ABSTRACT

We develop a model for the radio afterglow of the giant flare of SGR 1806-20 arising due to the interaction of magnetically-dominated cloud, an analogue of Solar Coronal Mass Ejections (CMEs), with the interstellar medium (ISM). The CME is modeled as a spheromak-like configuration. The CME is first advected with the magnetar’s wind and later interacts with the ISM, creating a strong forward shock and complicated backwards exhaust flow. Using three-dimensional magnetohydrodynamic simulations, we study various relative configurations of the magnetic field of the CME with respect to the ISM’s magnetic field. We show that the dynamics of the forward shock mostly follows the Sedov-Taylor blastwave, while the internal structure of the shocked medium is considerably modified by the back flow, creating a multiple shock configuration. We calculate synthetic synchrotron emissivity maps and light curves using two assumptions: (i) magnetic field compression; (ii) amplification of the magnetic field at the shock. We find that models with magnetic field amplification account better for the observed radio emission.

Key words: magnetohydrodynamics (MHD), stars: magnetars, ISM: supernova remnants

1 INTRODUCTION

Soft gamma repeaters (SGRs) are a type of slowly spinning neutron stars exhibiting X-ray and γ-ray bursts. Together with Anomalous X-ray pulsars they constitute a class of magnetars (Thompson & Duncan 1995), see reviews by Mereghetti (2008); Kaspi & Beloborodov (2017). Their emission is powered by the dissipation of magnetic field, that may reach $B \approx 10^{15}$ G. Occasionally, SGRs produce giant flares (GFs); GF from SGR 1806-20 on 27 December 2004 is the most notorious (Palmer et al. 2005; Hurley et al. 2005). GFs consist of bright, short initial spike peaking in γ-rays (with luminosities reaching $10^{47}$ ergs/s and duration ~ 100 millisecond), followed by a longer and dimmer tail peaking in hard X-rays modulated by the SGR’s rotational period and having luminosities upwards of $10^{44}$ ergs/s. Masada et al. (2010) suggest a model for magnetar giant flares based on solar flare/coronal mass ejection theory where the flare is the final outcome of prominence (loaded baryonic matter) eruption, triggered by explosive magnetic reconnection.

A week after the GF of SGR 1806-20, a bright radio afterglow was discovered (Cameron et al. 2005; Gaensler et al. 2005). The radio afterglow showed one-sided, mildly collimated and decelerating outflow with initial expansion velocity of $\approx 0.7c$ Taylor et al. (2005); Granot et al. (2006). The radio afterglow showed complicated behavior. At first, radio flux exhibited a moderate decay, $\sim r^{-1.5}$ to $\sim r^{-2}$ before 9 days after the giant flare, after which it underwent an achromatic steepening, $\sim r^{-2.7}$ between ~ 9 and ~ 25 days (Gaensler et al. 2005; Gelfand et al. 2005). Starting at ~ 25 days and peaking at ~ 33 days, a rebrightening in the radio light curve was observed (Gelfand et al. 2005), followed by a slower decay, $\sim r^{-1.1}$.

The afterglow arises due to the interaction of an ejected blob (analogue of a Solar Coronal Mass Ejection, CME) with the surrounding medium. Two contrasting suggestions of the composition of a CME were proposed: matter versus magnetic field-dominated ejections. In the former, the GF was accompanied by an ejection of $> 10^{-34}$ grams of baryonic material (this requires slicing off several meters from the whole surface of a NS) with mildly relativistic velocities (Palmer et al. 2005; Gelfand et al. 2005; Taylor et al. 2005; Granot et al. 2006).

In the latter model (Lyutikov 2006, 2015, “Solar flare paradigm”), GFs are magnetospheric events (not crustal events), driven by slow plastic evolution of the footpoints, qualitatively similar to Solar flares. Magnetars bursts and flares are driven by unwinding of the internal non-potential magnetic field via Hall (electron-MHD) drift (Goldreich & Reisenegger 1992; Gourgouliatos et al. 2013; Wood et al. 2014). This leads to a slow build-up of magnetic energy outside of the neutron star. For large magnetospheric currents, corresponding to a large twist of the external magnetic field, magnetosphere becomes dynamically unstable on the Alfvén crossing times scale of the inner magnetosphere. The ensuing reconnection processes, e.g. mediated by the tearing mode in the strongly magnetized plasma of magnetar magnetospheres (Lyutikov 2003; Komissarov et al. 2007; Ripperda et al. 2019), operates in a way qualitatively similar to the Sun. Since, in the “Solar flare paradigm”, GFs are magnetospheric events, no large baryonic loading is expected.

In this paper we perform MHD simulations of the interaction of the ejected light, nearly magnetically-dominated CME with the surrounding medium. We outline the numerical set-up in section 3, describe results of the MHD simulations in section 4, and derive integrated synthetic synchrotron emissivity maps and light curves in section 5. Discussion of results, conclusions, and future prospects are presented in section 6.

2 MAGNETAR’S EJECTION AS AN EXPANDING SPHEROMAK-LIKE MAGNETIC BLOB

2.1 Ejected magnetic blob in magnetar wind

In this paper, we perform numerical calculations of radio afterglows of magnetar giant flares, modeled as relativistic magnetized explosions (Lyutikov 2006). According to the “The Solar model of magnetars”, the explosions are magnetospheric-driven (not crustal driven Thompson & Duncan 1995) events (see also Levin & Lyutikov 2012; Lyutikov 2015). In the case of magnetospheric release of energy, one does not expect substantial baryonic loading of the expelled fireball.

Initially, at the moment of launching, the blob is over-pressurized (both due to pair plasma and the internal magnetic field) and has linear momentum implanted during the ejection. As the magnetic cloud expands, its pair density falls by many orders of magnitude forming light, magnetically dominated blob. Initially, the magnetic cloud is topologically connected to the star, but reconnection at the footprints disconnects it. We expect the blob material to be slightly different (a bit higher density) from the wind due to pair freeze-out.

The internal structure of the blob frozen into the wind may be approximated as a spheromak-like configuration, a spherical nearly force-free configuration of linked poloidal and toroidal magnetic fields. In the case of the Sun both spheromaks and flux ropes are used to model expanding structures (Lin & Forbes 2000; Chen & Shibata 2000; Vandas et al. 1998) (though flux ropes are generally preferred, Farrugia et al. 1995). In the case of the Sun the expansion from the surface to the Earth radius is a factor of ~100. In our case the expansion form the surface of a NS to the region of interaction with the ISM is more than 10 orders of magnitude. As a result the ejected material is likely to be disconnected. Hence we accept the spheromak as a model of the ejections.

