ABSTRACT: Recent progress in calculating lepton density functions inside the proton and simulating lepton showers laid the foundations for precision studies of resonant leptoquark production at hadron colliders. Direct quark-lepton fusion into a leptoquark is a novel production channel at the LHC that has the potential to probe a unique parameter space for large masses and couplings. In this work, we build the first Monte Carlo event generator for a full-fledged simulation of this process at NLO for production, followed by a subsequent decay using the POWHEG method and matching to the parton showers utilizing HERWIG. The code can handle all scalar leptoquark models with renormalisable quark-lepton interactions. We then comprehensively study the differential distributions, including higher-order effects, and assess the corresponding theoretical uncertainties. We also quantify the impact of the improved predictions on the projected (HL-)LHC sensitivities and initiate the first exploration of the potential at the FCC-hh. Our work paves the way toward performing LHC searches using this channel.

1 Introduction

Leptoquarks are hypothetical spin-0 or spin-1 particles carrying both lepton and baryon numbers and mediating a novel interaction among quarks and leptons. They stem from various theories beyond the Standard Model (SM), motivated by the idea of quark-lepton unification. They are predicted in scenarios of matter unification à la Pati-Salam [1] involving SU(4) gauge group or in grand unification theories with larger gauge groups like SU(5) [2], and SO(10) [3]. The phenomenology of leptoquarks is a mature topic (for a recent review see [4]), relevant for both low- and high-energy experiments. Leptoquarks at the TeV scale are particularly interesting for high-energy colliders.

The renewed interest in TeV-scale leptoquarks in recent years originates from several experimental anomalies in semileptonic decays of $B$-mesons [24–31] which naturally
highlight leptoquarks as possible explanation candidates. This is because leptoquarks contribute to the semileptonic transitions at the tree level. At the same time, they affect dangerous four-quark or four-lepton flavour-changing neutral currents, well described by the SM, at the one-loop level only. With anomalies continuing to persist, the TeV-scale leptoquarks with $O(1)$ couplings to the SM fermions are a clear target for current and future collider searches. Motivated in part by the developments in flavour physics, there has been an increasing effort within ATLAS and CMS experiments to hunt for leptoquarks (for recent results see [32–41]).

Since leptoquarks couple quarks and leptons, they necessarily carry SU(3) charge and can thus be pair produced in gluon fusion [42–50]. This production mechanism is dominant for small values of the leptoquark to quark and lepton coupling $y_{q\ell}$, depending only on the leptoquark mass and the strong coupling $\alpha_s$. However, the pair production is not optimal for heavy leptoquark searches due to rapid phase-space suppression with increasing leptoquark mass. For this reason, often discussed in the literature is the single leptoquark plus lepton production from quark-gluon scattering [50–53]. The production cross section for this process is proportional to $|y_{q\ell}|^2$, but suffers less phase-space suppression, and for $O(1)$ coupling, it compares to, and even wins over, the cross section for leptoquark pair production. Finally, a non-resonant effect of leptoquarks in the $t$-channel Drell-Yan process could be seen as a deviation in the high-$p_T$ tail of the dilepton invariant mass distribution [54–62]. Since, in this case, the cross-section scales as $|y_{q\ell}|^4$, the expectation is that this process dominates the leptoquark signatures for large couplings and masses beyond the kinematical reach for on-shell production.

Resonant leptoquark production from a direct lepton-quark fusion is another relevant process at a hadron collider put forward in [63]. However, before the precise determination of leptonic parton distribution functions (PDF) inside the proton in [64], this process could not be utilized in practice. The work of [64], therefore, provides a novel opportunity to discover leptoquarks at the LHC. The production cross section scales as $|y_{q\ell}|^2$ and enjoys the least phase-space suppression, making it the most sensitive process for certain parameter regions with $O(1)$ couplings and TeV-scale masses. The phenomenological collider simulation for this channel, performed in [65, 66], confirmed this statement and established the resonant leptoquark production mechanism as an exciting candidate for future experimental analyses. In particular, this mechanism surpasses the single leptoquark plus lepton production, which also scales as $|y_{q\ell}|^2$.

