Diatom ooze and diatomite–diatomaceous sediments in and around the North Pacific Ocean

Itaru Koizumi1* and Hirofumi Yamamoto2

The geographical distribution and geological occurrence of diatom ooze and diatomite–diatomaceous sediments were reviewed in and around the middle-high latitude of the North Pacific Ocean including the Bering and Japan seas. Diatoms are the most abundant microfossils found in the bottom sediments of the northern North Pacific Ocean, and the marginal Bering, Okhotsk and Japan seas. The marginal basins in the middle-high latitude of the North Pacific Ocean were formed by tectonic and volcanic activities in the late Oligocene–early Miocene. The early middle Miocene diatomite intercalated with siliceous sandstone to siltstone was deposited in shallow basins. The middle-late Miocene diatomite and diatomaceous mudstone was formed by global cooling and increased primary productivity under anoxic bottom-water conditions at bathyal depths. The late Miocene to early Pliocene diatomite and diatomaceous siltstone formed under oxic bottom-water conditions is widely distributed. During the late Pliocene-Pleistocene, turbidity sands and/or silts capped and diluted the diatomaceous sediment. The timing of these changes in sedimentary facies is simultaneous in the North Pacific region.

1. Introduction

Diatom ooze and diatomite–diatomaceous sediments occur concentrated in and around the middle to high latitudes of the North Pacific Ocean including the Bering, Okhotsk, and Japan seas. Diatom ooze contains large numbers of well-preserved diatom valves, which constitute more than 30% of the sediment components, and are formed by the sinking of abundant living diatoms in the surface water. The areas of diatom ooze coincide with nutrient-rich regions where high concentrations of nutrient such as nitrogen, phosphorous and silica are typically the result of upwelling ecosystem. With burial and compaction, the diatom ooze is transformed into the siliceous sedimentary rock diatomite, which consists of more than 50–60% amorphous silica (opal-A, SiO$_2$·nH$_2$O), the remains of diatom valves with the remainder made up of calcite, organic matter, and terrigenous components. Diatomite is diagenetically transformed into opal-CT (disordered cristobalite-tridymite) at temperatures between 50°C and 80°C (Hein et al., 1978). The diatomite and diatomaceous deposits form a remarkable belt of Neogene diatomaceous rock along the continental margins of the North Pacific rim, which develops in California, Oregon, Washington, the Aleutian Islands, the Kamchatka Peninsula, Japanese Islands, and the Korean Peninsula (Ingle, 1981).

Diatomite is easily crumbled into a fine white to light yellowish gray powder ranging from 10 to 200 μm in particle size. The powder is abrasive and has a low density as a result of its high porosity. The typical chemical composition of diatomite is 80 to 90% silica, with 2 to 4% alumina attributed to clay minerals, and 0.5 to 2% iron oxide. Therefore, diatomite is available commercially in several forms. It is a very famous story that Alfred Nobel (1833–1896) patented the properties of diatomite for the manufacture of dynamite, which could be transported and handled more safely than nitroglycerin and made a fortune during the late nineteenth century that now funds the Nobel prizes. After that, the major use of diatomite is in the following main categories: filtration including the purification of beer, liquors, and wine, the cleansing of greases and oils, production of cement, removal of microbial contaminations, mechanical insecticide, absorbent, matting agent, etc (Antonides, 1997; Crangle, 2013). Therefore, the most important field with the Nobel prizes should be “Material Sciences and Earth Sciences” than any other division.

The main purpose of this paper is to review the geographical distribution and geological occurrence based on the geological development of diatom ooze (diatomite) and diatomaceous sediments in and around the North Pacific Ocean including the Bering Sea and Japan Sea.

2. Diatom ooze and diatomaceous sediments in the North Pacific Ocean

Diatom ooze are concentrated in the middle to high latitudes of the North Pacific Ocean including the Bering, Okhotsk, and Japan seas (Fig. 1). Diatoms are present in the
Diatom ooze and diatomite–diatomaceous sediments in and around the North Pacific Ocean

surface sediments of the seafloor in the North Pacific Ocean and can be used to determine the characteristics of overlying water masses, even though considerable numbers of finely silicified diatom taxa living in surface waters may not be preserved in deep-sea sediments (Kanaya and Koizumi, 1966; Sancetta and Silvestri, 1986; Koizumi, 2008).

The modern North Pacific Ocean is subdivided into three different marine environments by the North Pacific Current which flows across the Pacific at around about 40°N latitude: (1) the Alaska Gyre containing cold nutrient-rich water, (2) the Subtropical Gyre containing warm nutrient-depleted waters, and (3) the Mixed Water Region of both subarctic and central water masses between 40°N and 42°N (Fig. 2).

The Kuroshio Current encounters the Oyashio cold water in the middle latitude of the western area of the North Pacific Ocean and forms a western boundary current. The California Current forms an eastern boundary current joining the flows from the Alaskan Current. The Tsushima Warm Current, a branch of the Kuroshio-bounded western side of the anti-cyclonical Subtropical Gyre, traverses the Japan Sea. Circulation in the subarctic Pacific Ocean is a cyclonic gyre with secondary gyres in the Okhotsk and Bering seas. They are sources for the subarctic water created by vertical and horizontal mixing. Diatom valves are generally well preserved in sediments under the subarctic Alaska Gyre, and the mixed zone of subarctic and central water masses (Fig. 1).

