Abstract. We present Giant Meterwave Radio Telescope (GMRT) observations of the H\textsubscript{i} 21 cm line and Very Large Array (VLA) observations of the OH 18 cm line from the Seyfert 2 galaxy Mrk 1. H\textsubscript{i} emission is detected from both Mrk 1 and its companion NGC 451. The H\textsubscript{i} emission morphology and the velocity field of Mrk 1 are disturbed. We speculate that the nuclear activities of Mrk 1 are triggered by tidal interactions. We estimate the H\textsubscript{i} masses of Mrk 1 and NGC 451 to be 8.0(0.6)×10\textsuperscript{8} M\textsubscript{⊙} and 1.3(0.1)×10\textsuperscript{8} M\textsubscript{⊙}, respectively. We have also detected the H\textsubscript{i} 21 cm line and the OH 18 cm line in absorption toward the nucleus of Mrk 1 at a blueshifted velocity with respect to its systemic velocity indicating an outflow of atomic and molecular gas. Two OH lines, at 1665 and 1667 MHz, are detected. Each of the profiles of the H\textsubscript{i} and OH absorption consists of two components that are separated by \sim 125 km s\textsuperscript{-1}. Gaussian fitting gave dispersions of \sim 44 km s\textsuperscript{-1} for both the components of the H\textsubscript{i} absorption. The profile of the OH absorption is qualitatively similar to that of the H\textsubscript{i} absorption. Both components of the OH absorption are thermally excited. The peak optical depths of the two components of the H\textsubscript{i} absorption are (7.3 \pm 0.4) \times 10\textsuperscript{-2} and (3.2 \pm 0.4) \times 10\textsuperscript{-2}. The corresponding peak optical depths of the 1667 MHz OH absorption are (2.3 \pm 0.3) \times 10\textsuperscript{-2} and (1.1 \pm 0.3) \times 10\textsuperscript{-2}. The higher velocity components of the H\textsubscript{i} and OH (1667 MHz) absorption lines are blueshifted from the [O\textsc{ii}]\lambda5007, [O\textsc{iii}]\lambda6300, and the systemic velocity by \sim 100 km s\textsuperscript{-1}, but are consistent with the [O\textsc{ii}]\lambda3727 velocity. We explain these velocity discrepancies as due to shock ionization of a region which is pushed forward due to shocks in front of the radio nucleus thereby giving apparent blueshift to H\textsubscript{i}, OH, and [O\textsc{ii}] velocities. The optical depth ratios $\tau_{H_i}/\tau_{1667}$ of both the components of the H\textsubscript{i} and OH absorption are \sim 3, indicating their origin in dense molecular clouds. Using OH/A\textsubscript{e} values for the Galactic molecular clouds, we obtain $9 < A_e < 90$ toward the line of sight of Mrk 1.

Key words. galaxies: active – galaxies: interactions – galaxies: individual (Mrk 1, NGC 451) – galaxies: ISM

1. Introduction

Both the AGN and the nuclear starburst activities in galaxies which require inflow of material toward the centre either to fuel the central black hole or to cause rapid burst of nuclear star formation can be accomplished by tidal interactions (Hernquist & Mihos 1995). It is not clear, however, in the case of Seyfert galaxies whether nuclear activities in these low luminosity active galactic nuclei (AGN) are due to interactions as found in QSOs, radio galaxies, and BL Lacs (see De Robertis et al. 1998 for a review on the subject). It is generally accepted that interactions leading to mergers (bound interactions) may play a significant role in triggering nuclear activities than unbound or hyperbolic encounters (De Robertis et al. 1998). Interactions can be effectively traced via H\textsubscript{i} 21 cm line emission from galaxies as H\textsubscript{i} disks often extend well beyond the optical radii of galaxies where the disks respond quickly to gravitational perturbations. H\textsubscript{i} emission studies may be particularly useful since most often the H\textsubscript{i} morphology provides evidences of interactions which are undetectable at optical wavelengths (e.g., Simkin et al. 1987).

H\textsubscript{i} in absorption can trace kinematics and distribution of atomic gas near the centres of active galaxies on the size scales of their background radio sources. The advantage of absorption studies is that it can detect relatively small quantities of gas irrespective of the redshift of the object. Recently, Gallimore et al. (1999) have found H\textsubscript{i} rich absorbing disks on the scales of

In this paper, we present synthesis observations of the Hα 21 cm line obtained with the GMRT and the OH 18 cm line obtained with the VLA of the infrared luminous active galaxy Mrk 1 and its companion NGC 451. The global properties of Mrk 1 are summarized in the next section. The details of observations and data analyses are given in Sect. 3. The results are presented in Sect. 4. Sect. 5 discusses the radio continuum properties, Hα emission, and Hα and OH absorption. The conclusions are in the last section.