However, the limitation of [65, 66] is the inadequate signal modeling, more precisely, the tree-level approximation and the absence of a lepton shower not available at the time. In this context, the recent computation of next-to-leading (NLO) corrections in [67], and the development of a lepton shower in [68], constitute a first step toward exploiting the full potential of the resonant leptoquark production, allowing for more advanced precision studies.

In this paper, we make a significant leap forward by constructing a full-fledged Monte Carlo tool for the resonant leptoquark production from a lepton-quark fusion at NLO merged with QCD and lepton showers. By NLO, we mean here that we include QCD corrections and a subset of enhanced QED corrections that makes them comparable with
the QCD ones, as we will explain in due time. We quantify the impact of higher-order corrections on the differential phase-space distributions. We assess the importance of the improved signal modeling on the projected LHC bounds derived in [65]. Additionally, we compute the inclusive cross sections for 100 TeV proton-proton center-of-mass energy and briefly discuss the potential offered by a future circular hadron collider (FCC-hh) [69]. Our ready-to-use Monte Carlo event generator will facilitate further phenomenological studies and enable the first experimental searches for this process at the LHC.

The paper is organised as follows. In section 2, we describe the implementation of the resonant leptoquark production in the POWHEG framework. In section 2.1, we define the scope of the leptoquark models and present the expressions for the required amplitudes at NLO. In section 2.2, we discuss the treatment of the total decay width, while in section 2.3 we report on the modifications of the POWHEG-BOX needed to support this process. In section 3, we discuss the most important phenomenological imprints of the resonant leptoquark production mechanism. In section 3.1, we validate the implementation against the inclusive NLO cross sections reported in [67] and provide new results for 100 TeV collider. In section 3.2, with quantify the impact of NLO corrections and parton shower effects on the differential distributions. In section 3.3, we quantify the error made due to the limited signal simulation in the sensitivity study of [65]. In section 3.4, we showcase a model example, the $S_3$ leptoquark. In particular, we estimate the sensitivity reach of 100 TeV proton-proton collider in the mass versus coupling plane. We finally conclude in section 4.

2 Implementation within the Powheg-Box

In this section we develop a Monte Carlo tool for the resonant leptoquark production at NLO (and subsequent decay) capable of generating Les Houches events (LHE) that can be directly processed by a Parton Shower (PS) program in order to obtain a complete simulation of the collision at the NLO+PS level.

2.1 Leptoquark models and scattering amplitudes

Our goal is a POWHEG-BOX-RES implementation of the resonant leptoquark production at NLO in both QCD and QED for all renormalisable scalar leptoquark models. The starting point is the Lagrangian in the broken phase, i.e. respecting $SU(3)_C \times U(1)_{\text{QED}}$ gauge symmetry,

$$\mathcal{L} \supset -y_{q\ell}^L \bar{q} P_L \ell \, S_{Q_{LQ}} - y_{q\ell}^R \bar{q} P_R \ell \, S_{Q_{LQ}} + \text{h.c.},$$

(2.1)

where $y_{q\ell}^{L,R}$ are general $3 \times 3$ Yukawa coupling matrices in flavour space, and $P_{L,R} = (1 \mp \gamma^5)/2$ are the chiral projectors. The SM chiral fermions $q_{L,R}$ and $\ell_{L,R}$ correspond to the mass eigenstates after the electroweak symmetry breaking. In general terms, the scalar leptoquarks, $S_{Q_{LQ}}$, are triplets of $SU(3)_C$, with their possible $U(1)_{\text{QED}}$ charges being $|Q_{Q_{LQ}}| = \left\{ \frac{1}{3}, \frac{2}{3}, \frac{4}{3}, \frac{5}{3} \right\}$. The viable flavour structure of the Born process involves the quark flavours $u,d,s,c,b$ (and $t$ at FCC-hh) and charged leptons $e, \mu, \tau$. For instance, a $c$-quark and a $\tau$-lepton can be used to create $S_{1/3}$ and $S_{5/3}$ leptoquarks, as specified by
\[ \mathcal{L} \supset - y^L_{c\tau} \tau_L S_{5/3} - y^R_{c\tau} \tau_L C L S_{1/3}^\dagger. \]

Note that any renormalisable scalar leptoquark model defined respecting the full SM gauge symmetry \([4]\) can be recast in the form of eq. (2.1) by separately considering the different SU(2)_L components of the leptoquark representation. In section 3.4, we will exemplify this with a weak triplet.