The North Pacific Ocean is the terminus of the deep ocean circulation route originating in the northern North Atlantic and the Southern oceans, and the beginning of the return surface circulation. These old and deep waters are nutrient-rich, oxygen-poor, and highly corrosive to calcium carbonate (Rea et al., 1995b).

2.1 Northwest Pacific Ocean

Both Sites 579 and 580 of the Deep Sea Drilling Project (DSDP) are located on the southern margin and in the north portion of the transition zone between the Subtropical and Alaska Subarctic gyres, respectively (Fig. 2). The transition zone defines the convergence of the Kuroshio and Oyashio currents, and is characterized by high biological productivity. The diatom abundances (%) are based on smear slide analyses by the on board sedimentologists (Shipboard

![Fig. 2. Surface currents in the modern North Pacific Ocean shown with DSDP and ODP drill sites used in this paper.](image-url)
Scientific Party, 1985a, 1985b), and the number of diatom valves per gram of dry sediment \(10^7\) valves/g are the results of diatom analyses by microscopic examination (Koizumi and Tanimura, 1985).

Site 579, at a water depth of 5737 m, obtained 149.5 m of thick lower Pliocene to Pleistocene siliceous clay. The diatom abundances vary according to lithological conditions of sedimentation (Fig. 3). High concentrations of diatoms, about \(5.0 \times 10^7\) valves/g, are recognized within the lower-upper Pliocene clayey diatom ooze in the interval of 149.5-102.5 mbsf (meters below sea floor). This unit contains 25–60% diatoms, averaging about 40% (Shipboard Scientific Party, 1985a). Site 580, at a water depth of 5375 m, obtained 155.3 m of thick upper Miocene to Pleistocene siliceous clay. The diatom abundances show wide fluctuations throughout the upper Pliocene to lower Pleistocene with an average of about \(6.0 \times 10^7\) valves/g and in the Pleistocene about \(5.0 \times 10^7\) valves/g. Diatom abundances increase from 10 to 70%, averaging about 30%. The clayey diatom ooze in the interval of 136.3-117.3 mbsf contains approximately 52% diatoms (Shipboard Scientific Party, 1985b).

At Site 435, 5240 m deep, located on a slightly flat part of the Japan Trench upper slope, lower Pliocene through lower Pleistocene diatom ooze including 30–50% diatoms was obtained from in 274.5-244.5 mbsf (Shipboard Scientific Party, 1980). Ocean Drilling Program (ODP) Site 1150, 2178 m deep, is located in the deep-sea terrace on the landward side of the Japan Trench. The upper Pleistocene at 0-1.56, 5.60 and 27.27-31.77 mbsf, and the upper Pliocene at 181.57 mbsf are mainly diatom ooze including 50–60% diatoms (Shipboard Scientific Party, 2000; Koizumi and Sakamoto, 2003).

At ODP Site 881, 5531 m deep, located in the deep northwestern Pacific Ocean, a total of 465.2 m thick of upper Miocene through Pleistocene diatom ooze was obtained (Shipboard Scientific Party, 1993a). Diatom abundances are consistently high within the late Miocene through Pliocene diatom ooze and, on average, greater than 80% in smear slide analyses (Fig. 3). At the Miocene/Pliocene boundary (5.4 Ma), the mass accumulation rate of diatoms was about \(0.4 \text{ g/cm}^2 \cdot \text{kyr}\) during the late Miocene, and increased to more than \(1.2 \text{ g/cm}^2 \cdot \text{kyr}\) in the early Pliocene (Shipboard Scientific Party, 1993a). Organic carbon increased and remained two to three-fold as much quantity in the ooze throughout the Pliocene and Pleistocene. After the Pliocene/Pleistocene boundary (2.6 Ma), volcanogenic and terrigenous materials increased. Diatom abundances are high, but variable, in the Pleistocene clayey diatom ooze, with minor amounts of diatom ooze, and generally range between 30% and 80% in the smear slide analyses (Fig. 3).

Paleoceanography since the warm Pliocene epoch in the middle latitudes of the northwestern Pacific Ocean was discussed based on diatom assemblages by Koizumi and Yamamoto (2013). The pre-glacial/glacial boundary occurred at 2.85-2.50 Ma in the Mixed Water Region around 40°N. Around 2.0 Ma, when the latitudinal thermal gradient between the equator and the subtropical/mid-latitudes steepened, and also just after the thermal gradient crossing west-to-east along the equator was formed, the major component of diatom assemblages changed from subtropical-warm neritic diatom *Thalassionema nitzschioides* s.l. to sub-littoral upwelling diatom *Chaetoceros* spores, which are a result of primary productivity.

### 2.2 Subarctic Pacific Transsect

Subarctic Pacific Ocean includes two major boundary currents, Oyashio and Alaskan currents, and an oceanic and atmospheric frontal zone, Subarctic Front (Fig. 2). Passes through the Aleutian and Kuril arcs provide exchange for deep waters, which exert a strong influence upon the properties of North Pacific Intermediate Water (Rea et al., 1995b). ODP Leg 145, crossed the subarctic Pacific Ocean and established that organic carbon and opal deposition was caused by the activity and productivity of the Oyashio and Alaskan currents in the North Pacific Ocean during the Neogene.

