Temperature Prior to Harvest Influences the Incidence and Severity of Clubroot on Two Asian Brassica Vegetables

Abstract. Shanghai pak choy (Brassica rapa L. subsp. chinensis (Rupr.) var. communis Ts and Lee) and Chinese flowering cabbage (B. rapa L. subsp. chinensis (Rupr.) var. utilis Ts and Lee) were seeded into organic (muck) soil naturally infested with the clubroot pathogen (Plasmodiophora brassicae Woronin) at the University of Guelph Muck Crops Research Station, Ontario, Canada, in June, July, and Aug, 2001 and May, June, July, and Aug, 2002. At harvest, clubroot incidence and disease severity index (DSI) were assessed. Data from 17 different seedings at the research station over 4 years were used to compare the relationship between disease incidence and DSI and weather conditions during crop development. Clubroot incidence and severity were highest for crops harvested in July and August and lowest for crops harvested in October. Mean air temperatures during crop development ranged from 15 to 22 °C and were positively correlated with clubroot incidence and severity for both pak choy (r = 0.68) and flowering cabbage (r = 0.73). The strongest correlations occurred between air temperatures and disease severity over the final 10 d before harvest (r = 0.82 for pak choy; r = 0.84 for flowering cabbage). The research suggests that clubroot damage in Asian Brassica vegetables could be minimized by seeding in early spring and late summer in areas infested with P. brassicae.

Clubroot, caused by the soilborne protist Plasmodiophora brassicae (Woronin), is a major pest of Brassica crops in Canada and worldwide. Infected roots of Brassica crops swell, blocking the vascular tissues of the roots. As a result, plants can become wilted and stunted. For short-season Asian Brassica crops such as Shanghai pak choy (Brassica rapa L. subsp. chinensis (Rupr.) var. communis Ts and Lee) and Chinese flowering cabbage (B. rapa L. subsp. chinensis (Rupr.) var. utilis Ts and Lee), severe symptoms can lead to delayed or variable maturity, rapid wilting during dry periods, and reduced yield. However, not all symptoms of clubroot cause a loss in marketable yield in these crops if soil moisture is sufficient, because the crops have often been harvested before the time when severe clubbing occurs. Several strategies have been developed for long-season Brassica crops to reduce damage in the field, including liming, fertilizers, crop rotation, and chemical controls, but these strategies often do not reduce losses in the field to tolerable levels.

Spores of P. brassicae germinate readily at soil temperatures at or above 14 °C and the germination rate increases as temperature increases (Einhorn and Bochow, 1990). It is generally accepted that the optimal soil temperature for disease development is from 18 to 25 °C (Colhoun, 1952, 1953). However, it is not known how spore germination rate relates to the rate of infection for many crops, including Asian Brassica crops. A daily mean air temperature of 19.5 °C was required for 100% infection to occur in a greenhouse study (Buczacki et al., 1978). In addition, clubroot severity on cabbage, Chinese cabbage, mustard, and radish was minimal below 14 °C and maximized between 20 and 22 °C (Thuma et al., 1983). The influence of environmental factors on host resistance to P. brassicae is poorly understood. Buczacki et al. (1978) suggested that high light during the second and third weeks after seeding increases clubroot severity, probably as a result of an increase in the concentration of gluco-brassicin, a precursor to club development.

Materials and Methods

Seedling date trial. Shanghai pak choy and Chinese flowering cabbage were seeded into organic (muck) soil at the University of Guelph Muck Crops Research Station, Holland/Bradford Marsh, Ontario, Canada (long. 44°58'W, lat. 79°35'N) in 2001 and 2002. The site was naturally infested with the clubroot pathogen. Each plot consisted of four rows, 42 cm apart and 5 m in length, and was direct-seeded using a Stanhay precision seeder (Stan Hay Co., Ashford, UK) with four replications per seeding date. The trials were conducted on separate sites within 50 m of each other in 2001 and 2002. The seeding date treatments were 25 June, 25 July, and 23 Aug. 2001 and 24 May, 24 June, 24 July, and 23 Aug. 2002. Calcium ammonium nitrate was applied at 200 kg ha⁻¹ on all planting dates, and phosphorus and potassium were applied based on soil tests according to Ontario recommendations (Ontario Ministry of Agriculture, Food, and Rural Affairs, 2000).