The pre-explosion wind is expected to accelerate linearly from the light cylinder, \( \Gamma \propto R_{LC} \) \( (R_{LC} \text{ is the radius of the light cylinder}) \). The over-pressurized blob is also expected to accelerate with the same scaling (similar to fireball model of GRBs Paczynski 1986). Thus, radial expansion of the blob and the wind are very similar - they virtually do not interact. The implanted linear momentum changes this picture only slightly: due to relativistic freeze-out in radially accelerated flow, the relative velocity of the blob with respect to the wind quickly becomes non-relativistic. Pressure balance is then established: the blob is frozen into the wind, and is advected with the wind.

As the wind expands and its rest-frame magnetic field decreases, the trapped blob will adjust to the changing confining pressure: the spheromak will expand (in fact, in accelerating flow the spheromak may even become causally disconnected internally). Gourgouliatos & Vlahakis (2010); Lyutikov & Gourgouliatos (2011) discuss the structure of expanding force-free structures. Expanding spheromak develops internal velocity and currents to compensate for different scalings of toroidal and poloidal components of the magnetic field.

Thus, we expect that by the time the wind starts interacting with the external medium (e.g. at the bow-shock Barkov et al. 2019), the ejected blob would have expanded to the size of the fraction of the radius. Before interacting with the ISM, the wind passes through the reverse shock. We assume that the blob identity is not destroyed (we do see an ejection!). A slightly denser blob will then start interacting with the ISM. Our simulations begin here, figure 1.

2.2 Magnetic blob - magnetized ISM interaction

We model the interaction of a magnetic blob with the ISM, figure 1. Magnetic blob is modeled as a spheromak-like configuration. Spheromaks are simply connected magnetically confined spherical structures which are spontaneously created due to plasma relaxation (Bellan 2018). A confined classical spheromak requires surface current. In order to avoid complication with internal resistive effects as the spheromak enters the ISM, we use a slightly modified magnetic field structure of Gourgouliatos et al. (2010) with vanishing toroidal and poloidal magnetic fields on the boundary; such a configuration is slightly non-force-free (see appendix A).

Interaction of the wind of the fast moving neutron star with the ISM is a complicated 3D MHD problem (Barkov et al. 2019). Interaction of the expelled spheromak with the ISM adds further complications. For examples, details will depend on the relative directions of the pulsar’s velocity and ejections vector. As a simplified model we consider planar case, neglecting the curvature wind-ISM boundary and the possible obliqueness of the ejection. Thus, we assume that the size of the spheromak is somewhat smaller than radius of curvature of the ISM-wind boundary (expected be \( \sim 10^{16} \text{ cm, e.g. Gaensler & Slane 2006} \)), and that the interaction is near the apex of the bow-shock (so that the impact is normal.)

In our simulations a spheromak-like magnetic blob (light grey in figure 1), embedded within a low-density SGR wind, impacts on the ISM (dark grey). Internal magnetic field within the blob may have three generic orientations with respect to the orientation of ISM’s uniform magnetic field \( B_{ISM} \). The blob’s magnetic moment \( \mu_{blob} \) can be (i) parallel (ii) anti-parallel (iii) perpendicular to the external field (panel 1). These three configurations are expected to produce somewhat different magnetic interactions between the ISM’s and the blob’s magnetic fields (see section 4.3).

3 THREE-DIMENSIONAL MHD SIMULATIONS

3.1 Numerical set-up

We perform 3-D MHD simulations to study the interaction of the aforementioned magnetic blob moving along with the low-density SGR wind, with an external ISM and consequently describe the radio nebula associated with the 2004 GF. Our aim is to simulate a strong shock (Mach number \( \sim 10 – 20 \)) that would result from the interaction of the fast moving blob and wind (in the ISM’s reference frame) with the ISM with low sound speed. A very strong shock is expected when material and magnetic fields ejected from the SGR’s flare hit the ISM with velocity \( \sim 0.3c \) as observations suggest. It is the synchrotron emission from this shock that we hypothesize to have been observed as the radio emission and whose properties we wish to analyze for comparison with the observed spectrum.

The simulations are performed using a 3-D Cartesian geometry using the PLUTO code\(^1\) (Mignone et al. 2007). PLUTO is a modular Godunov-type code entirely written in C, intended mainly for astrophysical applications and high Mach number flows in multiple spatial dimensions and designed to integrate a general system of conservation laws

\[
\frac{\partial U}{\partial t} = -\nabla \cdot T(U) + S(U)
\]  

\( U \) is the vector of conservative variables and \( T(U) \) is the matrix of fluxes associated with those variables. Our ideal MHD set-up does

Radio afterglow of magnetars’ giant flares

Figure 1. Top panel: Schematic representation of the set-ups used to analyze interaction of the blob with the ISM with three different orientations. The blob is enlarged to show the concentric flux surfaces that define the magnetic field structure within it. Bottom panel: Schematic representation of the anti-parallel set-up used to assess shock properties after the blob-ISM interaction with minimum effects of magnetic reconnection. $v$ is the velocity of the blob and SGR wind moving towards the ISM (see section 3.1 for details).

not use any source terms and $U$ and $T$ are

$$U = \begin{pmatrix} \rho \\ m \\ B \\ E \end{pmatrix}, \quad T(U) = \begin{pmatrix} \rho v \\ m v - B B + p_j I \\ v B - B v \\ (E + p_j) v - (v B) B \end{pmatrix}^T$$

(2)

$\rho$, $v$ and $p$ are density, velocity and thermal pressure. $m = \rho v$, $B$ is the magnetic field and $p_j = p + |B|^2/2$ is the total (thermal + magnetic) pressure, respectively. Magnetic field evolution is complemented by the additional constraint $\nabla \cdot B = 0$. Total energy density $E$

$$E = \frac{p}{\Gamma - 1} + \frac{1}{2} \left( \frac{|m|^2}{\rho} + |B|^2 \right)$$

(3)

along with an isothermal equation of state $p = c_s^2 \rho$ provides the closure. $\Gamma$ and $c_s$ are the polytropic index and isothermal sound speed, respectively. The plasma is approximated as an ideal, non-relativistic adiabatic gas, one particle species with polytropic index of 5/3. PARABOLIC interpolation, a third-order Runge–Kutta approximation in time, and a Harten-Lax-Van Leer approximate Riemann solver (Miyoshi & Kusano 2005) are used to solve the above ideal MHD equations. Outflow boundary conditions are applied in all three directions.