2. Global properties of Mrk 1

The global properties of Mrk 1 are listed in Table 1. Mrk 1 (NGC 449; B₀ = 14.53) is a member of a poor group (WBL 035) at a redshift of 0.017 (White et al. 1999). The other two members of this group viz., NGC 447 and NGC 451, are at projected separations from Mrk 1 of ~ 38 kpc and ~ 130 kpc respectively. Mrk 1 is classified as a SB O/a galaxy with a Seyfert type 2 nucleus (Markarian et al. 1989) with no signatures of interactions in the optical images. Mrk 1 is also a luminous Infrared galaxy (L₉₄₀₀₀ = 1.7 × 10^{10} L₀), indicating a high rate of star formation. Mrk 1 is one among 16 galaxies detected in the 22 GHz water megamaser emission in a sample of 354 active galaxies (Braatz et al. 1994). The nuclear optical spectrum of Mrk 1 studied by Koski (1978) and Weedman et al. (1968) shows strong emission lines typical of an active galaxy photo-ionized by hard continuum. The broad lines indicative of a hidden Seyfert nucleus are not found either in the infrared (Veilleux et al. 1997) or in the polarized light (Kay et al. 1994). High dispersion spectroscopic observation of the [OIII]5007 line by Bergeron & Durret (1987) shows a distinct blue asymmetry indicative of an outflow of gas. Keel (1996) suggested that the nuclear activities of Mrk 1 are due to an ongoing interaction with the nearby galaxy NGC 451.

The radio continuum emission from Mrk 1 is known to have a steep spectrum with a spectral index α (S ∝ ν⁻α) of 0.8 (Dickinson et al. 1976). The 1.6 GHz EVN image (resolution ~ 30 pc) of Kukula et al. (1999) shows the nuclear emission to

a few hundred parsecs in several Seyfert galaxies. As a result of intense nuclear activities, gas in the central regions of active galaxies may be perturbed due to interactions of the radio plasma with the surrounding ISM which may result in bulk outflows of material (e.g., Tadhunter et al. 2001, Morganti et al. 1998). The molecular gas near the centres of active galaxies can be traced

† Usable time, see section 3.2 for details

consists of an unresolved core surrounded by a weak diffuse emission with a total flux density of 34 mJy. The NVSS flux density at 1.4 GHz is 75.4 mJy.

The Arecibo observations by Hutchings (1989) detected H$\alpha$ emission and blueshifted H$\alpha$ absorption from Mrk 1. This single dish spectrum could not separate H$\alpha$ emission from Mrk 1 and NGC 451. Observations with the Nobeyama Radio Telescope detected CO (J = 1–0) emission with a total flux integral of 11.5 ± 1.6 K km s$^{-1}$ from the central 5 kpc region of Mrk 1 (Vila-Vilaro et al. 1998). The search for the 18 cm OH absorption by Schmelz et al. (1986) with the Arecibo reflector resulted in a non-detection with an rms sensitivity to an optical depth of 0.02.

3. Observations and data analyses

3.1. The GMRT observations

The GMRT observations of Mrk 1 were carried out in October, 2000. A summary of the main observational parameters are given in Table 2. At the time of the observations, the GMRT was not fully operational and hence not all 30 antennas were available for observations at any given time. Two runs of observations with 18–20 antennas, each with a field of view (FWHM) 24′ centered on Mrk 1, were carried out on two different days. The GMRT has a mix of both short and long baselines (see Swarup et al. 1991 for more details), making it sensitive to diffuse emission of extent as much as 7′ while having a maximum resolution of ~ 3″ at 1.4 GHz. The GMRT uses a 30-station FX correlator which produces complex visibilities over 128 spectral channels in each of the two polarizations. The bandwidth can be selected in multiples of 2 between 62.5 kHz and 16 MHz. These observations were carried out with a bandwidth of 8 MHz centered at 1395.0 MHz, which covered H$\alpha$ velocities in the range 3730 – 5460 km s$^{-1}$ with a velocity resolution of ~ 14 km s$^{-1}$.

