered seabed response and applied it with the 3D short-crested wave loading in front of a vertical breakwater. On the basis of the TRM method, Zhou et al. [28] proposed an analytical solution for a vertically layered seabed under the nonlinear wave loading. Considering the inertial terms of pore fluid and soil skeleton, Ülker [29] used a semi-analytical method to investigate the multi-layered seabed response. Effects of non-homogeneous soil properties on the seabed response against the inertial terms were examined in the study. Most of the above studies have adopted a so-called “layered” seabed in which the homogeneous soil properties were assumed in one specified layer. This neglects the distribution gradient terms of non-homogeneous soil properties in the governing equations and may lead to an inaccurate evaluation of the dynamic response in a non-homogeneous seabed. Jeng and Lin [30] developed a 2D finite element model for the wave-induced seabed response and assumed a continuous variation in non-homogeneous soil properties. The distribution gradient terms of soil properties were considered in the governing equations (QS model) of their study. Similar research can be seen in Zhang et al. [31] for a randomly heterogeneous porous seabed. More recently, Chen et al. [32] applied a 3D model for a non-homogeneous seabed, but they only considered the non-homogeneous properties and retained the gradient term in the vertical (z−) direction. Using the FD model equations, Zhang et al. [33] developed a 3D numerical model for the non-homogeneous seabed response. Their study retained all the gradient terms of the soil parameters, but the gradient terms in the governing equations were not fully separated out. They only compared the seabed dynamic response between a homogeneous seabed and non-homogeneous seabed, and the soil property distribution gradient terms in the non-homogeneous seabed, which play an important role, were not quantitatively examined. To the authors’ knowledge, the quantitative effects of the soil distribution gradient on the response of a non-homogeneous seabed have not yet been investigated.

This study focuses on the non-homogeneous seabed, in which the effects of the soil distribution gradient are emphasized. Compared with the authors’ previous work in Zhang et al. [33], the contributions of this study are summarized: (1) the distribution gradient terms of non-homogeneous
soil properties are separated out on the basis of the original governing equations of the soil dynamic response; (2) the effects of the distribution gradient on the soil dynamic response (pore water pressures, soil effective stresses) and liquefaction are examined. In a word, the previous studies in Jeng and Lin [30] and Zhang et al. [33] compared the soil responses between the homogeneous seabed and non-homogeneous seabed, while this study focuses on the non-homogeneous seabed and compares cases with and without the property distribution gradient terms. The outline of this paper is as follows. The governing equations (FD model) for the wave-induced seabed response are newly derived in Section 2, and the distribution gradient terms of soil properties are clearly highlighted. Model validations are then presented by comparing the present numerical results with available experimental data and field measurements. The validated model is then applied to evaluate the differences in pore pressure and soil effective stresses due to soil distribution gradient terms. Results are presented in Sections 3 and 4, in which the effects of the property gradient on the seabed response are examined by simulating an ideal 2D non-homogeneous seabed (Section 3) and a more realistic 3D non-homogeneous seabed around a mono-pile foundation (Section 4). Liquefaction analysis is presented in Section 5. Detailed discussions are presented in Section 6 and highlight the contributions of this study. Finally, the main conclusions from this study are presented in Section 7.

2. Numerical Model

This study adopts the FD model for the wave-induced seabed response. The governing equations are presented with the soil distribution gradient terms highlighted. Boundary conditions are provided to solve the nonlinear partial equations of the numerical model, which is validated using flume tests [34] and field measurements [26].

2.1. Seabed Model

On the basis of Biot’s consolidation theory, the FD model for the seabed response that considers the inertial terms of pore pressure and soil skeleton is

\[
\sigma_{ij} + \rho g_i = \rho u_i + \rho_f \bar{w}_i,
\]

\[
- p_i + \rho_f g_i = \rho_f u_i + \frac{\rho_f \bar{w}_i}{n} + \frac{\rho_f g_i}{k_i} \dot{w}_i,
\]

\[
u_{ij} + \bar{w}_{ij} = -n \dot{\beta} p,
\]

where \(\sigma_{ij}\) is the total stresses (\(i\) and \(j\) denote the directions of \(x, y, z\) in the Cartesian system), that is \(\sigma_{ij} = \sigma_{xx}\) or \(\sigma_{yy}\) or \(\sigma_{zz}\) for \(i = j\), and \(\sigma_{ij} = \tau_{xz}\) or \(\tau_{yz}\) or \(\tau_{xy}\) for \(i \neq j\). \(\rho\) is the average density of the porous medium, \(p\) denotes pore pressure, \(\rho_f\) is water density, \(g_i\) is gravitational acceleration in the \(i\)-direction, \(u_i\) is the displacement of the soil matrix in the \(i\)-direction, \(\bar{w}_i\) is the average relative displacement of the fluid to the solid skeleton in the \(i\)-direction, \(k_i\) is the permeability of the porous medium in the \(i\)-direction, and \(n\) is the porosity of soil. It should be noted that the above FD model will be reduced to the PD model by ignoring the accelerations due to pore water, while the PD model will be reduced to the QS model by further ignoring the acceleration due to the soil skeleton. The equivalent compressibility of pore water and entrapped air is defined as [8]

\[
\dot{\beta} = \frac{1}{k_{sw}} + \frac{1 - S_r}{\rho g d},
\]

where \(d\) is the water depth, \(S_r\) is the saturation degree, and \(k_{sw}\) is the bulk modulus of pure water and is taken as \(1.95 \times 10^9\) N/m². A poroelastic constitutive model of soil is adopted to govern the deformation of the soil skeleton. The total stresses can be written as

\[
\sigma_{ij} = \sigma'_{ij} - \delta_{ij} p,
\]
where \( \delta_{ij} \) is the Kronecker delta notation which equals 0 for \( i = j \) or 1 for \( i \) and \( j \), respectively. \( \sigma'_{ij} \) denotes the soil effective stresses and shear stresses. In this study, cross-anisotropic soil behavior is adopted:

\[
\mu_{vh} = \frac{E_h}{E_v} = \Omega \tag{6}
\]

\[
G_h = \frac{E_h}{2(1 + \mu_{hh})} = \frac{\Omega E_v}{2(1 + \mu_{hh})} = GE_v \tag{7}
\]

\[
G_v = \Lambda E_v \tag{8}
\]

where \( \mu_{vh}, \mu_{hv}, \) and \( \mu_{hh} \) are the Poisson ratios in different directions. Noted here that, \( h \) denote the horizontal plane including \( x \) and \( y \) directions, \( v \) denote the vertical direction \( z \), the subscript \( \nu_{vh} \) in \( \mu_{vh} \) means a contraction in direction \( x \) or \( y \) when an extension is applied in direction \( z \). Similar explanations are with \( \mu_{hv} \) and \( \mu_{hh} \). \( E_h \) and \( E_v \) are Young’s modulus in the horizontal and vertical directions, respectively; \( G_h \) and \( G_v \) are shear modulus in the horizontal and vertical directions, respectively; \( \Omega \) is a non-dimensional parameter; and \( \Lambda \) is the anisotropic constant. Note that for an isotropic seabed, \( \mu_{hh} = \mu_{vh}, \Omega = 1, \) and \( \Lambda = 1/2(1 + \mu_{hh}). \)