We performed a short, low-resolution simulation to resolve the magnetic field structure at early times and assess the effects of current sheet formation and magnetic reconnection when the magnetic blob and low-density SGR wind interact with the ISM with different magnetic field orientations with respect to the blob’s magnetic moment $\mu_{\text{blob}}$. Panel 1 shows a schematic of the physical set-up with parallel, anti-parallel and perpendicular orientations of $B_{\text{ISM}}$ with respect to $\mu_{\text{blob}}$. Specifically, we run the parallel and anti-parallel cases to analyze effects of reconnection and expect that the anti-parallel case, where $B_{\text{ISM}}$ and magnetic field at the blob’s left edge are aligned, would be favorable to minimize reconnection effects and analyze the shock properties to explain the radio emission from the GF.

The size of the domain is $x \in [-2.4r_0, 4r_0]$, $y \in [-2.4r_0, 4r_0]$, and $z \in [-2.4r_0, 2.4r_0]$ where $r_0$ is the radius of the blob. Uniform resolution is used throughout the computational domain with total number of cells $N_x = N_y = N_z = 256$. The blob’s initial magnetic field is defined by $A_8$, $A_9$ and $A_{10}$. We prefer low plasma-$\beta$ (high magnetization) of the blob so that effect of magnetic field is captured.
These requirements make the following choice of initial parameters justified: an initial velocity of the blob and SGR wind in the negative $x$ direction $v = -100\, c_{\rm GS}$, ISM pressure $p_{\rm ISM} = 0.5$ and ISM density $\rho_{\rm ISM} = 0.25$ giving the ISM sound speed $c_{\rm s, ISM} = 1.82$, uniform ISM magnetic field $B_{\rm ISM} = 0.25\, \mu{\text{T}}$, giving $\beta_{\rm ISM} = 16$. The wind pressure is $p_{\rm wind} = 0.5$, wind density $\rho_{\rm wind} = 3 \times 10^{-5}$, $r_0 = 50$, $\beta = 2$ (not very small value of beta of the blob used in the simulations comes from purely numerical limitations) and blob density $\rho_{\rm blob} = 0.1\, \rho_{\rm ISM}$.

All quantities are given in code units which are normalized $c_{\text{gs}}$ values

\[ \rho = \frac{\rho_{\text{cgs}}}{\rho_n}, \quad v = \frac{v_{\text{cgs}}}{v_n}, \quad p = \frac{p_{\text{cgs}}}{\rho_n v_n^2}, \quad B = \frac{B_{\text{cgs}}}{\sqrt{4\pi\rho_n v_n^2}} \]

$\rho$, $v$, $p$ and $B$ are density, velocity, pressure and magnetic field. Time is given in units of $t_n = L_n/v_n$. The normalization values used are $\rho_n = 1.67 \times 10^{-24}\, \text{gr/cm}^3$, $L_n = 1.5 \times 10^{13}\, \text{cm}$ and $v_n = 10^5\, \text{cm/s}$.

We describe results of this analysis later in section 4.3.

To model the radio emission from the GF, we choose the anti-parallel orientation (ii) of panel 1), with the ISM magnetic field aligned with the magnetic field at the blob’s left edge and capture the shock dynamics arising from the interaction of magnetized blob and low-density SGR wind with external ISM in high resolution for longer times. Cases (i) and (ii) of panel 1 evolve almost identically (not very small value of beta of the blob used in the simulations comes from purely numerical limitations) and blob density $\rho_{\rm blob} = 0.1\, \rho_{\rm ISM}$.

3.2 Theoretical expectations

The key physical inputs are: a blob (projectile) creates a bulk moving and over-pressurized region (implanted momentum and energy). Both, the implanted momentum and the implanted energy “push” the forward shock (FS). But in contrast to the spherical Sedov explosion (where opposite parts of the flow “push” against each other, thus not conserving the absolute value of momentum), in the case of projectile hitting the ground, energy and momentum can be lost to the backward flow. This energy/momentum loss is complicated: parts of the post-shock flow close to the FS move with nearly the velocity of the FS (3/4 of the shock velocity), and thus with supersonic velocities in the frame of the shell. Further downstream, bulk velocities decrease, become subsonic, and start to “feel” the absence of the back confinement - the resulting high pressure accelerates the flow backwards, toward the wind, forming complicated exhaust flows. Because of high initial pressure, the exhaust flows become supersonic and form a series of shocks as seen in figure 2.

The implanted momentum and the pressure loss through backward exhaust flow act in the opposite way: implanted momentum increases the FS velocity, while the pressure loss from the bulk drains the energy, and hence leads to the slowing down of the shock.

For the dynamics of the FS, the problem under consideration is somewhat similar to the classical problem of projectile hitting the ground (Zel’dovich & Raizer 1967; Whitham 1974): energy and momentum are implanted. Also, recall that in the bulk plasma the magnetization is low (beta-parameter in the ISM is $\beta_{\rm ISM} = 25$, so that magnetic fields in the ISM do not affect the flow considerably. But they are of primary importance for the production of radiation. As Zel’dovich & Raizer (1967) discuss, the resulting shock dynamics is limited between the two cases of energy and momentum conservation. For pure energy injection with $E_0$, we expect that the scaling of the shock’s radius follows the Sedov solution Sedov (1959)

\[ R_E \sim \left( \frac{E_0}{\rho} \right)^{1/3} \]

For pure momentum injection with $P_0 \sim \sqrt{M_0 E_0}$ ($M_0$ is the mass of the blob/projectile), we expect that the scaling of the shock’s radius follows the Kompaneets solution Kompaneets (1960)

\[ R_P \sim \left( \frac{P_0}{\rho} \right)^{1/4} \]

(We stress that the resulting dynamics is not self-similar, but is “bracketed” between these two self-similar solutions). Closeness to any of the above solution depends on the non-dimensionless parameter $E_0/P_0$, and hence cannot be easily quantified.

