Abstract

Preliminary results are presented from the CLEF hydrodynamics simulation, a large \((N = 2 \times 428^3\) particles within a 200 \(h^{-1}\) Mpc comoving box) simulation of the \(\Lambda\)CDM cosmology that includes both radiative cooling and a simple model for galactic feedback. Specifically, we focus on the X-ray properties of the simulated clusters at \(z = 0\) and demonstrate a reasonable level of agreement between simulated and observed cluster scaling relations.

Key words: cosmology, clusters of galaxies, X-ray, numerical simulations, hydrodynamics, galaxy formation

1 Introduction

As the largest and latest virialised structures to form, galaxy clusters are especially useful cosmological probes (e.g. see \cite{Viana2003} and references therein). Next generation cluster cosmology surveys, such as the XCS \cite{Romer2001}, will detect sufficiently large numbers of clusters that uncertainties in values of cosmological parameters will be mainly systematic, requiring for example an accurate calibration between cluster X-ray temperature and mass. Such measurements demand an improved understanding of

cluster physics, therefore realistic numerical simulations of the cluster population are essential.

In this paper we present a preliminary analysis of the $z = 0$ cluster population within the CLEF hydrodynamics simulation, a large state-of-the-art cosmological simulation that, besides gravity and gas dynamics, includes a model for the effects of galaxy formation. As we will show, the simulation does a reasonably good job at reproducing X-ray scaling relations at $z = 0$.

2 The CLEF hydrodynamics simulation

The CLEF (CLuster Evolution and Formation) hydrodynamics simulation (see Fig 1) is a large simulation of structure formation within the ΛCDM cosmology, with the following cosmological parameters: $\Omega_m = 0.3$, $\Omega_A = 0.7$, $\Omega_b h^2 = 0.0238$, $h = 0.7$ and $\sigma_8 = 0.9$. These values are in good agreement with recent WMAP analyses (Spergel et al., 2003).

Initial conditions were generated using a modified version of the COSMIC software package provided with the HYDRA code (Couchman, Thomas and Pearce, 1995). The appropriate transfer function, generated using CMBFAST (Seljak and Zaldarriaga, 1996), was read in and a displacement field generated for a $200 h^{-1}$ Mpc comoving box at $z = 49$. Two regular cubic grids of $428^3$ particles, separated by half the interparticle distance in each of the $x$, $y$ and $z$ directions, were then perturbed by these displacements to create the initial particle positions. Thus, the gas and dark matter particle masses were set to $m_{\text{gas}} = 1.4 \times 10^9 h^{-1} M_\odot$.
and \( m_{\text{dark}} = 7.1 \times 10^9 h^{-1} \, M_\odot \) respectively.

This initial configuration was then evolved to \( z = 0 \) using version 2 of the GADGET code [Springel, Yoshida and White, 2001], a hybrid Particle-Mesh/Tree gravity solver with a version of Smoothed Particle Hydrodynamics (SPH) that explicitly conserves entropy where appropriate. In addition, the gas could cool radiatively, assuming a fixed metallicity of \( Z = 0.3 Z_\odot \). Cooled gas, with \( n_\text{H} > 10^{-3} \, \text{cm}^{-3} \) and \( T < 1.2 \times 10^4 \, \text{K} \), could either form stars if \( r > f_{\text{heat}} \) or be reheated by stars if \( r < f_{\text{heat}} \), where \( r \) is a random number drawn for each particle from the unit interval and \( f_{\text{heat}} = 0.1 \) is the reheated mass fraction parameter. Each reheated gas particle was given a fixed amount of entropy, \( S_{\text{heat}} = 1000 \, \text{keV} \, \text{cm}^2 \), where \( S \equiv kT/n^{2/3} \), which further heats the ICM as the particle does work on its surroundings. Further details may be found in Kay et al. (2004).

3 X-ray scaling relations at \( z = 0 \)

In this paper, we concentrate on comparing a selection of simulated and observed X-ray cluster scaling relations at \( z = 0 \). Clusters were identified by first identifying local maxima in the density field and growing spheres around these maxima until the average density within each sphere was a fixed factor, \( \Delta \), above the critical density, \( \rho_{\text{cr}} = 3 H_0^2 / 8 \pi G \). Values of \( \Delta \) used will be given in each subsection. For the virial density (\( \Delta \sim 10^4 \)) there are > 400 clusters with \( kT_{\text{vir}} > 1 \, \text{keV} \) (> 60 above 3 keV).