ODP Site 883 was drilled at a water depth of 2385 m on a level plateau near the summit of Detroit Seamount (Fig. 2). An 830 m-thick layer of sediment was obtained at Site 883, the interval of 458.0-86.9 mbsf is nearly pure diatom ooze during the time between late Miocene (6.8 Ma) and late Pliocene (2.6 Ma), and represents the rapid siliceous sedimentation with a silica flux of average 3.0 g/cm² · kyr (Shipboard Scientific Party, 1993b). Dropstones and ash layers are common to abundant in sediment younger than 2.6 Ma after the onset of Northern Hemisphere glaciation. The interval of 597-458 mbsf is middle to upper Miocene calcareous diatom ooze (Fig. 4). Site 884 was drilled at a water depth of 3826 m on the lower, northeastern flank of Detroit Seamount (Fig. 2), and obtained an 854 m-thick layer
Fig. 3. General lithology, diatom zone, diatom abundance, and diatom ooze of the sedimentary section at DSDP Sites 579 and 580 (Shipboard Scientific Party, 1985a, 1985b), and ODP Site 881 (Shipboard Scientific Party, 1993a) in the northwest Pacific Ocean. A and B at column of Geological Age correspond to A and B of the Site 881 column.
of Cenozoic sediment (Shipboard Scientific Party, 1993c). Based on the different proportions of clay to diatoms, and the distribution of ash layers and dropstones, the interval of 440.2–128.0 mbsf, age-assigned to the late Miocene to Pliocene, is composed of clayey diatom ooze with less volcanic ashes (Fig. 4). The interval of 604.0–546.1 mbsf, age-assigned to the middle Miocene, is composed of diatomite with clay or sponge spicules and contains no volcanic ashes.

Sites 885/886 were drilled at a water depth of 5713 m in the eastern margin of the Chinoook Trough in the central North Pacific Ocean (Shipboard Scientific Party, 1993d), and obtained a 66 m-thick layer of sediment overlying basalt (Fig. 4). The interval of 50.3–17.3 mbsf is an upper Miocene to lower Pliocene diatom ooze with clay, and diatom abundances range from 54% to 95% and, averaging 81%. Sedimentation rates in this interval are in the range of 5 to 6 m/kyr, which increase two to three times more than in other sedimentary sections. Especially, diatoms are abundant above 50 mbsf at 9 Ma.

Site 887 was drilled at a water depth of 3631 m in the Gulf of Alaska on the platform level of the Patton-Murray Seamounts (Shipboard Scientific Party, 1993e), and obtained a 289 m-thick layer of sedimentary sequence. The interval of 45.0 mbsf is Pleistocene diatomaceous silty clay (Fig. 4). 174–90 mbsf is pure diatom ooze of the latest Miocene-late Pliocene, 235–174 mbsf late Miocene calcareous diatom ooze, and 270–235 mbsf late to middle Miocene siliceous ooze. The mass accumulation rate of diatoms was more than 1.0 g/cm²·kyr through the latest Miocene (5.7 Ma) to Pliocene (2.6 Ma).

All of the sites from Site 881 to Site 887 drilled in Leg 145 showed a rapid accumulation rate of opal (mainly diatoms) during the late Miocene through late Pliocene, and declined at about 2.6 Ma, when major Northern Hemisphere glaciation was established (Fig. 4). The Meiji sediment tongue (Scholl et al., 1977) was recognized to be a drift deposit (Rea et al., 1995b). The Meiji Drift contains northern-source diatoms and minerals from the Bering Sea region, and has been accumulating since the early Oligocene. Those sediments were formed by a sediment-laden current moving south through the Kamchatka Strait from the Bering to the northwest Pacific Ocean (Creager, Scholl, et al., 1973; Scholl et al., 1977). The seismic reflection profiles suggest that the Meiji sediment tongue extends 2000 km along the eastern flank of the Emperor Seamount chain from the Kamchatka Strait, and was formed by southward-flowing deep-sea currents (Mammerickx, 1985).

2.3 California Margin

The California Current system is in the eastern boundary current system of the North Pacific Subtropical Gyre (Fig. 2). The North Pacific Current flows across the Pacific Ocean, separating the cold nutrient-rich waters of the subarctic Alaska Gyre from the warm nutrient-depleted waters of the south. It carries cold and fresh surface water out of the Alaska Gyre, and mixes it with warmer saline water of the Subtropical Gyre. Since the California Current is an eastern boundary current, the region of southward flow diffuses against the cognate western boundary current, the Kuroshio, which flow northward. Coastal upwelling along the California coast is driven by equator-ward winds, and was associated with climate change since the middle Miocene.

During ODP Leg 167, 13 sites were drilled, Sites 1010 through 1022, along the California Margin with coastal and onshore/offshore transects from 30°N to 42°N (Lyle, Koizumi, Richter, et al., 1997). Site 1021 was drilled at a water depth of 4213 m, 100 km south of the Mendocino Fracture Zone, more than 360 km from the California Coast, and obtained a 310.2 m-thick sequence of middle Miocene through Pleistocene (12.5–0 Ma) sediments (Fig. 5). The interval of 310.2–204.3 mbsf is characterized by diatom abundant sediment of middle to late Miocene (12.5–7.0 Ma) indicating high biogenic productivity. From the later Miocene to early Pliocene, the clay component increases considerably.