Defining Sedov radius and time as

\[ R_S = \left( \frac{M_0}{\rho} \right)^{1/3} \]

\[ t_S = \frac{M_0^{5/6}}{(E_0)^{1/2} \rho^{1/3}} \]

the momentum injection dominates the FS dynamics at times and radii $t_S$, $R_S$.

\[ \frac{R_E}{R_P} = \left( \frac{E_0}{P_0} \right)^{3/20} \]

Though the overall dynamics is not self-similar, we may use the self-similar scalings $p \sim M^{-n} \sim R^{-3n}$ where $p$ is the shock pressure, $M$ is the mass encompassed by the shock wave and $R$ is the shock radius, with an exponent $n$ that may vary in time. Using the time dependences of shock pressure and radius (deduced in section 4.1 and figure 5), we find $n = 1.05$. This exponent value of shock attenuation is in excellent agreement to the proposed range $1 < n < 1.275$ for a self-similar concentrated impact for $\gamma = 5/3$. The lower limit corresponds to an energy conserving shock and the upper limit corresponds to momentum conservation. Thus, the FS’s self-similarity is intermediate between energy conserving and momentum conserving regimes. It is important to further note that the concentrated impact is closer to a point explosion in an infinite medium.

4 RESULTS

We performed a number of simulations with different resolutions - low ($256^3$) and high ($780^3$). In this section, we discuss various, quite complicated aspects of the resulting flow. The salient features are highlighted in figure 2, where we plot the $z$ (vertical) component of the velocity at late times, $t = 20$ in code units.

The flow is first shocked at the forward shock. This creates a region of high pressure. For spherical explosion, this region of high pressure has only one way to expand - by driving the FS. In the impact case, there is a second exit: forming a back flow. As a result, the high post-FS pressure is released both, through driving the FS, and through generation of the backward flow.
Radio afterglow of magnetars’ giant flares

5

Figure 2. Key features of the flow annotated. Plotted is the $z$ (vertical) component of velocity at fairly advanced time of $t = 20$. Upstream plasma (green color) is stationary. The forward shock (thick black line on the left) is, generally, oblique, inducing post-shock $z$ flow up/down in the upper/lower parts. In the bulk of the shocked material, soon after the FS, the rarefaction wave induces “exhaust flow” towards the back end (large white arrow). The exhaust flow becomes supersonic and terminates at the “exhaust termination shock” (thick black line near $x = 0$). The post-exhaust termination shock flow, collimated towards the symmetry axis, experiences further shocks at “exhaust Mach disks”. Near the regions where the FS intersects with the boundary, high post-shock pressure launches “exhaust curtains” back in the wind.

The overall dynamics of the FS is fairly simple: in the strong shock limit, it approximately follows a self-similar solution, though with not well-defined parameters, bounded by the limits of energy and momentum conservation (section 3.2). The back flow is more complicated. As the high post-FS pressure is converted into backward motion, the flow becomes supersonic. As a result, a termination shock forms (back black curve in figure 2). At this termination shock the flow is deflected toward the symmetry axis; it overshoots the pressure balance and forms repetitive Mach disks, similar to when a jet air plane flows at low altitudes (when the post-nozzle pressure does not match the ambient pressure).

Additional features appear at the intersection of the FS and the boundary between ISM and magnetar wind. High post-shock pressure drives an expansion curtain back into the wind, in a way similar to charged explosions hitting the ground, and asteroid impacts (Melosh 1989).

In addition to the hydrodynamically complicated flow, discussed in detail in sections 4.1 and 4.2, the presence of magnetic field in the blob, and its interaction with the external magnetic field adds few complications to the classical problem of charged projectile impact (section 3.2).

In the following discussion, we describe the high-resolution numerical results of the model described in section 3.1 and panel 1, namely 2-D slices of pressure, magnetic field, and $x$ component of velocity at $t = 5, 10, 15$ and 20 as well as time evolution of pressure and radius of the FS.

4.1 Pressure, velocity, and radius of the shock

At $t = 0$, the blob and low-density wind start moving to the left and hit the ISM boundary. This interface between the ISM and cavity wind is where the shock originates and the FS continues to propagate towards the left. We capture the FS until $t = 20$ after which it begins to exit the domain. Figures 3 and 4 are pressure and $x$ component of velocity $v_x$ projected in 2-D ($xz$ plane) at $t = 5, 10, 15$ and 20 where significant changes to the shock’s morphology can be observed.

At $t = 5$, after initial numerical fluctuations settle, a spherical FS is seen traveling to the left. At the same time, two wing-shaped low-pressure regions develop to the right of the FS into the cavity penetrated by a weak pressure peak just beginning to form. This is the recollimation shock being ejected out of the blob. The pressure depressions can be understood by noticing that at $t = 5$, material behind the FS is being blown to the right with much greater speeds than that of the material moving to the left.
At \( t = 10 \), as the FS penetrates deeper into the ISM, the recollimation shock is followed by a third pressure bump developing at the edge of the domain. This last shock is a result of external pressure in the wind zone as it thrashes against the recollimation shock and ISM. By this time, the FS is weakened by almost a third due to the strong “exhaust flows” described previously. Direction of moving material within the domain can be seen from its velocity map - FS moving to the left is followed by material moving right. This is followed by a weak recollimation shock and a powerful wind shock moving left at speed greater than the rest of the material.

Final stages of the shock at \( t = 15 \) and \( t = 20 \) are dominated by “exhaust” moving to the right at the edge of the domain caused due to reflected pressure waves. The recollimation and wind shocks are stronger but the FS is weakened nine-fold. The concave boundary prominent just to the right of the ISM-cavity interface is formed because material propagating to the right just behind the FS intercepts the wind propagating to the left at greater pressure than the wind’s pressure. This exhaust carries away pressure, hence energy from the bulk, thus slowing down the FS (by \( \sim 1/2 \) from \( t = 5 \) to \( t = 20 \)) as evident from the \( vx1 \), map.

Time evolution of pressure and radius of the FS are depicted in figure 5. We plot the peak pressure along \( z = 0 \) and radius of the shock, that is, distance traveled by the point where pressure peaks along \( z = 0 \), from \( t = 5 \) to \( t = 20 \) in steps of 0.5 in log-log scale. A linear fit to the plots gives power laws for both, pressure and radius of the shock: \( p(t) \propto t^{-1.52} \) and \( R(t) \propto t^{0.48} \).

4.2 Properties of the forward shock

Below we show that although the radial dynamics of the FS is approximately self-similar (see figure 5), the lateral and internal structures are not.