Next, we present the expressions for the amplitudes that are used by the code. Starting with the leading order (Born level), the resonant leptoquark production proceeds via fusion of a lepton and a quark in the initial state. Given the energies of the colliders in consideration, we approximate the aforementioned fermions to be massless, such that the possible interference terms between left- and right-handed Yukawa couplings vanish. Thus, the averaged squared matrix element for a particular flavour combination \(q\ell\) at the Born level reads

\[
\text{born} = \frac{1}{4} \left( |y^L_{q\ell}|^2 + |y^R_{q\ell}|^2 \right) \hat{s} \equiv \frac{1}{4} |y_{q\ell}|^2 \hat{s}, \tag{2.2}
\]

where \(\sqrt{\hat{s}}\) is the partonic-level center of mass energy. Moreover, when different flavour combinations in the initial state contribute to the production of the same leptoquark, the contributions to the averaged squared matrix element are added separately. The expression \(\text{born}\) matches the input of the POWHEG-BOX-RES that the process-specific code should provide in the routine

\[
\text{setborn}(p(0:3,1:1), \text{bflav}(1:1), \text{born},
\text{bornjk}(1:1,1:1), \text{bmunu}(0:3,0:3,1:1)).
\]

In our case, since we are dealing with the 2 \(\rightarrow\) 1 process, we set \(n\text{legborn} = 3\), and \(p(0:3,i)\) denote the components of the four-momenta of the \(i\)-th particle. We enumerate the particles in the process \(q + \ell \rightarrow LQ\) as 1 \(\rightarrow\) 2 \(\rightarrow\) 3, respectively, such that \(\hat{s} = p(0,3)^2 - p(1,3)^2 - p(2,3)^2 - p(3,3)^2\), while the color correlated squared amplitude, \(\text{bornjk}\), and the spin correlated one, \(\text{bmunu}\), read

\[
\text{bornjk}(1,2) = \text{bornjk}(2,3) = 0, \tag{2.3}
\]
\[
\text{bornjk}(1,3) = \frac{4}{3} \text{born}, \tag{2.4}
\]
\[
\text{bmunu} = 0, \tag{2.5}
\]

as explained in [70], with \(\text{bornjk}\) being symmetric.

Apart from the leading (Born) contribution, this process receives important NLO corrections from interactions with gluons and photons. As shown in [67], the QED corrections that we need to include are such that the smallness of the QED coupling is compensated by the PDF enhancement due to the photon in the initial state of the process \(\gamma + q \rightarrow \ell + LQ\), so that they are in fact of the same order as the QCD corrections.

In the context of QCD corrections, the first relevant partonic process is \(g(p_1) + \ell(p_2) \rightarrow q(k) + LQ(q)\), shown in figure 1 a) and b). The partonic cross-section for this process was computed in [71, 72].\(^1\) Here we present the matrix element squared required by POWHEG-BOX-RES. Averaging over spin and colors, and omitting the factor \(\alpha_s/2\pi\), with \(\alpha_s\) the

\(^1\)Notice that the diagram with the same structure of b), but with an incoming quark and an outgoing lepton, is not included here. It is part of the associated production of a leptoquark and a lepton and should be included in that context. See, for example [50].
strong coupling, as specified in [70], it reads

$$\text{amp}^2_{\text{real}}_{g+\ell} = -2\pi^2 |y_{q\ell}|^2 \frac{\hat{s} (\hat{u}^2 + m_{\text{LQ}}^4)}{\hat{t} (\hat{u} - m_{\text{LQ}}^2)^2},$$

(2.6)

where $\hat{s}, \hat{t},$ and $\hat{u}$ are the partonic-level Mandelstam variables defined as

$$\begin{align*}
\hat{s} &= (p_1 + p_2)^2 = 2 p_1 \cdot p_2 = 2k \cdot q + m_{\text{LQ}}^2, \\
\hat{t} &= (p_1 - k)^2 = -2 p_1 \cdot k, \\
\hat{u} &= (p_1 - q)^2 = -2 p_1 \cdot q + m_{\text{LQ}}^2.
\end{align*}$$