The complex gains of the antennas were determined every 30 minute using observations of an unresolved nearby (~ 4.5°) source (3C 48) for 5 minutes. 3C 48 was also used for the flux and the bandpass calibrations. The data were reduced, following standard calibration and imaging methods, using the Astronomical Image Processing Software (AIPS) developed by the NRAO. The data were calibrated for the amplitude, phase, and frequency response for all antennas separately for each polarization. The flux density of 3C 48 was estimated to be 16.228 Jy at the observing frequency using the 1999.2 VLA flux densities of the standard VLA flux calibrators and the formula given in the AIPS task ‘SETJY’. Due to the close proximity of 3C 48 to Mrk 1 and based on some previous test experiments, we expect that the flux calibration is accurate to within 5%.

A continuum data set was formed by averaging 80 line-free channels. The data were self calibrated in both phase and amplitude. The resulting antenna gain corrections were applied to all channels. The continuum images were made using the self-calibrated averaged data from the line-free channels. The continuum flux density from each individual channel was subtracted in the (u,v) dataset by a linear fit to the visibilities in the line-free channels. Since these observations were also sensitive to H$\alpha$ emission, the data points were “natural-weighted” to enhance sensitivity to extended features. The resulting spectral cubes were CLEANed for signals greater than 4 times the rms noise in the channel images. The cube was blanked for emission below a level of 1.5σ in the images after applying a Hanning smoothing of three velocity channels and Gaussian smoothing of five pixels (pixel size = 6″) in the spatial co-ordinates. The zeroth and first order moment maps were generated from the blanked channel images containing H$\alpha$ emission and two additional channels on both the sides.
These observations covered a velocity range of 4400 km s$^{-1}$.

Table 2. The data were recorded in the 1A correlator mode with a total bandwidth of 6.25 MHz divided into 128 channels.

The $H\alpha$ line emission was generated using "natural-weighted" continuum-free data to get maximum signal to noise ratio. The image cube was box-car smoothed along the frequency axis using a window of 3 channels and every second channel was discarded. The resulting image cube has a resolution of 5$''$ x 5$''$. The synthesized beam, shown in the bottom left hand corner, is 30$''$ x 30$''$. The rms noise is 0.35 mJy beam$^{-1}$ in the 1.4 GHz image and 0.19 mJy beam$^{-1}$ in the 1.6 GHz image. The peak flux densities in the images are 76.3 mJy beam$^{-1}$ at 1.4 GHz and 68.1 mJy beam$^{-1}$ at 1.6 GHz.

3.2. The VLA observations

The VLA ‘B’ configuration observations were carried out in March, 2001. The observational parameters are summarized in Table 2. The data were recorded in the 1A correlator mode with a total bandwidth of 6.25 MHz divided into 128 channels. These observations covered a velocity range of 4400 – 5550 km s$^{-1}$ for the 1667 MHz line of OH with a velocity resolution of ~ 9 km s$^{-1}$. These observations also covered the 1665 MHz line of OH in the velocity range of 4050 – 5200 km s$^{-1}$. A large fluctuation in the system temperature was noticed on the first day of observations which were carried out at a centre frequency of 1640.5 MHz. These fluctuations were later identified as due to strong signals from an external interfering source operating near the frequency of observations. The observations on the next day were carried out after reducing the front-end bandwidth from 25 MHz to 12.5 MHz and shifting the centre of the band to 1640.22 MHz to avoid the external interference. The data from the first day of observations were discarded.

The VLA observations and data analyses were carried out following the same strategy as adopted for the GMRT observations described in section 3.1. The flux density of 3C 48 was estimated to be 14.270 Jy at the observing frequency. The image cube was made with a resolution of 30$''$. These images were marginal detected ($\sim 4\sigma$) at both 1.4 GHz and 1.6 GHz. The channel images of $H\alpha$ emission were corrected for respective primary beam attenuations. The images are 76.3 mJy beam$^{-1}$ at 1.4 GHz and 68.1 mJy beam$^{-1}$ at 1.6 GHz. The peak flux densities in the images are 76.3 mJy beam$^{-1}$ at 1.4 GHz and 68.1 mJy beam$^{-1}$ at 1.6 GHz. The continuum images were made using the self-calibrated averaged data from the line-free channels.