A poroelastic constitutive model of soil is adopted to govern the deformation of the soil skeleton. Thus, the effective stress–strain relation can be written as [35]:

\[
\sigma'_x = E_v[C_{11}\frac{\partial u_x}{\partial x} + C_{12}\frac{\partial u_x}{\partial y} + C_{13}\frac{\partial u_z}{\partial z}] \tag{9}
\]

\[
\sigma'_y = E_v[C_{12}\frac{\partial u_x}{\partial x} + C_{11}\frac{\partial u_y}{\partial y} + C_{13}\frac{\partial u_z}{\partial z}] \tag{10}
\]

\[
\sigma'_z = E_v[C_{13}\frac{\partial u_x}{\partial x} + C_{13}\frac{\partial u_y}{\partial y} + C_{33}\frac{\partial u_z}{\partial z}] \tag{11}
\]

\[
\tau_{xy} = GE_v[\frac{\partial u_x}{\partial y} + \frac{\partial u_y}{\partial x}] = \tau_{yx} \tag{12}
\]

\[
\tau_{xz} = \Lambda E_v[\frac{\partial u_x}{\partial z} + \frac{\partial u_z}{\partial x}] = \tau_{zx} \tag{13}
\]

\[
\tau_{yz} = \Lambda E_v[\frac{\partial u_y}{\partial z} + \frac{\partial u_z}{\partial y}] = \tau_{zy} \tag{14}
\]

where

\[
C_{11} = \Omega(1 - \mu_{hh}\mu_{vh})/\Delta \tag{15}
\]

\[
C_{12} = \Omega(\mu_{hh}\mu_{vh} + \mu_{hh})/\Delta \tag{16}
\]

\[
C_{13} = \Omega\mu_{vh}(1 + \mu_{hh})/\Delta \tag{17}
\]

\[
C_{33} = (1 - \mu_{hh}^2)/\Delta \tag{18}
\]

\[
\Delta = (1 + \mu_{hh})(1 - \mu_{hh} - 2\mu_{hh}\mu_{vh}). \tag{19}
\]

In the present model, eight soil parameters are allowed to vary non-homogeneously, which is the function of spatial locations. These parameters are the porous media density \( \rho(x,y,z) \), water density \( \rho_f(x,y,z) \), permeability \( k(x,y,z) \), the porosity of the solid phase \( n(x,y,z) \), the bulk modulus of pore water \( k_f(x,y,z) \), vertical Young’s modulus \( E_v(x,y,z) \), vertical Poisson’s ratios \( \mu_{vh}(x,y,z) \), and horizontal Poisson’s ratios \( \mu_{hh}(x,y,z) \).
The velocity of pore water can be obtained from Equation (2):

\[
\dot{v}_i = \frac{k_i \left( -p_j + \rho_f g_i - \rho_f \dot{u}_i \right)}{\rho_f g_i}
\]  

(20)

From the above definitions, the governing equations can be derived. Substituting Equations (9)–(14) into Equations (1)–(3) and replacing the velocity of the pore pressure in Equation (3) with Equation (20) yield the governing equations for the dynamic response of a non-homogeneous seabed in the scalar form:

\[
E_v \left[ C_{11} \frac{\partial^2 u_x}{\partial x^2} + \frac{G}{\partial y^2} + \frac{\Lambda^2 \partial^2 u_y}{\partial x^2} + \frac{\partial C_{12} + G \partial^2 u_y}{\partial x \partial y} + \frac{C_{13} + \Lambda \partial^2 u_z}{\partial x \partial z} \right]
\]

\[
+ \frac{\partial C_{11} \partial u_x}{\partial x} + \frac{\partial G \partial u_x}{\partial y} + \frac{\partial \Lambda \partial u_x}{\partial z} + \frac{\partial G \partial u_y}{\partial x} + \frac{C_{12} \partial u_y}{\partial x} + \frac{C_{13} \partial u_z}{\partial x} + \frac{\partial E_v \left( \frac{\partial u_x}{\partial x} + \frac{C_{12} \partial u_y}{\partial y} + \frac{C_{13} \partial u_z}{\partial z} \right)}{\partial x}
\]

\[
+ \frac{\partial E_v \left( \frac{\partial u_x}{\partial z} + \frac{C_{13} \partial u_z}{\partial x} \right)}{\partial z} - \frac{\partial p}{\partial x} = \rho_f \frac{\partial^2 u_x}{\partial t^2} + \rho \frac{\partial^2 u_y}{\partial t^2}
\]  

(21)

\[
E_v \left[ \frac{G^2 u_y}{\partial x^2} + C_{11} \frac{\partial^2 u_y}{\partial y^2} + \frac{\Lambda^2 \partial^2 u_y}{\partial x^2} + \frac{\partial C_{12} + G \partial^2 u_y}{\partial x \partial y} + \frac{C_{13} + \Lambda \partial^2 u_z}{\partial x \partial z} \right]
\]

\[
+ \frac{\partial C_{12} \partial u_y}{\partial y} + \frac{\partial G \partial u_y}{\partial x} + \frac{\partial \Lambda \partial u_y}{\partial z} + \frac{\partial G \partial u_y}{\partial y} + \frac{C_{11} \partial u_y}{\partial x} + \frac{C_{13} \partial u_z}{\partial x} + \frac{\partial E_v \left( \frac{\partial u_y}{\partial x} + \frac{C_{12} \partial u_y}{\partial y} + \frac{C_{13} \partial u_z}{\partial z} \right)}{\partial y}
\]

\[
+ \frac{\partial E_v \left( \frac{\partial u_y}{\partial z} + \frac{C_{13} \partial u_z}{\partial y} \right)}{\partial z} - \frac{\partial p}{\partial y} = \rho_f \frac{\partial^2 u_y}{\partial t^2} + \rho \frac{\partial^2 u_y}{\partial t^2}
\]  