Using the pressure and magnetic field maps (figures 3 and 6), we plot the angular variation of pressure and magnetic field of the FS at \( t = 10 \) and \( t = 20 \) as shown in figure 7. \( \theta \) is the angle in radians, between the \( x \) axis and the line joining the center of the shock and the point of peak pressure/magnetic field along the FS when seen along several \( z = 0 \) cuts in the \( xz \) plane. Because the ISM-cavity interface moves with time, the shock center shifts slightly at the two time instances which has been accounted for while plotting the angular variation. We quantify the shape of the shock by fitting a polynomial to the numerical pressure and magnetic field data as shown by black dashed lines. As seen, pressure of the FS does not retain a self-similar shape over time in line with the discussion of section 3.2.
The lateral dependence of magnetic field is consistent with $\propto \cos \theta$ scaling, as expected from a point explosion in constant magnetic field. On the other hand, the scaling of pressure evolves with time, becoming flatter (more spherically symmetric). This indicates that the structure of the shocked medium with time evolves towards becoming more spherical, Sedov-Taylor-like solution.

Another measure to demonstrate the FS’s deviation from self-similarity is to compare its pressure (in units of the immediate post-shock value) versus radius (normalized by the shock radius) to the numerical and analytical Sedov solutions for a spherical blastwave as shown in figure 8. To make this comparison, we run low-resolution simulations ($N_X = N_Y = N_Z = 256$) of the radio blob and spherical Sedov blastwave. For brevity, we call the former “Impact” case and the latter “Sedov” case. We compare the radius dependence of pressure using the pressure map similar to figure 3 to the numerical Sedov solution as well as the analytical Sedov solution reproduced from Shu (1992) (figure 17.3) at $t = 5, 10, 15$ and 20. In case of the analytical Sedov solution (dashed black line in panel (b) of figure 8), pressure $p$ reaches a limiting value of 0.306 (for $\gamma = 5/3$) as $r/R \to 0$. Numerical Sedov blastwave solutions approach this analytical value at later times as expected. For the impact case, due to the “exhaust” as discussed in section 4, pressure drops more rapidly and approaches a much lower limiting value ($\sim 0$) than the Sedov limiting value. This again validates the discussion of section 3.2 that overall dynamics is not self-similar.

Finally, the intermediate self-similarity of FS between momentum and energy conserving regimes is established according to the discussion of section 3.2 where $n \approx 1.05$ - an excellent agreement between theory and numerical results.

4.3 Effects of reconnection between ejecta and ISM

Various orientations of the magnetic field of the blob as shown in panel 1 are expected to result in different magnetic configurations at early times, figure 9: some will be more prone to reconnection. We investigate these effects next. Upper panels of figure 9 depict the $y$ component of current $J_y$, where $\mathbf{J} = \nabla \times \mathbf{B}$ for the parallel and anti-parallel cases, respectively, projected in 2-D ($xz$ plane) at $t = 1.5$. Lower panels are profiles of $J_y$ plotted along $z = 0$ at the same time instant. Figure 10 is a schematic to understand current formation and magnetic reconnection.

At $t = 1.5$, going from left to right, magnetic field compression at the forward shock (shown by congregated arrows in figure 10) is accompanied by equal magnitudes of current for parallel and anti-parallel cases. However, for the parallel case, field compression is followed by a strong current sheet near the contact discontinuity (CD) as seen from the relative magnitudes of $J_y$ for the two cases at a distance of $\sim 10$. These current peaks are then followed by current in the blob material, evolving identically in both cases. In other words, both parallel and antiparallel cases exhibit similar magnetic
field compressions by the reverse shock passing through the blob material. Thus, numerical resistivity is not significant even in the highly compressed regions with oppositely directed magnetic fields.

Our results do not show any significant effects of magnetic reconnection as we do not see a considerable difference in the magnetic field structure between the parallel and anti-parallel orientations. Magnetic reconnection at the CD in the parallel case plays only a mild role and field evolution is mostly dominated by MHD-type dynamics. For the analysis of shock properties and describing the radio emission, we perform a high-resolution simulation of the blob-ISM interaction with the anti-parallel orientation to minimize the effects of magnetic reconnection, albeit a weak influence (see section 3.1 and panel 1).

5 EMISSIVITY MAPS AND LIGHT CURVES

5.1 Synthetic synchrotron emissivity

To analyze the radio emission from the 2004 GF, we create integrated synthetic synchrotron emissivity maps using models of Chevalier (1982) and Chevalier (1996) which estimate the evolution of synchrotron radio emission from supernova remnants (SNRs). Recall that our 3-D numerical results of pressure and radius are qualitatively similar to the evolution of a Sedov-Taylor blastwave, namely that the hydrodynamic evolution is approximately self-similar and $R \propto t^{5/3}$.

If absorption effects are neglected, the synchrotron luminosity of a radio SNR is (Chevalier 1982)

$$L_\nu \propto 4\pi R^2 \Delta R \kappa B (z_0) \frac{\gamma+1}{\gamma-1} \nu^{-\gamma}$$

Thus, the synchrotron volume emissivity is

$$j_\nu \propto KB^{\gamma+1}$$

The power-law energy distribution of emitting electrons is $N(E) = KE^{-\gamma}$, where $E$ is energy and $K$ is a constant. The value of $\gamma$ is determined by the observed radio spectrum. Observations of radio emission of the 2004 GF report the emission spectrum to be characterized by an unbroken power law with $\gamma = 2.5$ (Gaensler et al. 2005).

We create two emissivity maps: map1 (amplification of the field at the shock), and map2 (pure compression of magnetic field), see Reynolds (2017). Turbulent magnetic field amplification is a prominent mechanism for synchrotron emission in SNRs. Reynolds & Chevalier (1981); Duric & Seaquist (1986); Huang et al. (1994) discuss that to account for the observed radio synchrotron emission on average, magnetic field inside SNRs must be much higher than typical ISM values, $B_{\text{ISM}} \approx 5 \mu G$. A possible mechanism of magnetic field amplification in SNRs considered by Gull (1973); Fedorenko (1983); Duric & Seaquist (1986) is that of Rayleigh-Taylor instability of the CD, separating ejecta from the swept-up ISM. On the other hand, a very efficiently accelerated nuclear cosmic ray (CR) component can cause nonlinear magnetic field amplification near the shock (Lucek & Bell 2000). Observational evidence of such a mechanism is presented by analyzing the synchrotron spectrum of SN 1006 (Berezhko et al. 2002), Cassiopeia A (Berezhko & Völk 2004) and Tycho’s SNR (Völk et al. 2005). In addition, Kosenko et al. (2011, 2014) present numerical models to describe the role of cosmic ray acceleration in the evolution of SNRs, with particular focus on Tycho and SN 1006.