4. Results

4.1. Radio continuum

The radio continuum images shown in Fig. 1 have a resolution of 30$''$75 x 25$''$17 at 1.4 GHz, and 17$''$49 x 16$''$56 at 1.6 GHz. These images were made using only short (u,v) spacings to enhance the sensitivity to extended features. These images have an rms of 0.35 mJy beam$^{-1}$ at 1.4 GHz, and 0.19 mJy beam$^{-1}$ at 1.6 GHz. Continuum emission is detected from both Mrk 1 and NGC 451. NGC 447 is marginally detected ($\sim 4\sigma$) at both 1.4 and 1.6 GHz. The flux density of Mrk 1 is estimated to be 76 $\pm$ 4 mJy at 1.4 GHz, and 68 $\pm$ 3 mJy at 1.6 GHz. The spectral index between 1.4 and 1.6 GHz is 0.8. The flux density of NGC 451 is 3.3 $\pm$ 0.5 mJy at 1.4 GHz and 1.8 $\pm$ 0.4 mJy at 1.6 GHz. Mrk 1 remains unresolved down to a resolution of $\sim$ 1 kpc.

4.2. $H\alpha$ emission

The $H\alpha$ cube was made with a resolution of 30$''$67 x 27$''$28 x 13.7 km s$^{-1}$. The channel images have an rms of 0.92 mJy beam$^{-1}$. The corresponding $3\sigma$ sensitivity in $H\alpha$ column density is 5.0 $\times$ 10$^{19}$ cm$^{-2}$. The channel images of $H\alpha$ emission and absorption...
Fig. 2. Channel images from GMRT showing H\textsc{i} column density contours in the velocity range 4807 km s\(^{-1}\) – 5011 km s\(^{-1}\). The crosses mark the optical positions of Mrk 1 and NGC 451. Solid contours representing column density of H\textsc{i} emission are drawn at 3.6, 5.4, 7.2, 9.0, 10.8, and 12.7 \(\times 10^{19}\) cm\(^{-2}\). The negative contours (dashed curves) are drawn at 2, 3, 4, 5, 6 mJy beam\(^{-1}\). The HPBW of the synthesized beam (30\.'67 \times 27\.'28, PA = -80.4\(^\circ\)) is indicated at the bottom left hand corner of the first channel image. The velocity resolution in the cube is \(\sim 13.7\) km s\(^{-1}\).
Fig. 3. Channel images showing column density contours in the velocity range 4589 km s$^{-1}$ – 4793 km s$^{-1}$. The contour levels are the same as in Fig. 2. The H$\text{I}$ absorption is seen toward Mrk 1 as dotted contours.

The moment zero map shown in Fig. 5 indicates that the H$\text{I}$ emission from Mrk 1 is distributed in three clumps with almost all H$\text{I}$ seen outside the optical extent of Mrk 1. The individual clumps having velocity dispersions of 30 to 60 km s$^{-1}$ are distributed over an extent of $\sim$ 30 kpc. The velocity field of Mrk 1 shown in Fig. 5 indicates that there is a smooth rotation of H$\text{I}$ from one end to the other.

The H$\text{I}$ emission from NGC 451 shown in Fig. 3 looks like that of a disk galaxy with a total projected velocity width of 170 km s$^{-1}$. The H$\text{I}$ diameter of NGC 451 is $\sim$20 kpc which is about twice that of the optical disk. The global parameters of NGC 451 given in Table 3 were derived from a fit to the velocity field made using a higher resolution (17'' $\times$ 14'') H$\text{I}$ cube which is not shown here.
A. Omar et al.: Mrk 1 – GMRT and VLA observations

Fig. 4. Global H I emission profile of Mrk 1 and NGC 451 from GMRT. The flux integral is $1.93 \pm 0.11$ Jy km s$^{-1}$ which is consistent with the single dish observations of Hutchings (1989).

Fig. 5. The column density contours of the total H I image from GMRT of Mrk 1 (top) and NGC 451 (bottom) overlaid upon the grey scale optical image from the DSS (blue). The contour levels are 0.3, 0.8, 1.3, 1.8, 2.3, 3, 4, 5, 6, 7, 8, and 9 in units of $10^{20}$ cm$^{-2}$. The HPBW of the synthesized beam, shown in the bottom right hand corner, is $30\arcsec.67 \times 27\arcsec.28$, PA = $-80.4^\circ$. Although the H I emission is surrounding Mrk 1, H I absorption (marked as white circle) is detected toward Mrk 1 indicating the presence of cold H I gas in front of it.