Near Site 1021, DSDP Leg 18 Site 173 (39°57.7′N, 125°27.1′W; Water Depth 2927 m) locates the continental slope southwest of Cape Mendocino. Diatoms are rich in silty clay from 110 to 120 mbsf (lower Pliocene). The interval from 138 to 285 mbsf (upper Miocene–lower Miocene) is dominated by diatomite, in places with a high nannofossil content. Lower horizons of 285-286 mbsf (lower Miocene) are thin sandy mudstone or chert is underlain by up to 34 meters of glauconitic nannofossil ooze. Andesite (a thick flow or basement) is found at 320 mbsf (The Shipboard Scientific Party, 1973). The diatomite and diatomaceous sediments of the early Miocene through the latest Miocene assigned to the Monterey Shale of California and other similar deposits around the Pacific margin are similar succession: (1) The late Oligocene-early Miocene interval

Fig. 5. General lithology, diatom zone, diatom abundance, and diatom ooze of the sedimentary section at ODP Sites 1021, 1016, 1011, and 1010 in the California margin (Shipboard Scientific Party, 1997a, 1997b, 1997c, 1997d; Maruyama, 2000; Lyle et al., 2000). C: Crucidenticula. A, B, C, D, E, F, and G correspond to x, A, B, C, D, E, F, and G of Site 1010 column, respectively.
of volcanics, continental, or shallow marine debris. (2) the middle Miocene diatomite and diatomaceous sediments by rapid subsidence, and (3) The Pliocene and Pleistocene terrigenous clastics capping the diatomaceous intervals (Ingle, 1973).

Site 1016 was drilled at water-depth 3834 m, 70 km from the toe of the continental slope, and about 150 km west of Point Arguello. The obtained sedimentary section was 316.5 m thick, and of upper Miocene to Pleistocene (7.5–0 Ma) sequence (Fig. 5). The diagenetic boundary of transition from amorphous silica (opal-A) to cristobalite (opal-CT), corresponding to bottom-simulating reflection (BSR) was found at 298 mbsf, and massive chert and porcellanite layers extended down to 316.5 mbsf. The interval of 298.0–230.9 mbsf, diatomite and diatom clay under the upwelling conditions, is of upper Miocene (7.5–6.5 Ma). The interval of 230.9–163.6 mbsf (6.5–4.5 Ma) consists of diatom ooze with clay, and in 163.6–70.0 mbsf (4.5–1.5 Ma) gradually changes into diatom nannofossil ooze to nannofossil diatom ooze. Most of the portion of 70–0 mbsf (1.5–0 Ma) consists of diatom ooze with clay.

Site 1011 was drilled at a water depth of 2022 m in Animal Basin located about 100 km of the Ensenada, Mexico in the California Borderland (Fig. 2), and 276.4 m-thick layer of upper Miocene to Pleistocene (9.0–0 Ma) sediments was obtained (Fig. 5). Sediments consist of interbedded siliciclastic clays, nannofossil ooze, and siliceous ooze. At 204.3 mbsf of 7.5 Ma, nannofossil chalk with clay changes to diatomite with clay. The underlying unit, 262.1–204.3 mbsf (8.5–7.5 Ma), is characterized by decimeter-scale interbedding diatomite, similar to the shoreward basin deposits of the Monterey Formation in California (Shipboard Scientific Party, 1997c). Diatoms compose 50% to 70% of the sediment.

Site 1010 is the southernmost deep-water (3480 m) site, which crosses the California Current at about 30° N. It is located about 100 km north of Guadalupe Island, seaward of the toe of the Baja California continental slope. A 210.4 m-thick layer of middle Miocene to Pleistocene (15 to 0 Ma) sedimentary sequence was obtained (Fig. 5). The lower portion of sediments, 148.0–77.5 mbsf (5.5–12.9 Ma, late to middle Miocene), is siliceous ooze containing up to 70%–80% diatoms and radiolarians. The interval of 179.8–148.0 mbsf (13.1–12.9 Ma, middle Miocene), consists of alternating diatomite and nannofossil chalks, and the underlying unit, 210.4–179.8 mbsf, is porcellanite and chert caused by diagenetically formed opal-CT. The Miocene interval characterized by decimeter-scale interbedding of siliceous ooze and diatomite with clay can be correlated to shallower basin deposits in the Monterey Formation.

The deposition of opaline silica derived from diatom valves in the middle through upper Miocene in Sites 1021 and 1010 shows three step-like drops, in comparison to high opal deposition, in the middle Miocene: (1) about 11.5 Ma, (2) about 7.6 Ma which coincides with the end of the Monterey Formation, and (3) 6.5 Ma (Janecek, 2000; Lyle et al., 2000; Barron et al., 2002). Low opal values without high amplitude fluctuations characterize the intervals between 11.5 to 10.0 Ma, 7.6 to 6.5 Ma, and after 4.6 Ma (Barron et al., 2002). The periods when opal increased prior to 11.5 Ma, 10.0 to 7.6 Ma, and 6.5 to 4.6 Ma coincide with the period when the latitudinal thermal gradient increased and the southward flow of the California Current intensified. The Pliocene (4.6 to 2.7 Ma) is marked by the near absence of diatoms in offshore sites, while diatoms are masked by clastic components in onshore sections.