(22)

\[
E_v \left[ \frac{\Lambda^2 u_y}{\partial x^2} + \frac{\Lambda^2 \partial^2 u_y}{\partial x^2} + \frac{C_{13} \partial^2 u_y}{\partial y \partial z} + \frac{C_{13} + \Lambda \partial^2 u_z}{\partial x \partial z} \right]
\]

\[
+ \frac{\partial C_{13} \partial u_y}{\partial z} + \frac{\partial \Lambda \partial u_y}{\partial x} + \frac{\partial C_{13} \partial u_y}{\partial y} + \frac{\partial \Lambda \partial u_y}{\partial y} + \frac{\partial \Lambda \partial u_y}{\partial z} + \frac{\partial \Lambda \partial u_y}{\partial z} + \frac{\partial \Lambda \partial u_z}{\partial y} + \frac{\partial \Lambda \partial u_z}{\partial z}
\]

\[
+ \frac{\partial E_v \left( \frac{\partial u_y}{\partial x} + \frac{C_{13} \partial u_z}{\partial y} \right)}{\partial x} + \frac{\partial E_v \left( \frac{\partial u_z}{\partial x} + \frac{C_{13} \partial u_z}{\partial z} \right)}{\partial z} - \frac{\partial p}{\partial z} = \rho_f \frac{\partial^2 u_z}{\partial t^2} + \rho \frac{\partial^2 u_z}{\partial t^2}
\]  

(23)

\[
\frac{\partial p}{\partial x} = \rho_g \frac{\partial^2 w_x}{\partial t^2} + \rho_f \frac{\partial^2 w_x}{\partial t^2}
\]

(24)

\[
\frac{\partial p}{\partial y} = \rho_g \frac{\partial^2 w_y}{\partial t^2} + \rho_f \frac{\partial^2 w_y}{\partial t^2}
\]

(25)

\[
\frac{\partial p}{\partial z} + \rho_f g = \frac{\rho_g \partial w_z}{\partial t} + \frac{\partial^2 w_z}{\partial t^2} + \frac{\rho_f \partial^2 w_z}{\partial t^2}
\]

(26)
where $p$ is the wave height, $k$ is the wavenumber, $\omega$ is the wave frequency, and $p_b$ is the wave pressure at the seabed surface and is provided by the nonlinear wave model FUNWAVE 2.0. The FUNWAVE 2.0 Code was first developed by Kirby [36] on the basis of the nonlinear Boussinesq equations [37], and it is widely used to simulate the nonlinear wave-structure interactions in coastal areas. The phenomenon of wave reflection and diffraction around a monopile foundation can be well represented with the FUNWAVE 2.0 model [23]. Readers interested in the FUNWAVE 2.0 Code can refer to Kirby [36].

2.3. Model Validation

Model validation must be conducted before we can confidently apply the numerical model. Figure 1 is the comparison of the measured [34] and simulated (this study) vertical distributions of pore pressure. The analytical solution of Jeng [38] is also included for comparison. Pore pressure is seen to be relatively large at the seabed surface, and it sharply decreases at the deep soil. Figure 1 shows that vertical pore pressure depends significantly on the wave and seabed conditions. Results indicate...
that the large pore pressure within the seabed usually corresponds to a relatively large wave period ($T$) and soil saturation degree ($S_r$) for otherwise identical conditions. Good agreement is found between the simulation and the experimental data [34], as well as the analytical solution [38], indicating that the present model has high accuracy in simulating the seabed dynamic response.

\[
\begin{align*}
T &= 1.92 \text{s} \\
S_r &= 0.95 \\
T &= 2.27 \text{s} \\
S_r &= 0.994 \\
T &= 0.96 \text{s} \\
S_r &= 0.996
\end{align*}
\]

Model validation (Flume tests)

For Homogeneous seabed

\[
\frac{z}{h} \quad \text{and} \quad \frac{p}{p_0}
\]

Figure 1. Comparison of the measured [34] and simulated (this study) vertical distributions of pore pressure.

The seabed in the real coastal environment is usually non-homogeneous, which will significantly change the pore pressure in the vertical direction. Bennett and Faris [25] performed field measurements at the Mississippi Delta to measure the pore pressure distributions and attenuations in the vertical direction of the seabed. Yamamoto [26] assumed a constant saturation degree of soil and investigated the pore pressure distributions using analytical solutions. Figure 2 shows the comparison of the measured [25] and simulated pore pressures (this study), as well as the analytical solution from Yamamoto [26]. It is seen in Figure 2 that there exist large discrepancies between the measured [25] and theoretical results [26]; in the latter study, a constant saturation degree of $S_r = 0.9$ or $S_r = 1.0$ was used. In this study, a non-homogeneous saturation degree of soil is adopted with a linear variation in depth ($S_r = 1.0 + z/1250$), which obtains good agreement with the measured data by Bennett and Faris [25]. This validation example indicates that the non-homogeneity of soil is important and has to be considered in the simulation.
3. 2D Vertical Non-Homogeneous Seabed

An ideal 2D case for the wave-induced dynamic response of a vertical non-homogeneous seabed is studied (Figure 3) by considering the continuous variation in non-homogeneous soil properties (permeability and Young’s modulus). Previous studies have indicated that the porosity of the soil skeleton generally decreases with the increase in seabed depth, therefore leading to the decrease in soil permeability and the increase in the soil Young’s modulus \[30,39\]. Therefore, the model setup in this study adopts this distribution trend for soil permeability and Young’s modulus. Nine numerical examples, which are indicated by the symbol \(z_{ij}(i = 1, 2, 3 \text{ and } j = 1, 2, 3)\), are run for the 2D case. The subscript \(i = 1, 2, 3\) denotes the three categories of the depth function \((k_z(z)/k_0)\) for non-homogeneous permeability \((k_{z0} \text{ denotes soil permeability at the seabed surface})\). Type 1 \((i = 1)\) is for \(k_z(z)/k_{z0} = 1\) and represents uniform permeability of the seabed. Type 2 \((i = 2)\) is for \(k_z(z)/k_{z0} = 1 - 9z/h\), denoting linear variation in permeability. Type 3 \((i = 3)\) is for \(k_z(z)/k_{z0} = e^{2.303z/h}\), denoting an exponential relation in permeability with depth. Similarly, the subscript \(j = 1, 2, 3\) denotes the three categories of the depth function \((E_v(z)/E_{v0})\) for seabed Young’s modulus and are defined as \(E_v(z)/E_{v0} = 1\) (type 1, \(j = 1\)), \(E_v(z)/E_{v0} = 1 - 9z/h\) (type 2, \(j = 2\)), and \(E_v(z)/E_{v0} = e^{2.303z/h}\) (type 3, \(j = 3\)). Details of the wave and seabed parameters used in the simulations are listed in Table 1. The sketch of model setup for the non-homogeneous seabed response is illustrated in Figure 3a. Details of non-homogeneous permeability \(k_z\) and Young’s modulus \(E_v\) distributions can be seen in Figure 3b,c. When \(k_z(z)/k_{z0} \text{ and } E_v(z)/E_{v0}\) are equal to 1 (type 1 for \(k_z\) and \(E_v\)), it reflects a homogeneous seabed with constant properties. For the non-homogeneous \(k_z\) and \(E_v\), the distribution gradient (decreasing) of \(k_z(k_z(z)/z)\) (Figure 3b) with type 3 is larger than that with type 2 at the upper seabed (see the tangent slope), while it is smaller at the lower seabed. In contrast, the distribution gradient (increasing) of \(E_v(E_v(z)/z)\) (Figure 3c) with type 3 is smaller at the upper seabed and larger at the lower seabed (Figure 3c). Note that this difference in the distribution gradient between \(k_z\) and \(E_v\) has a significant influence on the wave-induced non-homogeneous seabed response (see below).
Figure 3. Model setup for the non-homogeneous seabed response: (a) Sketch map, (b) distribution of non-homogeneous permeability ($k_z$), (c) distribution of non-homogeneous Young’s modulus ($E_v$).