Map1 is based on the assumption of magnetic field amplification where the shock puts constant fractions of post-shock pressure $p = \rho_0 V_s^2$ ($\rho_0$ is the ISM density, $V_s$ is the shock speed) into the magnetic field energy (Bell & Lucek 2001) and electron energy. Thus, $K \propto p$ and $B^2 \propto p$ giving $j_\nu \propto p^{\gamma+1}$.

Map2 is based on the assumption that instead of being amplified, magnetic field is simply compressed from a uniform upstream value. In this case, $j_\nu \propto p B^{\gamma+1}$. With $\gamma = 2.5$, the two synthetic synchrotron maps are defined by the following scalings

$$j_\nu, \text{map1} \propto p^{1.875}$$

$$j_\nu, \text{map2} \propto p B^{1.75}$$

5.2 Emissivity maps

Figure 11 shows 2-D $\gamma = 0$ slices of the two synchrotron emissivity maps scaled as $p^{1.875}$ and $p B^{1.75}$ at late times, $t = 20$. Panel (a) mimics the pressure map of figure 3, just with a different scaling. It is seen that the shock front (apex at $x \sim -200$), which is the site for electron acceleration, is where all the emission originates. A slight rebrightening appearing at $x \sim 100$ is insignificant compared to the emission at the FS and does not contribute to the temporal evolution of luminosity. FS emission in case of magnetic field compression (panel (b)) is weaker than that with magnetic field amplification, presumably due to dissipation of magnetic field because of the interaction between the magnetized ISM and blob.

Figures 12 and 13 depict numerical 2-D ($yz$ plane) maps obtained by integrating late-time ($t = 20$) synthetic emissivities for the prescriptions $p^{1.875}$ and $p B^{1.75}$, respectively, along lines-of-sight at varying angles from $x$-axis, namely $\theta = 0, \pi/6, \pi/4$ and $\pi/3$. The bright spots near $y = 0$ and $z = \pm 150$ occur due to the ISM-wind interaction which has not been subtracted out from the total emission. The case with only magnetic field compression has a weaker integrated emission than the one with magnetic field amplification due to magnetic field interactions. It is seen from both maps that emission from the limb (outer boundary of the spherical emission) is bright and dominates over the apex ($z = 0$) emission along all oblique ($\theta > 0$) lines-of-sight.
Radio afterglow of magnetars’ giant flares

In an effort to understand the results of the simulations, we constructed semi-analytical emission maps shown in figure 14. We approximate the emitting volume as a half-sphere $z > 0$ with surface brightness given by the normalized pressure fit $p(\theta)_{t=20} = (1 - 0.14\theta^2)$ (at time 20) as described in section 4.2. The observer is located at angle $\theta_v$. We assume that emission is generated in a thin shell near the surface of the bubble. (As described previously, the post-shock pressure is released through back flow, leading to fast decrease of emissivity). We then calculate the observed emissivity map according to the prescription $p^{-1.875/(\cos \theta_{r-v} + c_1)}$, where $\theta_{r-v}$ is the local angle between the line-of-sight and the radial direction in the emitting bubble. Parameter $c_1 = 0.1$ is introduced to avoid unphysical values of emissivity when the line-of-sight is tangential to the surface.

Our semi-analytical results reproduce qualitatively the numerics of figures 12 and 13. Emissivity shows strong limb brightening due to longer path through emitting volume. On the other hand, effects of pressure (and thus emissivity) variations along the shock produce only mild variations of intensity.

5.3 Light curves

In figure 15, we show the temporal evolution of normalized luminosities obtained by integrating emissivity assuming an optically thin medium and isotropic emission, following the two scalings described by 12 and 13 over the entire computational box. Synthetic light curves are plotted from $t = 5$ to $t = 15$ in steps of 0.5 in log-log scale for a lower resolution $N_X = N_Y = N_Z = 256$. Unlike the integrated 2-D maps of figures 12 and 13, emission from the “exhaust flow” due to the ISM-wind interaction has been subtracted from the total emission to account only for the emission from the shocked ISM. To do this, we employed two tracers, one to trace the ISM material and another to trace the wind and blob. These tracers are “passive”, meaning they obey simple advection equations and behave as “tags” attached to the ISM and blob+wind so that the contributions from each can be isolated. A linear fit to the plots gives power laws for synchrotron luminosities: $L_{\nu,\text{map1}} \propto t^{-1}$ and $L_{\nu,\text{map2}} \propto t^{-0.1}$. As reported in observations, the radio light curve evolves as $\sim t^{-1}$ after undergoing rebrightening, which marks the self-similar Sedov-Taylor evolution phase of the radio nebula. Our synthetic emissivity map based on the assumption of magnetic field amplification is able to account for this observed temporal evolution. In addition, temporal evolution of
Figure 7. Angular variation of pressure and magnetic field at \( t = 10 \) (red circles) and 20 (blue circles) to describe self-similarity of the forward shock. \( \theta \) is the angle between the \( x \)-axis and the line joining the center of the shock and the point of peak pressure/magnetic field along the FS when seen along several \( z = 0 \) cuts in the \( xz \) plane. (a) The fitting equations of pressure are \( p(\theta)_{t=10} = 1 - 0.27\theta^2 \) and \( p(\theta)_{t=20} = 1 - 0.14\theta^2 \). (b) The fitting equations of magnetic field are \( B(\theta)_{t=10} = 1 - 0.45\theta^2 \) and \( B(\theta)_{t=20} = 1 - 0.42\theta^2 \). The pressure profile does not retain a self-similar shape over time as discussed in section 3.2.