2.3.1 Onshore sequences on the California Margin

The diatom ooze and diatomite was obtained offshore in Leg 167 corresponds to the middle to late Miocene Monterey Formation, which is the most well known marine diatomite and diatomaceous sedimentary sequence in the circum-Pacific (Garrison, 1975; Ingle, 1981; Isaacs, 1983; Barron, 1986; White et al., 1992). The Monterey Formation ranges as old as the late early Miocene, and the thick and pure diatomite is late Miocene to early Pliocene in age. Below the Monterey Formation, three formations develop in the Ventura Basin, California: (1) non-marine Eocene-Oligocene Sespe Formation, (2) upper Oligocene-lower Miocene Vaqueros Formation with terrigenous debris, and (3) uppermost Oligocene-lower Miocene Rincon Formation dominated by calcareous nannoplankton (Ingle, 1981). The massive diatomite, siliceous mudstone, and alternation of massive and laminated biosiliceous rocks in the Monterey Formation were deposited in the highstand system tract of the outer shelf (Garrison, 1992). In the Sisquoc Formation of Santa Barbara, opal (diatom) mass accumulation rate (MAR) increases in a series of steps from 10 Ma, and reach the highest MAR between 6 and 4 Ma. However, diatomaceous siliceous components in the Monterey and Sisquoc Formations were diluted by high influxes of terrigenous debris during the Pliocene (4.6 to
2.4 Bering Sea

The eastern half of the Bering Sea, from Bristol Bay to the Bering Strait, is covered by continental shelf. In contrast, the western half is a deep-sea floor of the Aleutian Basin, which is separated into eastern and western regions by the Shirshov Ridge and the Bowers Ridge (Fig. 6). The Alaskan Stream, an extension of the Alaskan Current, flows westward along the Aleutian Islands and enters the Bering Sea through Near Strait and Kamchatka Strait (Fig. 2). The most significant outflows run through the Kamchatka Strait (Stabeno et al., 1999).

The water above the Bering Sea continental shelf flows out into the Chukchi Sea through the Bering Strait. Inside of the Bering Sea, a large-scale anticlockwise surface water circulation is recognized along the Bering Sea shelf and the Aleutian Islands in the Aleutian Basin. The Bering Sea is a region of high surface productivity owing to the upwelling of nutrient-rich and consequently oxygen-poor deep water.

DSDP Leg 19 in 1971 is still unique in Bering Sea drilling history, but core recovery was poor in quantity and quality (Creager, Scholl, et al., 1973). Afterward, Integrated Ocean Drilling Program (IODP) Expedition 323 (Takahashi and the IODP Expedition 323 Scientists, 2011) provided the continuous Plio-Pleistocene (5-0 Ma) cores.

DSDP Site 192 at a water depth of 3000 m is located atop Meiji Guyot at the northwest end of the Emperor Seamount chain near ODP Sites 882–884 (Fig. 2). The 1044 m-thick sedimentary section overlies extrusive alkali basalt (The Shipboard Scientific Party, 1973d). The upper Miocene interval of 720-550 mbsf (9.5-8.0 Ma) is diatomaceous clay (The Shipboard Scientific Party, 1973d; Koizumi, 2010). The BSR occurs at about 720 mbsf. The upper Miocene through upper Pliocene interval of 550-140 mbsf (8.0-2.6 Ma) includes diatom ooze, and 140-0 mbsf, Pleistocene (0-2.6 Ma), includes abundant ice-rafted pebbles and volcanic ash beds (Fig. 7). Volcanic ash layers also occur in the upper Pliocene interval of 240-140 mbsf (3.1-2.6 Ma).

Site 190 is located at water depth of 3857 m in the southeastern part of Shirshov Ridge of the southwestern Aleutian Basin (Fig. 6), and a 627 m-thick sediment layer of upper Miocene to Pleistocene sequence was obtained (Fig. 7). The BSR occurs at about 615 mbsf (The Shipboard Scientific Party, 1973c). The upper Miocene mudstone in 627-615 mbsf includes a small piece of middle Miocene diatom-bearing limestone (Koizumi, 1973). The interval of 615-375 mbsf (6.5-3.6 Ma) is worm-burrowed and semi-
Diatom ooze and diatomite–diatomaceous sediments in and around the North Pacific Ocean

indurated clayey diatom ooze and diatomaceous silty clay. The interval of 375-175 mbsf (3.6-1.8 Ma) is silty diatom ooze, and 175-0 mbsf (1.8-0 Ma) is diatom-bearing rich silty clay with several size-graded sands and silts (Fig. 7). Displaced freshwater and benthic to littoral diatoms occur in 200 mbsf (2.2 Ma) in diatomaceous silty beds (Koizumi, 1973).

Site 188 is located at a water depth of 2649 m at the outer edge of the mid-slope terrace on the western flank of Bowers Ridge, and a 638 m-thick sedimentary sequence was obtained. The interval of 580 mbsf to 315 mbsf (5.5-2.2 Ma), semi-consolidated diatom ooze and diatomaceous silts, overlies the mudstone (638-580 mbsf) lacks diagnostic fossils (The Shipboard Scientific Party, 1973b). The BSR occurs at 580 mbsf. The interval of 315-0 mbsf (2.2-0 Ma) is unconsolidated diatom ooze accompanying volcanic ash layers, sands and silts. Very hard and fractured black mudstone occurs at 273 mbsf (~2 Ma).