At harvest on 1 Aug., 12 Sept., and 13 Oct. in 2001 and 4 July, 29 July, 29 Aug., and 11 Oct. in 2002, 30 plants from each plot were collected and assessed. The roots were thoroughly washed and graded for clubroot
Results

Seeding date trial. In the seeding date trial conducted in 2001 to 2002, clubroot incidence in 2001 was highest for the July seeding on both pak choy and flowering cabbage and was higher for the June seeding compared with the August seeding on pak choy (Table 2). In 2002, clubroot incidence was highest for the May and June seedings and low for the July and August seedings on pak choy, but there were no differences identified for flowering cabbage as a result of variability within the seeding dates. Overall, clubroot incidence was much higher in 2002 than in 2001. Clubroot severity, as determined by DSI at harvest, followed the same pattern as disease incidence in both years. Incidence and severity of clubroot were higher on pak choy than on flowering cabbage throughout the trial ($P < 0.0001$).

Multitrial comparison. Results from the combined data from 1999 to 2002 showed that clubroot incidence and severity increased with increasing air and soil temperatures for both pak choy and flowering cabbage, especially during the late growth period (Table 3). Air temperatures during the entire period from seeding until harvest were positively correlated with disease incidence and severity for both crops, but soil temperatures at 5-, 10-, and 20-cm depths were not correlated with disease incidence or severity during the same period (Table 3). When the season was divided into 10-d periods, the highest correlation occurred between air temperatures during the final 10 d of crop development and disease incidence and severity (Table 3; Fig. 1). There was no correlation between any of the temperature variables and disease incidence or severity during the period between 11 and 20 d before harvest (DBH) (Table 3) or any other 10-d

Multitrial comparison. In addition to the seeding date trials, nine trials containing Shanghai pak choy and Chinese flowering cabbage and one trial of only pak choy were conducted at the Muck Crops Research Station from 1999 to 2002. There were four replications in each trial, and the mean of the four replications was used for comparison with weather conditions. The seeding dates for the additional trials were 1 June and 9 Aug. 1999; 12 June and 24 Aug. 2000; 15 May, 30 May, and 1 June (two trials) 2001; and 21 May, 24 May, and 6 June (only Shanghai pak choy) 2002. The methods of clubroot assessment at harvest were the same for all trials and occurred on 2 July and 21 Sept. 1999; 24 July and 4 Oct. 2000; 11, 16, and 18 July 2001; and 27 June and 2 July 2002. The means of untreated controls along with data from the seven previously described seeding date trials were used in subsequent analysis of the effect of weather conditions during crop development on clubroot incidence and severity.

Weather. Air temperature (Campbell Scientific model HMP35C probe; Campbell Scientific, Edmonton, Alberta, Canada), soil temperatures at 5-, 10-, and 20-cm depth (Campbell Scientific model 107 probe), and rainfall (Campbell Scientific tipping bucket gauge) were collected at an automated weather station located within 75 m of all research trials. Data were recorded using a CR21X data logger (Campbell Scientific). The air temperatures were recorded on site at a height of 1.2 m, and the weather station was located over a mowed grass surface over organic soil. The weather data for the period between the day after seeding and the day before harvest were compiled for each trial using the weather station data. Data from all trials were pooled for analysis. Temperature and rainfall data for all of the trials are summarized in Table 1.

Analysis of variance was performed on the data from the seeding date trials in 2001 to 2002 combined over years. Means were compared using Fisher’s Protected LSD Test. The incidence and severity of clubroot were compared with weather variables using linear correlation analysis. Data were analyzed using Proc Corr and Proc GLM in SAS Version 9.1 (SAS Institute, Cary, NC). A type I error rate of 0.05 was used for all statistical tests.

*a*Nonsignificant.

When the final 15 DBH were divided into 5-d periods, the strongest correlations were between disease incidence and severity and soil temperatures during the final 5 DBH and disease incidence and severity and air temperatures between 6 and 10 DBH (Table 4). There was no correlation between clubroot incidence or severity and air or soil temperatures during the period from 11 to 15 DBH. When assessed based on 5-d periods, clubroot development occurred in some trials despite cold temperatures near harvest, and this can be explained by a relatively warmer period between 6 and 10 DBH in most cases (Table 5). Rainfall was not correlated with clubroot incidence or severity during any of the periods examined (data not shown).

Discussion

Seeding date influences the incidence and severity of clubroot on Shanghai pak choy and Chinese flowering cabbage. Disease incidence and severity were consistently highest for crops harvested during July and August and lowest for crops harvested in October. However, there was a difference between the 2 years in the clubroot incidence and severity in the July seeding date. In 2001, clubroot was severe in the July seeding despite relatively cool conditions during growth. However, in 2002, clubroot was much less severe in the July seeding despite relatively warm conditions during growth. Closer examination of the weather data reveals that, despite a relatively cool end of August and early September for the 2001 July seeding that delayed harvest, there was a warm period that occurred between 3 and 7 DBH. During this period, the mean air temperature was 24.5 °C. By contrast, for the same seeding date in 2002, mean temperatures were warm (mean, 21.6 °C) for the first 23 d after seeding (DAS), resulting in rapid crop development, but in the last 12 DBH, the mean air temperature was only 17.3 °C and 18.5 °C for the period from 3 to 7 DBH.