(2.7)

The second relevant partonic process is with the gluon in the final state $q(p_1) + \ell(p_2) \rightarrow g(k) + \text{LQ}(q)$, shown in figure 1 c) and d). Averaging over spin and colors, removing the factor $\alpha_s/2\pi$, the matrix element squared required by POWHEG-BOX-RES reads

$$\text{amp}^2_{\text{real},q+\ell} = \frac{16}{3} \pi^2 |y_{q\ell}|^2 \frac{\hat{u}}{\hat{t}} \frac{(\hat{s}^2 + m_{\text{LQ}}^4)}{(\hat{s} - m_{\text{LQ}}^2)^2},$$

(2.8)

with Mandelstam variables already defined in eqs. (2.7).

Additionally, in the context of QED corrections, there is an additional real matrix element from diagrams with a photon in the initial state computed in [67], $\gamma(p_1) + q(p_2) \rightarrow$
The averaged matrix element squared required by Powheg-Box-Res, divided by $\alpha_s/(2\pi)$, reads

$$\text{amp2real}_{\gamma+q} = \frac{\alpha_{\text{QED}}}{\alpha_s} 4\pi^2 |y_{\ell q}|^2 \left[ -Q_L^2 \frac{s}{t} - 2 Q_t Q_q \left( 1 + \frac{m_{LQ}^2}{s t} \right) - Q_L Q_L \frac{u}{s + t} \left( 1 - \frac{2 m_{LQ}^2}{s} \right) \right] \left( 1 + m_{LQ}^2 \right),$$

(2.9)

where $Q_L$, $Q_q$, and $Q_{LQ}$ are lepton, quark, and leptoquark electric charges, respectively. Since QED preserves charge conjugation, the cross section for the conjugated process is the same, i.e. there are no terms linear in the electric charge in eq. (2.9). For example, the amplitude is the same for $\gamma(p_1) + \bar{u}(p_2) \rightarrow \ell^-(k) + LQ_{1/3}(q)$ and $\gamma(p_1) + u(p_2) \rightarrow \ell^+(k) + LQ_{-1/3}(q)$.

Finally, the last ingredient which needs to be provided to Powheg-Box-Res is the finite part of the virtual corrections computed in dimensional regularization. The corresponding diagrams are shown in figure 1 h), i) and j). The result for the finite part of the virtual cross section for the process $q + \ell \rightarrow LQ$, derived in [71], rewritten in a way to match the form of $\text{virtual}$ in Powheg-Box-Res subroutine $\text{setvirtual}$ in [70] reads

$$\text{virtual} = -\frac{|y_{\ell q}|^2}{3} \left[ 2 + \frac{\pi^2}{6} + \log \left( \frac{\mu^2}{s} \right) \left( 1 + \frac{1}{2} \log \left( \frac{\mu^2}{s} \right) \right) \right],$$

(2.10)

where $\mu_R$ is the renormalization scale.

This completes the list of the standard ingredients needed to set up a process within the Powheg-Box-Res framework. There are other few peculiar aspects, related to the specific processes at hand, to be considered. Given that similar issues might also occur for other BSM applications, we decided to provide a flexible solution adding and/or modifying some parts of the Powheg-Box-Res code. We give more details in the following two dedicated sections.

In a full-fledged simulation, the hard scattering process needs to be matched with a parton shower.\footnote{The matching is straightforward in the case of a $p_T$ ordered shower, such as Pythia8 [73]. The matching to an angular ordered shower, such as Herwig [74], although more delicate, is also well understood [75].} Despite the recent interest and progress in the phenomenology of lepton induced processes in hadron-hadron collisions, the availability of Monte Carlo generators which handle initial-state leptons is rather limited. So far, only Herwig [74] provides a support for showering lepton initiated processes in a development branch which is publicly available [76]. As a first application, a Powheg NLO+PS generator for various lepton-lepton scattering processes relevant at the LHC has been put forward in [77]. In the present work, we make use of a similar setup and refer the interested reader to [77] for further details.