Figure 4 illustrates the comparison of pore pressure with (solid line) and without (red dashed line) the gradient terms in the governing equations for a non-homogeneous seabed in which $p_{max}$ is the maximum pore pressure within one wave period, and $p_0$ is the maximum pore pressure ($p_{max}$) at the seabed surface. It is seen from Figure 4 that the pore pressure at the seabed surface ($z = 0$) equals the dynamic wave pressure and decreases with the increase in seabed depth. No discrepancies in pore pressure between the case with and without the gradient terms are found with case $\xi_{11}$ (Figure 4a). This is because the distribution gradient of $k_z$ and $E_v$ equals zero with a homogeneous seabed. The first row of the nine subfigures (Figure 4a–c for cases $\xi_{11}$, $\xi_{12}$, and $\xi_{13}$, respectively) indicates the change in the $E_v$ distribution gradient with a constant $k_z$. It clearly shows that the pore pressure increases if the gradient term of $E_v$ is neglected. In addition, the discrepancies in pore pressure are only found at the lower part of the seabed, indicating that the effect of Young’s modulus gradient term ($\partial E_v/\partial z$) is limited to the region near the seabed bottom ($z/h < -0.8$). Meanwhile, the discrepancies in pore pressure ($\Delta p_{max}$, caused by the gradient term) increase in the order $\xi_{11}$, $\xi_{12}$, and $\xi_{13}$, which is probably because the gradient of Young’s modulus increases in that order at the lower seabed (Figure 3). The first column (Figure 4a,d,g for cases $\xi_{11}$, $\xi_{21}$, and $\xi_{31}$, respectively) shows the change in the $k_z$ distribution gradient.
$E_0$ with a constant $E_0$. In contrast to $E_0$ (Figure 4a–c), the pore pressure decreases if the gradient term of $k_z$ is neglected. The pore pressure discrepancy caused by the permeability gradient ($\partial k_z / \partial z$) mainly exists at the upper part of the seabed (around $z/h = -0.5$), which indicates that the permeability gradient has a more significant influence at that part. It also illustrates that the discrepancy in pore pressure increases in the order $\xi_{11}$, $\xi_{21}$, and $\xi_{31}$, which is mainly because the gradient of permeability $k_z$ increases in that order at the upper seabed. The other subfigures (Figure 4d–f, h–i for cases $\xi_{22}$, $\xi_{23}$, $\xi_{32}$, and $\xi_{33}$, respectively) reflect a seabed in which $k_z$ and $E_0$ are both non-homogeneous. An interesting phenomenon is found: the pore pressure decreases at the upper part while increasing at the lower part of the seabed. This is probably the result of the combined influence of the distribution gradient in $E_0$ and $k_z$.

![Comparison of pore pressure with (solid line) and without (red dashed line) the gradient terms of the governing equations in a non-homogeneous seabed](image)

**Figure 4.** Comparison of pore pressure with (solid line) and without (red dashed line) the gradient terms of the governing equations in a non-homogeneous seabed: (a) Case $\xi_{11}$, (b) Case $\xi_{12}$, (c) Case $\xi_{13}$, (d) Case $\xi_{21}$, (e) Case $\xi_{22}$, (f) Case $\xi_{23}$, (g) Case $\xi_{31}$, (h) Case $\xi_{32}$, (i) Case $\xi_{33}$.

The maximum pore pressure discrepancy ($\Delta p_{\text{max}}$) due to the distribution gradient of non-homogeneous properties is quantitatively shown in Figure 5, in which $\Delta p_{\text{max}} = \max(p_{\text{max}}(\text{no gradient}) - p_{\text{max}}(\text{gradient}))$, while $p_{\text{max}}(\text{no gradient})$ and $p_{\text{max}}(\text{gradient})$ respectively indicate the pore pressure without and with the gradient term of soil properties. Therefore, $\Delta p_{\text{max}}$ can be seen as the effect of the property gradient on the non-homogeneous seabed.
response. Figure 5a shows $\Delta p_{\text{max}}$ for cases of $\xi_{11}$, $\xi_{12}$, and $\xi_{13}$, and it represents the quantitative effect of the Young’s modulus gradient term ($\partial E_v / \partial z$). As $\xi_{11}$ indicates the case with a homogeneous seabed ($\partial E_v / \partial z = 0$), $\partial p_{\text{max}}$ with $\xi_{11}$ is equal to zero accordingly. It shows $\partial p_{\text{max}} = 0.74 p_0$ for $\xi_{12}$ and $\Delta p_{\text{max}} = 1.76 p_0$ for $\xi_{13}$, indicating that the distribution gradient effect of $E_v$ is more significant if the exponential variation of $E_v$ distribution is adopted ($\xi_{13}$). By comparison, Figure 3b shows $\Delta p_{\text{max}}$ for cases of $\xi_{11}$, $\xi_{21}$, and $\xi_{31}$, and it describes the quantitative effect of the permeability gradient ($\partial k_z / \partial z$). Similar to that in Figure 5a, the maximum $\Delta p_{\text{max}} = -4.2 p_0$ is found with $\xi_{31}$, indicating that the largest effect of the $k_z$ gradient occurs for exponential variation ($\xi_{31}$). It is also found that the maximum $\partial p_{\text{max}} = -4.2 p_0$ induced by the $k_z$ gradient is larger than the maximum $\Delta p_{\text{max}} = 1.76 p_0$ induced by the $E_v$ gradient. This indicates that the pore pressure ($p$) is more sensitive to the permeability ($k_z$) distribution gradient.

![Figure 5](image-url) Quantitative study on the maximum pore pressure discrepancies ($\Delta p_{\text{max}}$) due to (a) the Young’s modulus gradient and (b) the permeability gradient.