numerical emissivity closely matches that of an ideal Sedov remnant with magnetic field amplification, characterized by \( R(t) \propto t^m \) and \( m = 0.4 \). For such a case, the shock puts constant fractions of the post-shock pressure into electron energy and magnetic-field energy, that is, \( K \propto \rho_0 V_e^2 \) and \( B^2 \propto \rho_0 V_e^2 \). Since volume integrated emissivity \( L_v \propto R^3 K B^{1+\alpha} \) and \( V_e \propto t^{m-1} \), \( L_v \propto t^{m(3+\alpha)-(3+\alpha)} \) (Reynolds 2017), where \( \alpha = \frac{7-1}{2} = 0.75 \) based on observations. Thus, \( L_v \propto t^{-1.05} \). On the other hand, if we use the values of exponents from the simulated radius and pressure evolution, that is, \( R(t) \propto t^{m_1} \) and \( p(t) \propto t^{m_2} \) (section 4.1), unlike the ideal Sedov case where pressure and radius are mutually dependent, volume integrated emissivity \( L_v \propto R^3 p^{(3+\alpha)/2} \propto t^{[6m_1+3m_2(3+\alpha)]/2} \). This gives a semi-analytical estimate of luminosity \( L_v \propto t^{-1.4} \), consistent with numerics. The slight discrepancy is expected because of the faster pressure drop due to considerable “exhaust flow” in the impact case. It is also important to note that the nearly flat light curve in case of field compression \( L_v, \text{map2} \propto t^{-0.1} \) (blue squares) is a consequence of energy conservation and would be exactly constant without a significant backflow.

6 DISCUSSION AND CONCLUSIONS

In this work we model the radio afterglow emission from the 27 December 2004 giant flare from SGR 1806-20. We consider the interaction of light, magnetically dominated cloud (CME) ejected during the magnetar flare with the surrounding ISM. We identify the observed emission features with the forward shock created by the impact. The magnetic blob is first advected with the magnetar wind, and later impacts on the ISM. The impact creates a forward shock, and a complicated backward flow.

Since the CME implants both energy and momentum into the ISM, the flow is not self-similar. Yet, we find that the dynamics of the forward shock (e.g. motion of the apex point) closely follows the Sedov-Taylor (energy conserving) prescription. We find that the lateral structure of the shock is not self-similar, it evolves with time.
Radio afterglow of magnetars’ giant flares

Figure 8. Internal structure of the shocked ISM compared to the Sedov-Taylor case. Plotted are normalized pressure versus radius of the FS of the “Impact” case (panel a) and Sedov-Taylor (panel b). In the impact case, the pressure in the bulk of the flow drops rapidly due to backflow of material and reaches a much lower limiting value than that of a Sedov-Taylor blastwave.

At late times, it approaches Sedov-Taylor like spherical symmetry. At the same time, internal structure of the shocked material is strongly modified by the backward exhaust flow: the pressure in the bulk decreases much faster than in Sedov-Taylor case.

We identify a number of magnetohydrodynamic features of the interaction that can contribute to particle acceleration and the production of radio emission: (i) reconnection between the CME’s and ISM’s magnetic field; (ii) forward shock generated in the ISM; (iii) reverse shock in the CME, and (iv) shocks in the exhaust flow of the ISM.

Relative importance of these contributions is expected to depend mostly on the parameters of the CME. We adopt a magnetically-dominated paradigm for the ejected CME (if a flare was a magneto-spheric event, large baryonic loading is not expected). The CME is then “light and fast”: it carries a lot of energy, but not much mass or momentum. As a result of this assumption, the contribution from the reverse shock in the ejecta is insignificant. We also find that for our parameters, reconnection between the internal and ISM magnetic fields does not contribute considerably: it is the forward shock and the shocks in the exhaust flow that dominate the pressure.

To compare with observations we employ two prescriptions to connect MHD properties with radio emissivity: pure compression of the magnetic field, as well as turbulent amplification. This is, naturally, the weakest point of the model. Accounting for radio emission, that carries a tiny fraction of luminosity and total energetics, is a notoriously difficult problem in the study of SNRs (Kenne
cor 1984; Atoyan 1999; Reynolds 2017). However, the mechanism of magnetic field amplification is often invoked to explain synchrotron emission in SNRs (Reynolds & Chevalier 1981; Duric & Seaquist 1986; Huang et al. 1994).

Observations (Cameron et al. 2005; Gaensler et al. 2005) are similarly complicated, showing somewhat different evolution at different frequencies and changing temporal behavior. However, considering the simplicity of the MHD model and complications involved in quantifying radio synchrotron emission, our analysis with field amplification produces a light curve \( \sim t^{-1} \) consistent with the observed temporal evolution of the SGR 1806-20 radio nebula \( \sim t^{-1.1} \) in the self-similar phase. This, in turn, could mean that field amplification might indeed play a significant role in radio afterglow from magnetar giant flares.

An interesting feature of the observed radio light curve is rebrightening at \( \sim 25 \) days when the radio flux increases by a factor of \( \sim 2 \) (Gelfand et al. 2005). A scenario with a pre-existing shell around the SGR is invoked to explain this flux increase when the emission from swept-up material dominates the light curve (Granot et al. 2006; Gelfand 2007). We test this hypothesis through our MHD simulation. Although the presence of a dense shell produces a break in the temporal evolution of flux, we find no evidence of rebrightening in the light curve due to the impact of the magnetic cloud on the shell. Interestingly, the late-time light curve with only magnetic field compression \( \sim t^{-1} \) does better at accounting for observations, if the shell scenario is accepted.

Several prospects can be explored in the future. One of the limitations of the present approach is not so small beta-parameter of the blob, \( \beta \sim 2 \). This is a purely numerical limitation as the code needs to resolve highly different properties of the wind/the blob and the ISM.

In this study, interaction of the magnetic blob with a constant-density ISM/shell was considered. It would be worthwhile to explore a broader parameter space for the blob and ISM. For example, interaction between the blob and an ISM with varying density profiles such as \( \rho \propto r^{-2} \) or an exponential profile can be analyzed. In addition, effects of a denser or a larger/smaller blob can be tested. Emissivity maps and light curves can be calculated for both prescriptions, and compared with theoretical estimates for Sedov remnants as discussed by Reynolds (2017) as well as with the observed light curve. This exercise can provide a better understanding about the nature of the outflow ejected by the SGR flare and its astrophysical environment. Secondly, a better investigation of the effect of a pre-existing shell around the SGR can be performed by testing the MHD code in dif-

APPENDIX A: ANALYTICAL MODEL: THE GRAD-SHAFRANOV EQUATION AND ITS SOLUTION

In MHD equilibria, the Lorentz force is balanced by the pressure gradient hence demanding

$$\nabla p = J \times B$$  \hspace{1cm} (A1)

where $p$ is plasma pressure, and $J$ and $B$ are current density and magnetic field.