3.1 Temperature–mass relation

We begin by showing in Fig. 2 the relation between hot gas mass-weighted temperature (\( T_{\text{gas}} \equiv \Sigma_i m_i T_i / \Sigma_i m_i \), where the sum is over all gas particles with \( T_i > 10^9 \, \text{K} \)) and total mass for a density contrast \( \Delta = 2500 \). All clusters with \( M_{2500} > 3 \times 10^{14} h^{-1} \, M_\odot \) are considered. The dashed line is a best-fit relation to the clusters for a fixed slope of \( 2/3 \), as expected if the clusters form a self-similar population. This relation is

\[
\log(kT_{\text{gas}}/\text{keV}) = (0.614 \pm 0.003) + (2/3) \log(M_{2500}/M_{14}),
\]

where \( M_{14} = 10^{14} h^{-1} \, M_\odot \). When the slope is allowed to vary, the best-fit relation (solid line) is

\[
\log(kT_{\text{gas}}/\text{keV}) = (0.608 \pm 0.004) + (0.65 \pm 0.01) \log(M_{2500}/M_{14}),
\]
Fig. 2. Gas mass-weighted temperature versus mass, evaluated at $\Delta = 2500$. The dashed line is the best-fit relation with the self-similar slope $2/3$. The solid line is the best-fit relation, allowing both the normalisation and slope to vary. The solid band is the best-fit relation to clusters studied by Allen, Schmidt and Fabian (2001). It is more common in the literature for observed temperature-mass relations to be presented at larger radii, using spectroscopic (photon-weighted) temperatures and mass estimates assuming $\beta$-model surface brightness profiles and polytropic-model temperature profiles (e.g. Nevalainen, Markevitch and Forman 2000; Finoguenov, Reiprich and Böhringer 2001; Sanderson et al. 2003). These results generally suggest a slope closer to $1/2$ than $2/3$, attributed to non-gravitational processes (see below), and a normalisation that is offset in mass from simulation predictions by $\sim 40$ per cent. Examining, for example, the X-ray emission-weighted temperature-mass relation from our simulation at $r_{500}$, $T_X - M_{500}$ [$T_X \equiv \Sigma_i m_i n_i \Lambda(T_i) T_i / \Sigma_i m_i n_i \Lambda(T_i)$, where $\Lambda$ is an energy-dependent cooling function], we find a similar slope to the observations ($0.53$) but an offset in normalisation comparable to previous simulations. The cause of this offset is likely due to incorrect estimates of cluster masses (e.g. Rasia et al., 2004) and is something we will return to in a future paper.

3.2 Entropy–temperature relation

Galaxy formation increases the entropy of intracluster gas, producing a relationship with temperature that is flatter than the self-similar scaling ($S \propto T$). We plot this relation in Fig. 3, again using an X-ray emission-weighted temperature for each cluster. Two radii are considered ($0.1r_{200}$ and $r_{500}$) and only clusters with $kT_X > 1\text{keV}$ are studied. Again, the simulated clusters are in reasonably good agreement with the observations (Ponman, Sanderson and Finoguenov).
Fig. 3. Entropy versus X-ray emission-weighted temperature at $0.1r_{200}$ (lower points) and $r_{500}$ (upper points), with the solid lines being fits to these data. Crosses are data from Ponman, Sanderson and Finoguenov (2003) and dashed lines are self-similar scalings, normalised to their hottest clusters.

2003, containing an excess of entropy that is larger in smaller systems. For $0.1r_{200}$

$$\log\left(\frac{S}{\text{keV cm}^2}\right) = (2.14 \pm 0.008) + (0.46 \pm 0.03) \log\left(\frac{kT_X}{\text{keV}}\right)$$  \hspace{1cm} (3)

and for $r_{500}$

$$\log\left(\frac{S}{\text{keV cm}^2}\right) = (2.84 \pm 0.003) + (0.63 \pm 0.01) \log\left(\frac{kT_X}{\text{keV}}\right).$$  \hspace{1cm} (4)

3.3 Luminosity–temperature relation

Finally, we show bolometric X-ray luminosity versus X-ray emission-weighted temperature in Fig. 4. Again, only clusters with $kT_X > 1\text{keV}$ are considered. Symbols with errors are observational data from Markevitch (1998) and Arnaud and Evrard (1998). To remain approximately consistent with this data, emission from within $50\,h^{-1}\text{kpc}$ of our simulated cluster centres is omitted.

The dashed line is a best-fit relation for a fixed slope equal to 2 (self-similar), clearly a poor fit to the observations. When the slope is allowed to vary, the best-fit relation (solid line) is

$$\log\left(\frac{L_X}{L_{40}}\right) = (1.89 \pm 0.01) + (3.84 \pm 0.05) \log\left(\frac{kT_X}{\text{keV}}\right),$$  \hspace{1cm} (5)

where $L_{40} = 10^{40}\,h^{-2}\text{erg s}^{-1}$, considerably steeper than the self-similar case. In fact, the simulated relation is not adequately described by a power law since...
the local gradient becomes progressively flatter with increasing temperature. Fitting clusters with $kT_X > 3\text{keV}$ (dot-dashed line) yields

$$\log(L_X/L_{40}) = (2.47 \pm 0.03) + (2.88 \pm 0.05) \log(kT_X/\text{keV}),$$

(6)

in reasonable agreement with the observations although the normalisation is a bit too high. Better agreement was reached by Kay et al. (2004), who used a slightly smaller gas fraction (0.15 rather than 0.162 used here, which is a closer match to the WMAP value). It is likely however that fine tuning of the feedback model parameters would improve the agreement between the simulated and observed relations.