4.3. H I absorption

The channel images shown in Fig. 3 also show H I absorption from Mrk 1 (dotted contours at the location of Mrk 1) in the velocity range 4589 km s$^{-1}$ to 4752 km s$^{-1}$. The H I absorption spectrum shown in Fig. 7 is extracted at the radio position of Mrk 1 from a H I cube made with a resolution of $6\arcsec.23 \times 4\arcsec.39 \times 13.7$ km s$^{-1}$. The rms in this cube was 0.6 mJy beam$^{-1}$. The spectrum shows a broad multi-component absorption in between the velocities 4500 km s$^{-1}$ and 4800 km s$^{-1}$. Two Gaussian components were fitted to the H I absorption profile. The resulting parameters of the fit are given in Table 4. The peak optical depths of the two components are $0.073 \pm 0.004$ and $0.032 \pm 0.004$ respectively and the velocity dispersions are $\sim 44$ km s$^{-1}$ for both the components. The column density of H I is estimated using the relation $N_{\text{HI}} = 1.82 \times 10^{18} \times (T_{\text{spin}}/f) \int \tau \, dv$ cm$^{-2}$; where $T_{\text{spin}}$ is the spin temperature of H I in kelvin, $f$ is the covering fraction of H I gas, $\int \tau \, dv$ is the velocity integrated optical depth in km
Fig. 6. The velocity fields of Mrk 1 and NGC 451 from GMRT are shown as contours and in grey scale.

\textsuperscript{†}: Estimated from the mean velocity of $\mathrm{H}i$ emission

\textsuperscript{‡}: Estimated from a fit of curves of constant velocities to the $\mathrm{H}i$ velocity field

s\textsuperscript{-1}. We assume $f$ to be unity. $T_{\text{spin}}$ is an unknown quantity and we adopt a value of 100 K, typical of cold clouds in our Galaxy. The $\mathrm{H}i$ column densities are then 1.5(±0.2) × 10\textsuperscript{21} cm\textsuperscript{-2} and 6.0(±1.5) × 10\textsuperscript{20} cm\textsuperscript{-2} for the two components respectively.

Table 4. H\textsc{i} and OH absorption results

| Parameter | H\textsc{i} | OH(1667) | OH(1665) |
|-----------|------------|----------|----------|
| $\tau_{1}$ | 0.073 ± 0.004 | 0.023 ± 0.003 | 0.014 ± 0.004 |
| $v_{1}$ (km s\textsuperscript{-1}) | 4705 ± 5 | 4721 ± 6 | 4710 ± 19 |
| $\sigma_{v_{1}}$ (km s\textsuperscript{-1}) | 44.2 ± 4.4 | 44.2 | 44.2 |
| $\tau_{2}$ | 0.032 ± 0.004 | 0.011 ± 0.003 | 0.006 ± 0.004 |
| $v_{2}$ (km s\textsuperscript{-1}) | 4579 ± 10 | 4585 ± 12 | 4601 ± 45 |
| $\sigma_{v_{2}}$ (km s\textsuperscript{-1}) | 43.4 ± 9.1 | 43.4 | 43.4 |

4.4. OH absorption

The OH spectrum shown in Fig. 8 was extracted at the radio position of Mrk 1 from the image cube made using the VLA data with a resolution of 5\textquoteleft.43 × 4\textquoteleft.95 × 27 km s\textsuperscript{-1}. The cube has an rms of 0.5 mJy beam\textsuperscript{-1}. 

Fig. 7. The GMRT spectrum showing H\textsc{i} absorption in Mrk 1. The dotted curve is the Gaussian fit to the absorption spectrum. The fitted parameters are given in Table 4. The vertical lines along the velocity axis mark the positions of several velocity systems as indicated.

Fig. 8. The VLA spectrum showing OH absorption from Mrk 1. The velocity axis corresponds to the 1667 MHz line. The dotted curve shows the model spectrum of the 1665 and 1667 MHz OH lines. The fitted parameters are given in Table 4. In this velocity definition, the 1665 MHz line will appear at +360 km s\(^{-1}\) from the 1667 MHz line. Two vertical lines in the velocity axis mark the expected positions of 1665 MHz absorption corresponding to the 1667 MHz absorption detected near 4721 and 4585 km s\(^{-1}\).