In the Grad-Shafranov framework (Shafranov 1966; Grad 1967) the axisymmetric magnetic field can be represented by a scalar flux function $\psi$ in spherical coordinates

$$B = \nabla \psi \times \nabla \phi + \lambda \psi \nabla \phi$$  \hspace{1cm} (A2)

Force balance A1 gives the Grad-Shafranov equation

$$\frac{\partial^2 \psi}{\partial r^2} + \frac{\sin \theta}{r^2 \sin \theta} \frac{\partial}{\partial \theta} \left( \frac{1}{\sin \theta} \frac{\partial \psi}{\partial \theta} \right) + F(\psi) r^2 \sin^2 \theta + G(\psi) = 0$$  \hspace{1cm} (A3)

where $F(\psi) = 4\pi dp/d\psi$.

We model the radio emission using the magnetic field structure of Gourgouliatos et al. (2010) namely a structure demanding vanishing magnetic field on the surface due to unmagnetized external plasma. We will call this the ‘magnetic blob’ henceforth. This mathematical problem requires both Dirichlet and Neumann boundary conditions to be satisfied, meaning both the flux function $\psi$ and its normal derivative $\partial_r \psi$ should be continuous at the boundary. Following Gourgouliatos et al. (2010), for solutions of A3 of desired properties, $F(\psi) = 4\pi dp/d\psi = F_0$ and $G(\psi) = \lambda^2 \psi$ are chosen. This choice along with $\psi = \sin^2 \theta f(r)$ leads to the analytical solution for the radial part of $\psi$

$$f(r) = A_0 \lambda r j_1(\lambda r) - \frac{F_0}{\lambda^2}$$  \hspace{1cm} (A4)

where $j_1(\lambda r) = \frac{\sin(\lambda r)}{\lambda r} - \frac{\cos(\lambda r)}{\lambda r}$ is the spherical Bessel function.

Thus, it is observed that the solution is simply a force-free spheromak superposed with a uniformly twisted magnetic field (Gourgouliatos et al. 2010)

$$\psi = \sin^2 \theta \left( A_0 \lambda r j_1(\lambda r) - \frac{F_0}{\lambda^2} \right)$$  \hspace{1cm} (A5)

Next, we determine the normalizing constant $A_0$. We consider...
the flux to be confined within a structure of radius $r_0$ which can take several values unlike Gourgouliatos et al. (2010) where they consider a unit radius. This enables us to write all following equations in terms of $r_0$ giving the flexibility of testing the code for radius dependence, if desired. The first boundary condition of zero magnetic field on the surface $f'(r_0) = 0$ gives

$$F_0 = \frac{A_0 \lambda^3}{r_0} j_1(\lambda r_0)$$

(A6)

The second boundary condition of zero surface currents $f''(r_0) = 0$ gives

$$\tan(\lambda r_0) = \frac{3 \lambda r_0}{3 - 4 \lambda^2 r_0^2}$$

(A7)

The smallest positive root of this equation is $\lambda \approx 5.763/r_0$ giving $F_0 = -31.7 A_0 / r_0^4$. Magnetic field components are

$$B_r = \frac{2 \cos \theta}{r^2} f(r)$$

(A8)

$$B_\theta = \frac{\sin \theta}{r} f'(r)$$

(A9)

Since the blob is held together by magnetic field, pressure profile within the sphere in pressure balance with the ambient medium having pressure $p_0$ can be given as

$$p = p_0 + \frac{F_0 \psi}{4\pi} = p_0 - \frac{B_{\text{max}}^2}{8\pi}$$

(A11)

where $B_{\text{max}}$ is the maximum pressure at the center of the sphere. Defining a plasma-$\beta$ as $\beta = p_0/B_{\text{max}}^2$ along with maximizing $f(r)$ and using the value of $F_0$ gives the normalizing constant

$$A_0 \approx 0.11 \sqrt{\frac{p_0}{\beta^2}}$$

(A12)

As seen from A11, there is a dip in pressure at the center of the blob. This dip is determined by $B_{\text{max}}$ and hence $\beta$. To prevent negative pressure at the center, $\beta > 0.5$. Thus, initial magnetic field within the blob used to model the radio emission is completely defined by its initial radius, initial plasma-$\beta$ and pressure of the ambient medium.
The light curve for the case of magnetic field compression and no amplification, \( L_{\nu, \text{map2}} \propto pB^{1.75} \), undergoes only a single break and can be fit with two power laws: at early times \( \sim 2 < t < 7 \), the blob’s interaction with the dense shell is characterized by a shallow decay in luminosity \( \sim t^{-1.2} \), followed by an even steeper decay \( \sim t^{-1.7} \) between \( t = 9 \) to \( t = 20.5 \) as the shock propagates through the shell and finally breaks out. At late times \( t > 20 \), as effects of the shell weaken after the shock crosses the shell, luminosity undergoes a shallow decay, approaching a steady time evolution \( \sim t^{-0.3} \). It is important to note that the late-time flattening of the light curve is due to the wind-ISM shock and not due to the blob-ISM shock.

The light curve for the case of magnetic field amplification and no compression, \( L_{\nu, \text{map1}} \propto p^{1.875} \), can be fit with three power laws: at early times \( \sim 2 < t < 8.5 \), the blob’s interaction with the dense shell is characterized by a steep decay in luminosity \( \sim t^{-1.2} \), followed by an even steeper decay \( \sim t^{-1.7} \) between \( t = 9 \) to \( t = 20.5 \) as the shock propagates through the shell and finally breaks out. At late times \( t > 20 \), as effects of the shell weaken after the shock crosses the shell, luminosity undergoes a shallow decay, approaching a steady time evolution \( \sim t^{-0.3} \). It is clear that effect of magnetic field is important and causes the shell to play a dominant role in the evolution of synchrotron emission.

Our analysis of the shock dynamics in the presence of a pre-existing shell indicates that although the shell might produce a break in the radio synchrotron emission at the shock’s shell crossing time, it does not account for rebrightening as reported in observations. At very late times, we expect the effects of shell to taper down significantly, thus causing the light curves to evolve similarly as the case without a shell. The shell might cause rebrightening in some regime with the appropriate shell thickness, density, and magnetic field. Hence, we are unable to conclusively eliminate this possibility. Investigation of appropriate regimes and shell parameters that might cause a flux increase can be a subject for future work.