Based on the results of the correlation analysis, the effect of seeding date on incidence and severity of clubroot can be attributed to differences in air and soil temperatures during the final 10 d before harvest. Also, we noted that temperature has a similar influence on disease incidence and severity as previously reported (Colhoun, 1953). However, temperature during the 11 to 20 DBH period and earlier was not correlated with incidence or severity. Soil temperatures were slightly less correlated with disease incidence and severity than air temperature, which may be the result of differences between the plots and the weather station where the temperatures were recorded. Because the soil temperature measurements were taken under a mowed grass surface, they would generally be cooler than the soil temperatures in the trial and less responsive to changes in air temperature. Because clubroot develops below the soil surface, soil temperatures at 5-cm depth probably have a significant influence on clubroot development. However, it is possible that the influence of temperature on clubroot development is partly the result of changes in the rate of development of the host, which would be directly affected by air temperature. The research indicates that air temperatures can be an effective indicator of the potential for disease development, which would be useful for instances in which soil temperatures are not available.

HortScience Vol. 43(5) August 2008
Based on previous research, it is possible to estimate the timing of different stages of the life cycle of *P. brassicae* in our experiments. The period between seeding and harvest for these crops averaged 41 d and ranged from 31 to 50 d. It is not known how much the timing of optimal temperatures for club development are influenced by host, and consequently, it is difficult to compare the timing of different stages in the life cycle among studies on different crops. However, infection of the roots by zoospores probably occurs ≈10 to 14 DAS (Buczacki et al., 1978; Tommerup and Ingram, 1971). Under optimal conditions, the latent period would last ≈14 d (Tommerup and Ingram, 1971) and under field conditions, this period has been suggested to last 20 to 25 d (ChoongHoe et al., 2000; Grsic-Rausch et al., 2000). Thus, symptom development would likely begin 24 to 39 DAS. Einhorn and Bochow (1990) defined the incubation period as the period between seeding emergence and symptom development. In that study, there was a negative linear relationship between temperature and the length of the incubation period. The length of the incubation period could be described using the following equation (Einhorn and Bochow, 1990):

\[ \text{Incubation period} = 73.74 - 2.55 \times \text{soil temperature} \]

Using this equation and assuming seeding emergence occurs 4 DAS, symptoms would develop in the range of 27 to 42 DAS in our studies. Using either of these estimates, club development would begin within the last 10 DBH for all crops in our study, so the effect of temperature during the final 10 DBH is primarily on club development. Because air or soil temperatures in earlier periods of crop development did not have much influence on clubroot incidence or severity, it is possible that infection by *P. brassicae* and subsequent development in the roots has a similar optimal temperature as the host plant. If this is the case, then conditions that favor rapid crop development also favor rapid progression of *P. brassicae* through different stages in the roots. Our research indicates that the optimal temperature for club development may differ from that of the host. Rainfall was not correlated with disease incidence or severity. Because plots were irrigated before seeding if necessary, and the crops were only in the field for 31 to 50 d, soil moisture would have been adequate throughout the season, regardless of rainfall, as a result of the high waterholding capacity of the organic soil.

Overall, the research indicates that several strategies can be used to reduce clubroot severity in Asian Brassica vegetables in Ontario. Seeding susceptible crops in early spring, earlier than the late May planting in this study, or in August or September could effectively minimize disease severity in most cases. This strategy was also suggested for cauliflower in Germany (Einhorn and Bochow, 1990). Over the summer months, nonsusceptible crops can be grown. If this is not possible, it is likely that any strategy that will keep soil temperatures cool during the final 10 DBH will also reduce the severity of the disease. The use of organic or reflective mulches has been effective in reducing soil temperatures for other crops (Davis et al., 1970) and may minimize clubroot if mulches can be incorporated into the production system. Other strategies could include timely irrigation or living mulches. It is also possible that season-extending strategies such as row covers could potentially increase clubroot severity if soil temperatures are increased.

In summary, clubroot on Asian Brassica crops was influenced by air and soil temperatures during the late growth period. This effect was consistent among crops and years. Thus, methods to reduce temperatures during this period could reduce the severity of clubroot. Combining these methods with existing control strategies could prevent major losses resulting from clubroot in the field.