The peak optical depths of the two components of the 1667 MHz absorption are 0.023 ± 0.003 and 0.011 ± 0.003 respectively. The column density of OH is estimated using the relation \( N_{\text{OH}} = 2.35 \times 10^{14} \times (T_{\text{ex}}/f) \times \int \tau_{1667} \, dv \) cm\(^{-2}\); where \( T_{\text{ex}} \) is excitation temperature which is assumed to be 10 K and \( \int \tau_{1667} \, dv \) is the velocity integrated optical depth of the 1667 MHz line in units of km s\(^{-1}\). The OH column densities are estimated to be 6.0(±1.0) \times 10^{15} \) cm\(^{-2}\) and 2.9(±0.9) \times 10^{15} \) cm\(^{-2}\). The peak optical depth ratio \( \tau_{1667}/\tau_{1665} \) of the stronger OH component is 1.6 ± 0.5, indicating that this component is excited under LTE conditions – the ratio is predicted to be in between 1.0 and 1.8 for LTE excitations. This ratio for the weaker component, viz., 1.8 ± 1.3 indicates that this is also most likely thermally excited.
Table 5. Interaction properties of the Mrk 1–NGC 451 system

| Parameter                        | Value   |
|----------------------------------|---------|
| Projected velocity difference (km s$^{-1}$) | 117     |
| Projected separation (kpc)       | 38      |
| Total dynamical mass (M$_{\odot}$) | $\sim 10^{11}$ |
| Tidal radius (Mrk 1) (kpc)       | 24      |
| Tidal radius (NGC 451) (kpc)     | 29      |
| Impact parameter                 | $\sim 0.1$ |
| Dynamical friction time (Gyr)    | $\sim 0.2$ |
| Orbital time (Gyr)               | $\sim 2.0$ |

5. Discussion

5.1. Interaction of Mrk 1 with NGC 451

The disturbed H$_{\text{i}}$ morphology of Mrk 1 (Fig. 5) indicates a gravitational interaction possibly with the nearest companion NGC 451. We explore this possibility using the two body interaction described in Binney & Tremaine (1987). The dynamical masses of galaxies are estimated using rotation curves. Since the H$_{\text{i}}$ morphology of Mrk 1 is disturbed, it was not possible to obtain a reliable H$_{\text{i}}$ rotation curve. We used the H$_{\alpha}$ rotation curve of Mrk 1 (Keel 1996). The dynamical mass of NGC 451 was estimated using the H$_{\text{i}}$ rotation curve. The dynamical masses of Mrk 1 and NGC 451 are 3.4 $\times$ 10$^{10}$ M$_{\odot}$ and 4.5 $\times$ 10$^{10}$ M$_{\odot}$ respectively. The interaction parameters are listed in Table 5.

The projected velocity difference between Mrk 1 and NGC 451 of $\sim 117$ km s$^{-1}$ indicates a minimum dynamical mass of this pair to be $\sim 10^{11}$ M$_{\odot}$. This value of dynamical mass is in close agreement with the dynamical masses of Mrk 1 and NGC 451, indicating that Mrk 1 and NGC 451 are most likely in a bound system. Tidal radii (cf. eq. 7-84, Binney & Tremaine 1987) for the given masses of Mrk 1 and NGC 451 indicate that the outer regions of the H$_{\text{i}}$ disk of Mrk 1 can be perturbed easily. The dynamical friction time scale (cf. eq. 7-26 and 7-13b, Binney & Tremaine 1987) of $\sim 0.2$ Gyr for this system is much smaller than their orbital time scale of $\sim 2$ Gyr. This implies that the interaction is bound and will lead to a merger within a small fraction of the orbital time period of the two galaxies.

5.2. Comparison of H$_{\text{i}}$ and OH velocities with other velocity systems

Comparison with optical line velocities—From the comparison of the H$_{\text{i}}$ and OH absorption velocities of Mrk 1 with the optical line velocities listed in Table 1, it appears that the higher velocity components of the H$_{\text{i}}$ and OH absorption are consistent with the [O II]$\lambda$3727 line velocity, but are blueshifted by $\sim 100$ km s$^{-1}$ from the [O III]$\lambda$5007, [O I]$\lambda$6300 and the systemic velocity. We explain this discrepancy in terms of co-existence of photo-ionized and shock ionized gas in active galaxies. The [O II]$\lambda$5007 line is primarily due to excitation from a hard continuum, and therefore, should be arising close to the nucleus. The [O II]$\lambda$3727 line intensity is enhanced in shock ionized regions (Dopita & Sutherland 1995). Most often, optical line profiles are asymmetric and only peak line velocities are quoted without fitting a line profile. Mrk 1 is known to be such a case (Bergeron & Durret 1987, Dickinson et al. 1976). Such an analysis of the optical spectrum may bias the line velocities of different species toward different regions, e.g., the peak of the [O II] line may indicate a region which is shock ionized while the [O III] line velocity may indicate gas which is close to the nucleus. We speculate that the higher velocity H$_{\text{i}}$ and OH absorption component in Mrk 1 arises in a region which is pushed forward due to shocks, thereby giving an apparent blueshift to H$_{\text{i}}$, OH, and [O II] lines. The fact that the [O I] line velocity is close to the [O III] line velocity, and hence associated with photo-ionized regions, is not surprising since the [O I] line intensity is suppressed in the shock excited regions (Dopita & Sutherland 1995).