Figure 6 shows the comparison of soil effective stresses ($\sigma'_{z_{\text{max}}}$) with (solid line) and without (red dashed line) the gradient terms of the governing equations for a non-homogeneous seabed. It is shown that the soil effective stresses ($\sigma'_{z_{\text{max}}}$) vanish at the seabed surface because there is no compaction of soil particles there. It is seen in Figure 6a-c (the change in the $E_v$ gradient with constant $k_z$) that the soil effective stresses ($\sigma'_{z_{\text{max}}}$) increase if the gradient of Young’s modulus is neglected. The largest discrepancy in the soil effective stresses ($\Delta \sigma'_{z_{\text{max}}}$) is found at the seabed bottom. This phenomenon is similar to that of the pore pressure ($p_{\text{max}}$) distribution (Figure 4), except that the discrepancy in the soil effective stresses ($\Delta \sigma'_{z_{\text{max}}}$) is much larger than that with pore pressure. Figure 6a,d,g (the change in the $k_z$ gradient with constant $E_v$) show that the soil effective stresses ($\sigma'_{z_{\text{max}}}$) increase if the permeability gradient is neglected. The discrepancy in the soil effective stresses ($\Delta \sigma'_{z_{\text{max}}}$) caused by the permeability gradient is insignificant and mainly appears at the upper seabed. Finally, Figure 6e,f,h,i (non-homogeneous $E_v$ and $k_z$) demonstrate that the soil effective stresses ($\sigma'_{z_{\text{max}}}$) increase if the gradients of properties (both $E_v$ and $k_z$) are neglected. It is also found that the distribution pattern of $\sigma'_{z_{\text{max}}}$ in the case $\xi_{22}$, $\xi_{33}$ is similar to that in the case $\xi_{12}$, while $\sigma'_{z_{\text{max}}}$ in $\xi_{32}$, $\xi_{33}$ is similar to that in $\xi_{13}$. This means that the Young’s modulus distribution gradient ($\partial E_v / \partial z$) dominates the distribution pattern of $\sigma'_{z_{\text{max}}}$.

Figure 7 is the quantitative analysis of the maximum soil effective stress discrepancy ($\Delta \sigma'_{z_{\text{max}}}$) caused by (a) the Young’s modulus gradient and (b) the permeability gradient. It is found that the discrepancy in the soil effective stresses ($\Delta \sigma'_{z_{\text{max}}}$) with $\xi_{11}$ is equal to zero, which is also the case for the homogeneous seabed. Figure 7a illustrates the $\Delta \sigma'_{z_{\text{max}}}$ for $\xi_{11}$, $\xi_{12}$ and $\xi_{13}$, and it shows the gradient effect of Young’s modulus on the soil effective stresses. Figure 7b reveals that $\Delta \sigma'_{z_{\text{max}}} = 6.7 p_0$ for the case $\xi_{12}$ and $\Delta \sigma'_{z_{\text{max}}} = 74.7 p_0$ for the case $\xi_{13}$. These results indicate that the largest effect of the Young’s modulus gradient on the soil effective stresses occurs when the variation in $E_v$ (case $\xi_{13}$) is...
exponential. In addition, Figure 7a also shows $\Delta\sigma'_{z_{\text{max}}}$ for $\xi_{11}$, $\xi_{21}$, and $\xi_{31}$, and it shows the effect of the permeability gradient ($\partial k_z / \partial z$) on the soil effective stresses. It is seen that $\Delta\sigma'_{z_{\text{max}}} = 2.7p_0$ for the case $\xi_{31}$ is larger than $\Delta\sigma'_{z_{\text{max}}} = 1.2p_0$ for the case $\xi_{21}$, indicating that the permeability gradient has a greater effect for the exponential variation of $k_z$ ($\xi_{31}$). It is also found that the maximum $\Delta\sigma'_{z_{\text{max}}} = 74.7p_0$ caused by the $E_v$ distribution gradient is much larger than the maximum $\Delta\sigma'_{z_{\text{max}}} = 2.7p_0$ caused by the $k_z$ distribution gradient. This indicates that the distribution of soil effective stresses ($\Delta\sigma_z'$) is more sensitive to the Young’s modulus ($E_v$) distribution gradient.

The above quantitative analysis (Figures 5 and 7) involves the cases of only non-homogeneous Young’s modulus ($E_v$) with constant permeability ($k$) (case $\xi_{12}$, $\xi_{13}$) or the cases of only non-homogeneous permeability ($k$) with constant Young’s modulus ($E_v$) (case $\xi_{21}$, $\xi_{31}$). Figure 8 illustrates the quantitative analysis of $\Delta p_{\text{max}}$ and $\Delta\sigma'_{z_{\text{max}}}$ for non-homogeneous seabed with both non-homogeneous permeability and Young’s modulus ($\sigma_{22}$, $\xi_{23}$, $\xi_{32}$, and $\xi_{33}$). It clearly shows that all the values of $\Delta\sigma'_{z_{\text{max}}}$ are positive, while all $\Delta p_{\text{max}}$ values are negative, which indicates that the soil effective stresses $\sigma_z'$ (pore pressure $p$) increase (decrease) if the property gradient is neglected.
In addition, the discrepancies $\Delta \sigma'_{z_{\text{max}}}$ (4.5\%$p_0$, 5\%$p_0$, 68.7\%$p_0$, and 68.9\%$p_0$) are generally greater than $\Delta p_{\text{max}}$ ($-2.7\%p_0$, $-4.8\%p_0$, $-2.64\%p_0$, and $-4.76\%p_0$). This confirms, by comparison with the pore pressure ($p$), that the soil effective stresses ($\sigma'_z$) are more easily affected by the property distribution gradient of a non-homogeneous seabed.

**Figure 8.** Quantitative analysis of the discrepancies in pore pressure and soil effective stresses for a seabed with both non-homogeneous permeability and Young’s modulus (cases $\xi_{22}$, $\xi_{23}$, $\xi_{32}$, and $\xi_{33}$).

4. 3D Non-Homogeneous Seabed around a Mono-Pile

A mono-pile is commonly used as a support for marine structures, such as offshore wind turbines, platforms, and sea bridges. Most previous studies have indicated that the long-term rocking of a mono-pile will cause size sorting of the soil particles around the pile. This may be because smaller-sized particles have high mobility and can move into the deep seabed. As a result, a 3D non-homogeneous seabed is generated accordingly. This inverse grading of soil particles is referred to as the “Brazil nut effect” [40,41]. Cuéllar et al. [41] experimentally investigated particle size sorting around a long-term rocking mono-pile. They found that two seabed zones, named the convected zone (within the inverted cone in Figure 9a) and static zone (outside the inverted cone in Figure 9a), emerged around the mono-pile after approximately 5 million cycles of rocking (horizontal) of the pile (Figure 9). Particle
size sorting is only found within the convected zone, in which the relatively coarser soil is at the upper part, while the relative finer soil is at the lower part of the seabed. It is noted that the seabed in the static zone is not affected by the rocking of the pile.