2.2 The line shape and the decay width

For most of the parameter space, we can factorize the leptoquark production from decay by using a narrow width (NW) approach. This is a good approximation for inclusive
observables such as the total production rate. However, the relevance of the resonant leptoquark mechanism in the context of the LHC searches crucially relies on modeling the line shape. The leptoquark mass is reconstructed from its decay products, the lepton-jet system. The shape of the reconstructed mass peak depends not only on the intrinsic width but also on QCD and QED radiation, jet reconstruction, and detector resolution. The latter effects, which lead to a broadening of the peak, are usually dominant in weakly-coupled ultraviolet (UV) completions. Therefore, when considering a narrow leptoquark, we can neglect the intrinsic width when generating the fixed order events to be subsequently fed by the parton shower.

However, this approach is not sufficient for UV models featuring moderate-to-strong leptoquark couplings. The description of the leptoquark line shape in our simulation is improved by incorporating the finite width effects. This impacts the large couplings in eq. (2.1) predicting a broad resonance, but which are still within the realm of perturbation theory, e.g. $\Gamma_{LQ}/m_{LQ} \sim \mathcal{O}(0.1)$ where $\Gamma_{LQ}$ is the total leptoquark decay width. Following ref. [78], we recast the LO differential partonic cross section for the production of a scalar leptoquark in lepton-quark collisions in the following factorised form,

$$
d\hat{\sigma}_{LO} = \frac{1}{2s} d\Phi_2 |M_{q+\ell \to q'+\ell'}|^2
d\hat{\sigma}_{q+\ell \to LQ}(M^2) \frac{1}{2} \frac{m_{LQ}\Gamma_{LQ}}{M^2 - m_{LQ}^2} \frac{M\Gamma_{LQ \to q'+\ell'}(M)}{m_{LQ}\Gamma_{LQ}} .
$$

(2.11)

Here we used the factorisation properties of the $2 \to 2$ matrix element, where

$$
d\hat{\sigma}_{q+\ell \to LQ}(M^2) = 2\pi \delta(s - M^2) |M_{q+\ell \to LQ}|^2 \quad \text{and} \quad \Gamma_{LQ \to q'+\ell'}(M) = \frac{|y_{q'\ell'}|^2}{16\pi} M ,
$$

(2.12)

are the partonic cross section for the production of an on-shell leptoquark of mass $M$, and the LO partial decay width for $LQ \to q' + \ell'$, respectively.\footnote{We observe that the strict NW approximation is recovered by taking the limit \begin{align*}
\frac{1}{\pi} \frac{m_{LQ}\Gamma_{LQ}}{M^2 - m_{LQ}^2} \frac{M\Gamma_{LQ \to q'+\ell'}(M)}{m_{LQ}\Gamma_{LQ}} \rightarrow \delta(M^2 - m_{LQ}^2) .
\end{align*}}

The events are generated according to the following simulation chain:

1. Set up \text{Powheg} for a $2 \to 1$ kinematic at Born level;
2. Compute the BRs in the different lepton-quark channels;
3. Generate isotropic leptoquark decays according to the BRs when finalising the LHE events.

Instead, the finite width effects are turned on/off by setting the flag \text{BWgen} to 1(0) in the input card. These effects are included by implementing the last line of eq. (2.11) within the above simulation chain as follows:

1. Set up \text{Powheg} for a $2 \to 1$ kinematic at Born level;
2. When generating the Born phase space, add an extra integration over the squared invariant mass $M^2$ (note that the pole mass is $m_{LQ}$) in a given finite window $[M_{\text{min}}^2, M_{\text{max}}^2]$ and include the Breit-Wigner factor as a weight. That is, generate $M^2$ according to
\[
dF_{BW} = dM^2 \frac{1}{\pi} \frac{m_{LQ} \Gamma_{LQ}}{(M^2 - m_{LQ}^2)^2 + m_{LQ}^2 \Gamma_{LQ}^2};
\] (2.13)

3. Compute all Born and real matrix elements setting the leptoquark mass to $M$ and include the extra multiplicative factor $f = M^2/m_{LQ}^2$ which takes into account the kinematic dependence of the third term in eq. (2.11),
\[
\frac{M \Gamma_{LQ \rightarrow q' + \ell'}}{m_{LQ} \Gamma_{LQ}} = \frac{M^2 \Gamma_{LQ \rightarrow q' + \ell'}(M)}{m_{LQ}^2 \Gamma_{LQ}/m_{LQ}} = \frac{M^2}{m_{LQ}^2} \text{BR}(LQ \rightarrow q' + \ell'),
\] (2.14)