Comparison with H$_{2}$O megamaser and CO emission—The water megamasers are seen from Mrk 1 at a velocity of 4868 km s$^{-1}$ (Braatz et al. 1994). Since these masers are redshifted by $\sim 90$ km s$^{-1}$ from the systemic velocity of the galaxy, they are most likely the high velocity “satellite” features commonly seen in water megamaser galaxies (Braatz et al. 1997) and thought to originate in the accretion disks near the nuclei (Neufeld et al. 1994). Since the observed H$_{\text{i}}$ and OH absorption velocities in Mrk 1 are blueshifted from both the water megamaser velocity and from the systemic velocity of the galaxy, the absorption in the present case is most likely not related either to the gas in the accretion disk or to the torus close to the nucleus. The mean velocity of the CO emission from Mrk 1 is 4850 km s$^{-1}$ (Vila-Vilaro et al. 1998), which is redshifted by $\sim 150$ km s$^{-1}$ from H$_{\text{i}}$ and OH absorption velocities, implying that the gas traced via H$_{\text{i}}$ and OH absorption in Mrk 1 is also not related to the molecular gas traced by CO emission.
Table 6. Properties of the absorbing gas

| Parameter | Value |
|-----------|-------|
| $N_1(\text{HI})$ (cm$^{-2}$) | 1.5(±0.2) × 10$^{21}$ |
| $N_2(\text{HI})$ (cm$^{-2}$) | 6.0(±1.5) × 10$^{20}$ |
| $N_1(\text{OH})$ (cm$^{-2}$) | 6.0(±1.0) × 10$^{13}$ |
| $N_2(\text{OH})$ (cm$^{-2}$) | 2.8(±1.0) × 10$^{13}$ |
| $N_{\text{total}}(\text{HI})$ (cm$^{-2}$) | 2.1(±0.6) × 10$^{21}$ |
| $N_{\text{total}}(\text{OH})$ (cm$^{-2}$) | 8.8(±3.4) × 10$^{13}$ |
| $\tau_{\text{HI}}/\tau_{\text{OH}, 1667}$ (1) | 3.2 ± 0.4 |
| $\tau_{\text{HI}}/\tau_{\text{OH}, 1667}$ (2) | 2.9 ± 0.9 |
| $\tau_{\text{OH}, 1667}/\tau_{\text{OH}, 1665}$ (1) | 1.6 ± 0.5 |
| $\tau_{\text{OH}, 1667}/\tau_{\text{OH}, 1665}$ (2) | 1.8 ± 1.3 |
| $N_{\text{total}}(\text{H}_2)$ (cm$^{-2}$) | ~ 10$^{23}$ |
| $N_{\text{total}}(\text{OH})/N_{\text{total}}(\text{HI})$ | ~ 4.3 × 10$^{-6}$ |
| $A_v$ (mag) | 9–90 |
| $N_\text{HI}$ cm$^{-2}$ | ~ 1.1 × 10$^{23}$ |
| $A_{\text{photonic}}$ | ~ 30 |

†: Assuming $T_{\text{kin}}=100$ K; ‡: Assuming $T_{\text{ex}}=10$ K; ††: Assuming OH/H$_2=10^{-7}$

5.3. Kinematics and composition of the absorbing gas

The general properties of the gas seen in absorption are summarized in Table 6. The total column density of OH is comparable to that observed in other active galaxies (e.g., Schmelz et al. 1986, Baan et al. 1985, 1992). Both components of the OH transitions appear to be thermally excited as their optical depth ratios ($\tau_{1667}/\tau_{1665}$) are between 1.0 and 1.8; the values predicted for excitations in LTE conditions. The optical depth ratios $\tau_{\text{HI}}/\tau_{\text{OH}}$ for both the components of the absorbing gas are ~ 3. This ratio has been found to be varying from as low as 5 to more than 400 in Galactic clouds (Dickey et al. 1981). The smaller values correspond to the molecular clouds while larger values correspond to the diffuse clouds. It is therefore suggested that the H$\text{I}$ and OH absorption, in the present case, are associated with dense molecular clouds.