On the basis of the study by Cuéllar et al. [41], this study assumes a homogeneous seabed within the static zone and a non-homogeneous seabed within the convected zone (Figure 9b). The radius of the convected zone at the seabed surface is three times that of the pile radius ($R_p$), and the depth is $1/3$ times the pile insertion length ($l_p$). In addition, with increasing depth, the soil permeability decreases while Young’s modulus increases. The linear relationship of soil property variation is adopted for the first approximation. The interface between the convected zone and the static zone is described as

$$S_1 = \sqrt{x^2 + y^2} = -\frac{z^2}{4} - \frac{5z}{8} + 3R_p \quad (-\frac{1}{3}R_p \leq z \leq 0),$$

where $S_1$ is the distance from the interface to the middle line of the pile (Figure 9b), which is depth-dependent in this study. Note that Zhang et al. [33] only adopted a linear wave theory in which wave transformations around the mono-pile were not considered. In this study, the non-homogeneous seabed response is investigated while considering wave reflection and diffraction. Furthermore, the discrepancies in pore pressure ($p$) and soil effective stresses ($\sigma'_z$) caused by the property distribution gradient in a non-homogeneous seabed are examined. The pile radius ($R_p$) is set at 2.5 m and the pile insertion depth ($l_p$) is 8 m. Other parameters for the wave and seabed are listed in Table 2, and the sketch of the model setup is illustrated in Figure 9b.

Figure 10 illustrates the distribution of maximum pore pressures for (a) a non-homogeneous seabed ($p_{1\text{max}}$), (b) a homogeneous seabed ($p_{2\text{max}}$), and (c) their difference ($\Delta p_{\text{max}}$) around a mono-pile foundation. It is found that the magnitude of pore pressures is larger at the head of pile than at the rear. This is because the wave reflection in front of the pile will lead to greater wave loading there. By comparing Figure 10a with Figure 10b, it can also be found that the pore pressure a with non-homogeneous seabed is much larger than that with a homogeneous seabed. The largest difference caused by non-homogeneous soil properties is in front of the pile (Figure 10c). This is because the soil permeability is larger in the convected zone of the non-homogeneous seabed, thus making it easier for the pore pressure to penetrate the seabed.
Table 2. Wave and seabed parameters used in this study (3D case).

| Item          | Parameter                  | Notation | Magnitude | Unit   |
|---------------|----------------------------|----------|-----------|--------|
| Wave          | Wave height                | $H$      | 0.4       | m      |
|               | Wave period                | $T$      | 4         | s      |
|               | Water depth                | $d$      | 4         | m      |
| Static zone   | Soil permeability          | $k$      | $1 \times 10^{-3}$ | m/s |
|               | Soil Young’s modulus       | $E$      | 0.05      | GPa    |
|               | Soil porosity              | $n$      | 0.3       | -      |
|               | Soil Poisson’s ratio       | $\mu$    | 0.333     | -      |
|               | Soil saturation degree     | $S_r$    | 0.992     | -      |
|               | Soil density               | $\rho$   | $2.65 \times 10^3$ | kg/m$^3$ |
| Convected zone| Soil permeability          | $k$      | $9 \times 10^{-4}z + 3 \times 10^{-3}$ | m/s |
|               | Soil Young’s modulus       | $E$      | $-11 \times 10^{-3}z + 0.035$ | GPa |
|               | Soil porosity              | $n$      | 0.3       | -      |
|               | Soil Poisson’s ratio       | $\mu$    | 0.333     | -      |
|               | Soil saturation degree     | $S_r$    | 0.985     | -      |
|               | Soil density               | $\rho$   | $2.65 \times 10^3$ | kg/m$^3$ |

Figure 10. The distribution of maximum pore pressures with (a) a non-homogeneous ($p_{1\text{max}}$) (b) a homogeneous seabed ($p_{2\text{max}}$), and (c) their difference ($\Delta p_{\text{max}}$) around a mono-pile foundation.

Figure 11 illustrates the distribution of maximum soil effective stresses for (a) a non-homogeneous seabed ($\sigma_{1\text{max}}^\prime$), (b) a homogeneous seabed ($\sigma_{2\text{max}}^\prime$), and (c) their difference ($\Delta \sigma_{\text{max}}^\prime$) around a mono-pile foundation. Similar to the pore pressure (Figure 10), the soil effective stresses are also larger in front of the pile because of wave reflection and diffraction (Figure 11a,b). However, contrary
to the larger pore pressure found with a non-homogeneous seabed (Figure 10), the soil effective stresses are smaller if a non-homogeneous seabed is considered (Figure 11c). This is because the total force of the soil skeleton will be balanced by the combination of pore pressure and soil effective stresses. Therefore, the increase in pore pressure in a non-homogeneous seabed will naturally lead to a decrease in the soil effective stresses.

![Figure 11](image_url)

**Figure 11.** The distribution of maximum soil effective stresses with (a) a non-homogeneous seabed ($\sigma'_{z_{1_{\text{max}}}}$), (b) a homogeneous seabed ($\sigma'_{z_{2_{\text{max}}}}$), and (c) their difference ($\Delta\sigma'_{z_{\text{max}}}$) around a mono-pile foundation.

Figures 10 and 11 above compares the seabed response between a non-homogeneous and homogeneous seabed. Next, Figure 12 illustrates the discrepancy in (a) the pore pressure and (b) the soil effective stresses caused by the soil property gradient term in a non-homogeneous seabed around a mono-pile (in the $x$-direction, $y = 0$, $z = -1.43$ m). The convected zone and static zone are specified around the mono-pile (Figure 12). It is found that the pore pressure ($p$) and the soil effective stresses ($\sigma'_z$) increase (decrease) in front (at the rear) of the mono-pile because of the wave reflection and diffraction. In addition, the gradient term of non-homogeneous soil properties has a great influence on the distribution of $p$ and $\sigma'_z$. Specifically, the pore pressure decreases (Figure 12a) while the soil effective stresses increase (Figure 12b) if the gradient term is neglected. This is consistent with the main findings of the gradient effects on $p$ (Figure 4) and $\sigma'_z$ (Figure 6) for the 2D case in this study. In addition, the discrepancy in the pore pressure ($\Delta p$) and the soil effective stresses ($\Delta \sigma'_z$) is found to be larger in front of the pile ($\Delta p_{\text{max}} = 0.12 p_0$, $\Delta \sigma'_{z_{\text{max}}1} = 0.25 p_0$) in comparison with that found at the rear ($\Delta p_{\text{max}} = 0.08 p_0$, $\Delta \sigma'_{z_{\text{max}}1} = 0.17 p_0$), which is probably because the wave pressure is larger there (see the relevant discussions in Figures 10 and 11). This indicates that the effect of the soil property distribution gradient on the seabed response is larger in front of the pile. It can be seen
that the maximum discrepancy in the pore pressure ($\Delta p_{\text{max}1}$) caused by the distribution gradient is $0.12p_0$ (Figure 12a), while the maximum discrepancy in the soil effective stresses ($\Delta \sigma'_{z\text{max}1}$) is $0.25p_0$ (Figure 12b). This confirms that the soil property distribution gradient has a more significant effect on the soil effective stresses than on the pore pressure within the non-homogeneous seabed around the mono-pile.