Site 185 at a water depth of 2110 m is located on the southern flank of the broad spur, southeastern Bering Sea. A 728 m-thick sedimentary sequence was obtained (The Shipboard Scientific Party, 1973a). The upper Miocene through Pleistocene interval of 600-0 mbsf (6-0 Ma) is clayey diatom ooze, and diatom content ranges from 40% to a maximum of 90%, about 65% on average. Ice-rafted exotic pebbles, volcanic ash layers, and very hard and fractured black mudstone occur at 120-100 mbsf (2.6-2.0 Ma) at the Plio-Pleistocene boundary (Fig. 7). The BSR occurs at 587-670 mbsf.

The diatomite in the Cape Plosky, Yunjuvayamian, Limimtevayamian, and Ust-Limimtevayamian Suites in Tjushevskaya and Ust-Kamchatska of eastern Kamchatka is age-assigned to the late Miocene (9.5 Ma) through late Pliocene (3.5 Ma) based on diatoms (Gladenkov, 1984). The diatomite sequence from 796.8 to 580.5 mbsf was obtained from Hole Central-1 at a water depth of 90.1 m on the Chukchi shelf of the Anadyr Depression and recognized to be of middle Miocene through lower Pliocene age based on the lithology and diatom assemblage (Gladenkov, 2013a). The oldest marine diatoms in the lower course of the Anadyr River were previously reported as late Eocene to Oligocene age (Sheshukova-Poretzkaya, 1968), and, further, a middle Eocene diatom assemblage was reported from the Kylan Formation of the II’pinskii Peninsula, northeastern Kamchatka (Gladenkov, 2013b).

2.5 The Japan Sea

The Japan Sea is a semi-enclosed marginal sea located at the eastern end of the Asian continent with its eastern margin bounded by the Japanese Island Arc (Fig. 8). The Japan Sea is divided into two different parts by the Yamato Rise at 40°N parallel. The Yamato Rise, which represents a slab of rifted continental crust, is composed of two major banks, Kita-Yamato Bank and Yamato Bank separated by a longitudinal depression, the Kita-Yamato Trough. The northern half of the sea is comparatively simple, but the Japan Basin and the southern half possess complex bathymetry characterized by a series of basins and ridges.

Water exchange between the Japan Sea and adjacent seas has mainly occurred through four narrow and shallow straits (Fig. 8). Therefore, it has responded to eustatic sea-level changes influenced by tectonic and climatic changes. The main current, Tsushima Warm Current, which is a branch of the Kuroshio, meanders in the southern part and then flows out into the North Pacific Ocean through the Tsugaru Strait and Okhotsk Sea through the Soya Strait.

Upper Miocene through upper Pliocene diatom ooze has been recognized earlier using the Lamont-Doherty Geological Observatory (L-DGO) piston cores which were obtained around the periphery of the Yamato Rise, and RC12-377 obtained at the western end of the Marginal Plateau off the Oki Island (Koizumi, 1978; Koizumi and Yamamoto, 2017). On the other hand, the diatomaceous clay at 601–260 cm depth in RC12-394, taken from the northeast flank of the Yamato Rise (Fig. 8), is age-assigned to lower Miocene, and of brackish-water origin accompanying the Daijima-type flora (Koizumi, 1988).

ODP Site 797 is located at a water depth of 2862 m in the southwestern Yamato Basin, and a 900 m-thick sequence of lower Miocene carbonaceous siltstone and obtained sandstone intercalated with altered basalts
Fig. 7. General lithology, diatom zone, diatom abundance, and diatom ooze of the sedimentary section at DSDP sites in the arctic North Pacific Ocean and Bering Sea (Creager, Scholl, et al., 1973; Koizumi, 1973, 2010). Diatom ooze and diatomite–diatomaceous sediments in and around the North Pacific Ocean

was recovered (Shipboard Scientific Party, 1990c). The upper Miocene through upper Pliocene interval of 224.0-119.9 mbsf is a clayey diatom ooze with diatom abundance of $4.08 \times 10^7$ valves/g on average, and in the upper Pliocene interval of 119.0-90.0 mbsf, diatoms increase in abundance of $7.07 \times 10^7$ valves/g on average (Fig. 9). The diagenetic opal-A/opal-CT (cristobalite) boundary occurs between 294.3 and 299.1 mbsf.

Site 794 is located at a water depth of 2811 m in the northern Yamato Basin, and a 544 m-thick sequence of middle Miocene claystone was obtained at 654 mbsf (Shipboard Scientific Party, 1990a). The upper Miocene through upper Pliocene interval of 216.9-92.3 mbsf is diatom ooze in which the diatom abundance is $2.8 \times 10^7$ valves/g on average, peaking to $7.7 \times 10^7$ valves/g twice. Further in the lower-middle Pleistocene diatom abundance increases remarkably, also peaking to $15.4 \times 10^7$ valves/g twice. The diagenetic opal-A/ opal-CT boundary occurs at about 300 mbsf.

Site 795 is located at a water depth of 3300 m in the northern Japan Basin (Shipboard Scientific Party, 1990b). Pleistocene to middle Miocene clay, diatom ooze, diatom claystone, siliceous claystone, tuff, and claystone with minor pyroclastics during the interval of 0-684 mbsf, and basaltic andesite and basalts in 684-761 mbsf were obtained. The lower to upper Pliocene interval of 325-123 mbsf is diatom ooze including more than 30% diatoms by smear slide analysis, and diatom abundances are, on average, $6.6 \times 10^7$ valves/g (Fig. 9). The Pleistocene silty clay indicates increasing diatom abundance with peaks at 60 mbsf $15.5 \times 10^7$ valves/g and at 10 mbsf $7.7 \times 10^7$ valves/g. The diagenetic opal-A/ opal-CT boundary occurs at about 325 mbsf.