The observed velocity dispersion ($\sigma$) of the 1667 MHz OH absorption, viz., 44 km s$^{-1}$ is higher than the typical velocity dispersions ($\sigma = 3$–7 km s$^{-1}$) in giant molecular clouds (GMCs) of the Galactic disk. However, several high dispersion clouds ($\sigma$ ~ 40 km s$^{-1}$) have been detected in 18 cm OH absorption within a kpc of the Galactic centre (Boyce & Cohen 1994). The simplest explanation for such a high velocity dispersion could be a chance alignment of several normal GMCs along the line of sight, but Kumar & Riffert (1997) have shown that the probability of such alignments is small. Alternatively, if the velocity dispersion is due to a single gravitationally bound system in virial equilibrium, the mass of such an object (assuming a size of 50 pc) could be ~ 10$^7$ M$_\odot$. Cloud–cloud collisions (Klein et al. 1994b) and interaction of shock with ISM (Klein et al. 1994a) are also known to enhance the internal velocity dispersions of molecular clouds.

The OH column density is known to correlate with the visual extinction, $A_v$, of molecular clouds in our Galaxy (Magnani et al. 1988). Magnani et al. (1988) found that N(OH)/$A_v$ ratios are in the range of 10$^{44}$ – 10$^{45}$ cm$^{-2}$ mag$^{-1}$. For the OH column density toward Mrk 1, these ratios indicate 9 < $A_v$ < 90 toward the line of sight of Mrk 1. In comparison, Veilleux et al. (1997), based on some infrared measurements, obtained a lower limit on $A_v$ to be 26 consistent with above predictions.

Using OH/H$_2 = 10^{-7}$ (Liszt & Lucas 1996), the implied column density of H$_2$ is ~ 10$^{23}$ cm$^{-2}$. Using values of the photoelectric absorption cross sections from Morrison & McCammon (1983) for a gas having the solar abundance, a total hydrogen column density of ~ 10$^{23}$ cm$^{-2}$ indicates that the optical depth for X-ray absorption at 1 keV will be ~ 30. Such a high value of the optical depth will absorb almost all soft X-radiation from the nucleus of Mrk 1. Consistent with this prediction, Mrk 1 has not been detected as a X-ray source down to a sensitivity of ~ 10$^{41}$ erg s$^{-1}$ (Fabbiano et al. 1992).

6. Conclusions

We have presented the observations of the Seyfert 2 galaxy Mrk 1 in the H$\text{I}$ 21 cm line using the GMRT and in the OH 18 cm line using the VLA. Unlike the optical morphology, the H$\text{I}$ emission morphology of Mrk 1 indicates that this galaxy is disturbed which we interpret as due to tidal interactions with the nearby companion NGC 451. We also showed based on the dynamical study of Mrk 1 – NGC 451 system that the interaction is bound leading to a merger within a small fraction of their orbital time period. This is consistent with the hypothesis that the bound interactions should be more efficient in triggering nuclear activities than unbound interactions. The H$\text{I}$ and OH absorption detected toward the nucleus of Mrk 1 indicates an outflow of both atomic and molecular gas. The column densities of the detected H$\text{I}$ and OH absorption indicate that the line of sight toward the nucleus of Mrk 1 is rich in both atomic and molecular gas. The gas detected in absorption is kinematically different than that traced via...
CO emission and water megamaser emission from Mrk 1. We found evidence that shocks (presumably due to nuclear activities) can affect the kinematics of gas near the nucleus. The H\textsc{i} and OH absorption being blueshifted from the systemic velocity and the [O\textsc{iii}]\lambda5007 velocity while consistent with the [O\textsc{ii}]\lambda3727 velocity is understood in terms of the shock ionization of gas (which predicts enhancement of the [O\textsc{ii}] line intensity) and an outflow of ISM in front of the shock. Based on the optical depth ratios and the line widths of the H\textsc{i} and OH absorption, we speculate that the absorption is arising in turbulent molecular clouds of similar types as those found near the Galactic centre. These observations also imply that the line of sight toward the nucleus of Mrk 1 is heavily obscured.