![Figure 12](image_url)

**Figure 12.** The discrepancy in (a) the pore pressure and (b) the soil effective stresses caused by the soil property gradient term in a non-homogeneous seabed around a mono-pile (in the $x$-direction, $y = 0$, $z = -1.43$ m).

Figure 13 shows the discrepancy in (a) the pore pressure and (b) the soil effective stresses caused by the soil property gradient term in a non-homogeneous seabed around a mono-pile (in the $y$-direction, $x = 0$, $z = -1.43$ m). In contrast to Figure 12, the distribution of pore pressure ($p$) and soil effective stresses ($\sigma'_z$) is found to be symmetric about the middle line of the pile ($y = 0$). This is because the dynamic wave pressure behaves symmetrically at the sides (in the $y$-direction) of the pile. Consequently, this generates symmetry in the discrepancy of the pore pressure ($\Delta p$) and the soil effective stresses ($\Delta \sigma'_z$), indicating that the effect of the gradient term on the soil dynamic response is also symmetric. Figure 13 also illustrates that the maximum discrepancy in the soil effective stresses ($\Delta \sigma'_{z\text{max}3}$) is $0.14p_0$, which is larger than that of $\Delta p_{\text{max}3}$. This indicates that the distribution gradient of the soil properties has a more significant influence on the soil effective stresses at the sides of the pile ($y$-direction).
Figure 13. The discrepancy in (a) the pore pressure and (b) the soil effective stresses caused by the soil property gradient term in a non-homogeneous seafloor around a mono-pile (in the y-direction, \( x = 0, \) \( z = -1.43 \) m).

Figure 14 further illustrates the discrepancy in (a) the pore pressure and (b) the soil effective stresses caused by the soil property gradient term in a non-homogeneous seafloor around a mono-pile (in the z-direction, \( x = -1.5 \) m, \( y = 0 \)). Figure 14 shows that the pore pressure \( (p) \) decreases from the seafloor surface to the deep seafloor; this is because of the natural attenuation of pore pressure with increasing seafloor depth (Jeng, 2012). The soil effective stresses \( (\sigma_z') \) are seen to initially increase then decrease quickly when it deepens in the vertical direction. This is because the soil effective stresses are equal to zero at the seafloor surface (because there is no compaction of the soil particles) and reach the minimum in the deep seafloor (because there is minimal influence from wave loading). Compared with the pore pressure \( (\Delta p_{\text{max}4} = 0.1 p_0) \), the soil effective stresses \( (\Delta \sigma_{\text{zmax}3} = 0.22 p_0) \) are much more affected by the gradient term of the soil property. This is similar to that of Figure 12 (x-direction) and Figure 13 (y-direction), indicating that this conclusion is applicable in the 3D space of a non-homogeneous seafloor. In addition, Figure 14 also shows that the maximum discrepancy in the pore pressure \( (\Delta p_{\text{max}4} = 0.1 p_0) \) and the soil effective stresses \( (\Delta \sigma_{\text{zmax}3} = 0.22 p_0) \) occurs around the interface (the dashed line) between the convected zone and the static zone. This is perhaps because the soil properties change considerably (large gradient term) at the interface, and it indicates that the property distribution gradient has the largest effect on the seafloor response in that location in the vertical direction.
Figure 14. The discrepancy in (a) the pore pressure and (b) the soil effective stresses caused by the soil property gradient term in a non-homogeneous seabed around a mono-pile (in the $z$-direction, $x = -1.5$ m, $y = 0$).

5. Liquefaction

Liquefaction occurs if the excess pore-water pressure exceeds the overburden soil weight. This leads to the disappearance of soil effective stresses, thus potentially causing seabed instability around marine structures. In this section, the effects of the soil distribution gradient on the liquefaction depth are investigated. Parametric studies with various soil and wave parameters are also presented to examine the importance of the distribution gradient terms. For simplicity, the 2D propagating wave cases are adopted when the linear wave theory is used. The liquefaction criterion can be expressed as

$$\max(p - p_b) > \gamma_w z$$

where $\gamma_w$ is the submerged weight of the soil.

Figure 15 illustrates the comparison of the liquefaction depth between cases with (solid line) and without (dashed line) the distribution gradient terms of non-homogeneous soil properties. The curves are the values of $\{\max(p - p_b) - \gamma_w z\}$; thus, the liquefaction depth can be denoted by the interaction points between the curve ($\{\max(p - p_b) - \gamma_w z\}$) and the vertical line of $x = 0$. It can be observed that the seabed can be liquefied around the seabed surface ($z > -0.1$ m). The liquefaction depth with the distribution gradient terms ($ld_1 = -0.72$ m) is larger than that without the distribution gradient terms ($ld_1 = -0.7$ m). The present numerical results indicate that common approaches that neglect the distribution gradient terms will underestimate the liquefaction of a non-homogeneous seabed.

Parametric studies on the importance of the distribution terms are illustrated in Figure 16. The non-dimensional ratio of $(ld_1 - ld_2)/ld_2$ is adopted as the indicator of the degree of importance, which is plotted with various wave and seabed parameters. It is found that the ratio $(ld_1 - ld_2)/ld_2$ increases with increasing wave height ($H$) and decreasing wave period ($T$) and water depth ($d$). It does not notably change with the degree of saturation ($S_r$). This indicates that the effects of the distribution gradient terms will be more pronounced with larger wave heights, lower wave periods, and lower water depth.
Figure 15. Comparison of non-homogeneous seabed liquefaction between cases with (solid line) and without (dashed line) distribution gradient terms of non-homogeneous soil properties.

Figure 16. Parametric studies on the importance of the distribution terms to the liquefaction depth with various (a) wave heights $H$ ($T = 8$ s, $d = 8$ m, $S_r = 0.980$), (b) wave periods $T$ ($H = 3$ m, $d = 8$ m, $S_r = 0.98$), (c) water depths $d$ ($H = 3$ m, $T = 8$ s, $S_r = 0.98$), and (d) degree of saturation $S_r$ ($H = 3$ m, $T = 8$ s, $d = 8$ m) (the other parameters are found in Figure 15).