Upper Miocene through Pliocene diatomite and diatomaceous sediments are distributed widely on the floor of the Yamato and Japan Basins, and form the

Fig. 9. General lithology, diatom zone, and diatom abundance of the sedimentary section at ODP Sites in the Japan Sea (Shipboard Scientific Party, 1990a, 1990b, 1990c; Koizumi, 1992).
Diatom ooze and diatomite–diatomaceous sediments in and around the North Pacific Ocean

In diatom assemblages contained in the diatomite and diatomaceous sediments, which L-DGO cores and Sites 794-797 obtained, cold-water species dominates, but warm-water species appear 3.5 Ma at Site 794 and 3.0 Ma at Site 797. It indicates that the Japan Sea opened in the northern area but was almost closed in the south near the Tsushima Strait from the late Miocene to the Pliocene age. A warm-water (paleo-) Tsushima Current did not penetrate into the Japan Sea through the (paleo-) Tsushima Strait during the late Miocene through Pliocene age (Koizumi, 1992).

2.5.1 Onshore sequences around Japan Sea

The Japan Sea opened by the rifting along the eastern margin during the late Eocene to Oligocene based on the litho- and chrono-stratigraphy in the back-arc onland subaerial to shallow-water successions (Kano et al., 2007), and ended during the late Pliocene to Pleistocene (Ingle, 1975; Koizumi, 1983). Initial slow rifting was rapidly accelerated, and rifting and spreading established through temporal thermal doming during the early to middle Miocene at 20-15 Ma (Kano et al., 2007). The late Oligocene to early Miocene diatomite and diatomaceous sediments consists of terrestrial to lacustrine deposits and shallow marine volcanic rocks, and contains the cool Aniai-type flora different from a warm Daijima-type flora (Koizumi, 1988).

The diatomite and diatomaceous sediments accompanied with the Aniai-type floras are fresh-brackish water in origin. And the Chojaburu Diatomite of Iki Islands, the Yamatoda Diatomite of Noto Peninsula, and the Magaribuchi Formation of northern Hokkaido are listed as the same type of sediments (Fukusawa and Koizumi, 1994). In the Pohang section of South Korea, the lower Miocene diatomaceous mudstone and diatomite was obtained and includes 40–70% siliceous microfossils, predominantly diatom (Garrison et al., 1979; Ingle, 1992). Also the Aniai-type floras are preserved in the laminated mudstone or shale in the lower part of the Pohang section (Koizumi, 1988).

The lower to middle Miocene marine sediments that accumulated during the time of rapid spreading and subsidence around Japan Sea contributed to a nearly continuous sequence, which is exposed on the Oga Peninsula of northeastern Japan and can be correlated with most of the onshore Neogene sequences which are widely scattered along the eastern margin of the Japan Sea (Koizumi et al., 2009). The diatomite and diatomaceous sediments are subdivided mainly into three stages (Koizumi, 1983; Koizumi and Yamamoto, 2017): (1) The early middle Miocene diatomite in Kumi of Oki Islands, Hojuji, Iida and Nadaura of Noto Peninsula, and Hirasawa of Oga Peninsula, and intercalated with siliceous sandstone and siltstone, which contain glauconite and phosphate. (2) The middle to late Miocene diatomite and diatomaceous mudstone was deposited in Izuka, Wakura and Sugata in Noto Peninsula, Nakayama of Sado Island, Onnagawa of Oga Peninsula, Tsuzureko and Yorinobe of Akita Prefecture, Numanokubo of Iwate Prefecture, and Maruyamskaya of southern Sakhalin. This deposition was related to global cooling, and increased primary productivity under dysoxic to anoxic bottom-water conditions at bathyal depths (Ingle, 1981; Koizumi, 1983). (3) The late Miocene to early Pliocene diatomite and diatomaceous siltstone that accumulated under oxic bottom-water conditions that are widely distributed in Yabuta of Noto Peninsula and Enbetsu of Hokkaido. By the Pleistocene, turbidite sands and/or silts capped and diluted the diatomaceous sediments. During the early Pleistocene, bathyal turbidite sequences and neritic deposits rapidly filled basins, and an episode of uplift and folding in the Neogene basinal sequences followed during the late Pleistocene.

3. Conclusions

The Neogene diatomite and diatomite–diatomaceous sediments in and around the margin of the North Pacific Ocean occur within similar tectonic, stratigraphic, and paleoenvironment histories in spite of widely separated areas (Fig. 10). They were formed by synchronous geological events: (1) volcanic, continental to shallow marine clastics and coal layers deposited in the marginal basin by tectonics and volcanism during the late Oligocene to early Miocene age, (2) silled marginal basins subsided and then developed, and was followed by deposition of marine coarse calcareous sandstone which contain shallow warm marine mollusks and larger foraminifera in the early Miocene age (Ingle, 1973), (3) the area of silica deposition shifted from the North Atlantic Ocean to the North Pacific and Indian oceans, the so-called “silica switch”, in the early middle Miocene (Keller and Barron, 1983; Koizumi, 1990; Rea et al., 1995b), (4) diatom ooze and diatomaceous sediments were deposited in the silled margin basins under anaerobic waters with phosphates.
Fig. 10. Correlation of the Neogene marine sequences, including diatomaceous sediments and genetically related porcellanites and cherts, in and around the margin of the North Pacific Ocean, eustatic sea level curve (Haq et al., 1987), benthic δ¹⁸O and δ¹³C data in DSDP Sites 588 and 590 of the southwest Pacific (Kennett, 1986), and tectonic and climatic events (Pagani et al., 1999; Zachos et al., 2001). Mi: Miocene isotope events represent inferred glacial maxima (Miller et al., 1991; Pagani et al., 1999). CM: Carbon maxima events represent inferred episodic organic carbon burial (Woodruff and Savin, 1991; Pagani et al., 1999). Event A-D: Changes in diatom MAR with spliced benthic δ¹⁸O in Sites 588 and 590, and with major events by closure of the Panama Isthmus (Barron, 1998).
Diatom ooze and diatomite–diatomaceous sediments in and around the North Pacific Ocean during the middle to late Miocene and Pliocene age, (5) amorphous silica (opal-A) was diagenetically transformed to cristobalite-tridymite (opal-CT) (Creager, Scholl et al., 1973; Hein et al., 1978), and (6) coarse terrigenous clastics were rapidly deposited and capped underlying diatomaceous sediments during the late Pliocene-Pleistocene age (Ingle, 1973, 1981; Keller and Barron, 1983; Koizumi, 1990; Tamaki et al., 1992; Rea et al., 1995a; Barron, 1998; Koizumi et al., 2009).

The general regressions and transgressions recognized in the sea level curve coincide with the epoch boundaries, and increases and decreases in benthic ($\delta^{18}O$ and $\delta^{13}C$) values (Fig. 10). Fluctuations in benthic $\delta^{18}O$ values explain nine glacial intervals (from Mi-1 to Mi-7, and Mi-1a and Mi-1b), and $\delta^{13}C$ values and seven peaks of increasing organic carbon burial (from CM1 to CM7), respectively, during the Miocene (Woodruff et al., 1981; Miller et al., 1991; Woodruff and Savin, 1991; Pagani et al., 1999). The benthic $\delta^{18}O$ is low during the early Miocene, indicating the middle Miocene climatic optimum at 16.5-15.5 Ma. Major increases, however, occur at 15.5 Ma (Mi-2), and between 15.0 and 12.0 Ma with Mi-3 at 13.0 Ma and Mi-4 at 12.0 Ma. The high $\delta^{13}C$ values fluctuate between 17 and 13 Ma and coincide with increases in $\delta^{18}O$ values. Sea level drops, especially at 11 Ma just after Mi-4, and keeps today’s level with small rises and drops during the late Miocene. Those events indicate the major permanent accumulation of the East Antarctic ice sheet and cooling of bottom waters. High-latitude surface waters cooled while low-latitude water temperatures warmed (Flower and Kennett, 1993), leading to a stronger latitudinal temperature gradient, increased vertical-water mass stratification, and inferred strengthened surface water circulation (Pagani et al., 1999). However, the increase of benthic $\delta^{13}C$ values (CM7) in the early late Miocene at 15.5-10.5 Ma is not supported by sea level regression and a further increase in benthic $\delta^{18}O$ values after Mi-4.

Global Miocene climatic events shifted from a non-glacial to glacial climate, and this shift was responsible for acceleration of upwelling and diatom productivity, beginning at 16-15 Ma, in the marginal North Pacific Ocean. Climatic cooling also occurs at 10.0 Ma (Mi-5), 9.0 Ma (Mi-6) and 8.5 Ma (Mi-7) in the early late Miocene. During the middle Pliocene, increase in benthic $\delta^{18}O$ suggests increasing global ice volume and cooling of bottom waters. After that, during 2.6 and 2.4 Ma, the onset of Northern Hemisphere glaciation occurred.

Four major changes in diatom mass accumulation rates (MARs) occurred in response to high-latitudes cooling and changes in surface and deep waters circulation due to shoaling of the Panama Isthmus (Barron, 1998). (1) At 9 Ma (Event A), diatom MARs increased in the northwest Pacific Ocean by an enrichment of nutrients in North Pacific deep waters and “carbonate crash” (Lyle et al., 1995) due to shoaling of the Panama Isthmus. (2) Before 6.2 Ma (Event B), a major cooling event occurred in the high latitudes of the southern Pacific Ocean by the expansion of the western Antarctic ice-sheet at about 6.5 Ma (Kennett, 1986) and the onset of “latest Miocene-earliest Pliocene biogenic bloom” began in the eastern equatorial Pacific Ocean at 6.7 Ma (Farrell et al., 1995). (3) At about 4.5 Ma (Event C), diatom productivity decreased in sub-boreal to boreal areas but increased in the northwest Pacific Ocean due to warmer temperature during the Mio-Pliocene warm period (Barron, 1998) and paleoceanographic changes due to shoaling of the Panama Isthmus (Haug et al., 1995). (4) After 2.7 Ma, diatom MARs declined abruptly and coincidently with a major increase in ice rafted detritus in the high latitudes of the North Pacific Ocean caused by the rapid onset of major Northern Hemisphere glaciation (Haug et al., 1995; Barron, 1998; Prueher and Rea, 1998).