It should be noted that, the above discussions on the liquefaction are called the “potential liquefaction”, which means the prediction of the possible maximum liquefaction depth that can be reached with the wave loadings. These are based on the assumption of the static elastic porous seabed. Qi and Gao [42] noted that the seabed liquefaction would shift downward the interface between the seabed and fluid, thus decreasing the liquefaction depth. This means the liquefaction depth predicted in this study is conservative to the engineering practice. Similar research and assumptions can be extensively seen in the previous studies [4,19,32,43]. The simulations on the soil behaviour after the real liquefaction moment may need more sophisticated models, which would be considered in our future studies.
6. Discussion

The distribution gradient of soil properties naturally exists in the governing equations for the wave-induced non-homogeneous seabed response (Equations (21)–(27)). Most previous studies [28,29] have neglected the soil distribution gradient terms by simply adopting the assumption of a layered seabed. A few studies [30,33] considered the gradient terms when simulating the non-homogeneous seabed response; however, the corresponding effect was not quantitatively investigated. The study herein fills this gap by carefully examining the effect of the distribution gradient of soil properties on the dynamic response of a non-homogeneous seabed.

The distributions of the pore pressure ($p$) and the effective stresses ($\sigma'_z$) with and without the property gradient terms are simulated for nine cases ($\xi_{ij}$) of a 2D non-homogeneous seabed. Results show that the pore pressure (the soil effective stresses) decreases (increase) if the soil distribution gradient term is neglected (see Figures 4 and 6). A large discrepancy in the pore pressure and large soil effective stresses due to the property gradient term occur respectively at the upper seabed and the lower seabed. This means that the largest effect of the property distribution gradient takes place at the upper part of the seabed for the pore pressure, while the largest effect appears at the lower part of the seabed for the soil effective stresses. In addition, pore pressure significantly changes as a result of the change in the permeability gradient (Figure 5), while soil effective stresses significantly change as a result of the change in the Young’s modulus gradient (Figure 7). This indicates that the soil effective stresses and the pore pressure are more sensitive to the distribution gradient of the soil Young’s modulus and permeability, respectively. The maximum discrepancy in the soil effective stresses caused by the soil distribution gradient is about 68.9% ($p_0$) (see Figure 8), indicating that the property distribution gradient cannot be neglected in the governing equations, especially for cases in which the soil effective stresses are the main concern.

The discrepancy in the pore pressure and the soil effective stresses caused by the soil property distribution gradient is investigated for the 3D non-homogeneous seabed around a mono-pile foundation (Figures 9–14). The wave reflection and diffraction phenomenon is considered in the vicinity of the mono-pile. It is found that the conclusions obtained from the 2D case can be extended to the 3D case of the non-homogeneous seabed around the mono-pile. In spite of this, the effect of the soil property distribution gradient on the non-homogeneous seabed response is found to be significantly affected by wave transformations around the pile. The discrepancy in the pore pressures and the soil effective stresses caused by the property distribution gradient is larger in front of the pile than at the rear of the pile. This is because the relatively large wave loading occurs in front of the pile. In addition, a large discrepancy in the seabed variables (i.e., the pore pressure and the soil effective stresses) are found at the convected/static zone interface within the 3D non-homogeneous seabed, indicating that this location is much more influenced by the property distribution gradient than the other part.

Effects of the soil distribution gradient on the liquefaction are also examined in this study. It is found that the liquefaction depth can be underestimated if the distribution gradient terms are neglected. However, it has to be acknowledged that the discrepancy in the liquefaction depth due to the gradient terms are within 3%. This is because the liquefaction occurs at the seabed surface, where there are minor discrepancies of pore pressure caused by the gradient terms (see Figure 4). Therefore, the distribution gradient terms can be neglected in the evaluation of liquefaction in engineering practice.

7. Conclusions

Using a 3D Fully Dynamic (FD) seabed model, this study numerically investigated the effect of the soil property distribution gradient on the non-homogeneous seabed response by adding the gradient terms to the governing equations. The model was well validated by comparing results with available experimental and field measurements. A 2D vertical non-homogeneous seabed case and a 3D non-homogeneous seabed case around a mono-pile were simulated to evaluate the effect of the soil property distribution gradient in different environmental situations. The following conclusions can be drawn:
(1) The pore pressure will decrease while the soil effective stresses will increase if the gradient term of non-homogeneous soil properties is neglected. This influence is much more remarkable for the soil effective stresses, for which the maximum discrepancy can reach 68.9% of $p_0$ for the current cases.

(2) The above effects mainly occur at the upper part of the seabed for pore pressure, while they are more pronounced at the lower part of the seabed for soil effective stresses.

(3) For the non-homogeneous seabed around the mono-pile, the largest effect from the soil property distribution gradient is found in front of the pile, which is the result of wave reflection and diffraction. In the vertical direction, it will occur around the interface of the convected/static zone because this is where the largest change in soil properties occurs.

(4) The effects of the soil distribution gradient on liquefaction increase with the increase (decrease) in wave height (wave period and water depth). The above effects cause a discrepancy in the liquefaction depth of less than 3% for a non-homogeneous seabed.

It should be noted that this study only considered soil properties that vary in space. The much more complex cases with time- and space-based non-homogeneous variables need more advanced models, which may be considered in a future study. The main contribution of this study is the clarification of the effects of the soil distribution gradient on the wave-induced response and liquefaction of a non-homogeneous seabed. This study concludes that the soil distribution gradient terms can significantly affect the soil effective stresses, but such effects on the liquefaction depth are limited. This validates the usage of the simplified approach (neglects the gradient terms) in the evaluation of seabed liquefaction; however, it should be attended to carefully when soil effective stresses are involved.

Author Contributions: Conceptualization, methodology and formal analysis, T.S.; Formal analysis, Y.J., Z.W., J.S.; Supervision, C.Z.

Funding: This research was funded by the National Natural Science Foundation (Grant No. 51909076), the Fundamental Research Funds for the Central Universities (2017B15814), the International Postdoctoral Exchange Fellowship Program (20170014), the National Natural Science Foundation (Grant No. 41706087; Grant No. 51879096), the National Science Fund for Distinguished Young Scholars (Grant No. 51425901), Natural Science Foundation of Jiangsu Province (Grant No. BK20161509), Marine Science and Technology Innovation Project of Jiangsu Province (HY2018-15).

Acknowledgments: The authors thank for the three anonymous reviewers for their critical comments helping us to improve this paper.

Conflicts of Interest: The authors declare no conflict of interest.