4. Compute the BRs for all lepton-quark channels;

5. Generate isotropic leptoquark decays according to the BRs when finalising the LHE events.

The partial decay width of the scalar leptoquarks, including the NLO QCD corrections reads [72]
\[
\Gamma_{LQ \rightarrow q + \ell} = \frac{|y_{q\ell}|^2}{16 \pi} m_{LQ} \left(1 + \alpha_s \pi \left(\frac{9}{2} - \frac{4 \pi^2}{9}\right)\right).
\] (2.15)

Here we assume $m_q + m_\ell \ll m_{LQ}$. In POWHEG-BOX-RES the user can opt for using eq. (2.15) to compute the total width automatically given the input coupling matrix, or instead specify the arbitrary value for the width accounting for possibly missing decay channels.

The expressions for the Born, real, and virtual matrix elements in section 2.1, as well as the decay width in eq. (2.15) are completely general, and are valid for all possible scalar leptoquarks. With the appropriate choice of leptoquark charge $Q_{LQ}$ and couplings parametrised by the Yukawa matrices, this code can be used to explore any renormalisable scalar leptoquark model as discussed below eq. (2.1).

2.3 Modifications of the Powheg-Box

The POWHEG-BOX code provides advanced and automatised implementation of the FKS subtraction method [79] for computing QCD and EW corrections in the context of the SM. This allows to add new SM processes in a straightforward way once the corresponding matrix elements are available, as described in the previous sections. However, when dealing with exotic particles for BSM applications, several process-dependent hacks are required to complete the calculation. While working on the implementation of the scalar leptoquark, we introduced new features necessary for these circumstances. Therefore, before moving to the phenomenological results, we take the occasion to document such novelties which are available in POWHEG-BOX-RES.4

4These modifications are publicly available for beta testing in the folder Beta-progress.
The first feature concerns new particles that are charged under the QCD gauge group, SU(3)_{C}. By default, the program will not recognise them as a possible emitter of radiation and, correspondingly, will miss to consider the associated soft singularities. To account for this, we introduced a facility which enables the developer of the new process to assign the colour representation of the new particle by calling the subroutine

```
subroutine set_colour(pid,rep,setget)
```

The first argument, `integer pid`, is an identification number of the particle. In principle it should be the identification code of the particle according to the Monte Carlo numbering scheme [80]. If the particle does not have an identification code any integer value can be used except for those already assigned to the SM particles. The second argument, `character * 4 rep`, represents the colour representation of the particle. It can assume the values ‘3’, ‘3bar’ and ‘adj’ for fundamental, anti-fundamental and adjoint representations, respectively. The third argument, `character * 3 setget` specifies the behavior of the subroutine. When `setget='set'`, it assigns the representation `rep` to the particle with identifier `pid`. When `setget='get'`, the subroutine returns the value of the representation of the particle with identifier `pid` and stores it in the variable `rep`. The latter is required for internal usage, while the process-specific code should just use ‘set’.

As an example, our scalar leptoquark transforms according to the fundamental representation of SU(3)_{C}. In this case, we just need to add the following line within the `init_processes`

```
call set_colour(42,‘3’,‘set’)   
```

where we assign the leptoquark with the identifier number 42. With this, the program will correctly handle the singular region associated to the leptoquark emitting a soft gluon including the corresponding soft terms in the calculation.

The second feature concerns the treatment of the collinear remnants associated to initial state radiation. POWHEG-BOX automatically generates those contributions on the basis of the possible underlying Born configurations. The algorithm inspects initial state partons, and, if they are coloured and/or electrically charged (when QED corrections are turned on), adds the remnants related to all possible splitting. However, this mechanism may fail for non-standard applications. For example, in the scalar leptoquark case, we consider, together with QCD ones, a subset of QED radiative corrections associated only to the photon-to-lepton initial-state splitting. In this case, the algorithm will process an underlying Born amplitude characterised by the presence of both a lepton and a quark in the initial state. Since the quark carries a non-vanishing electric charge, it will also add a spurious remnant associated to the photon-to-quark emission, which, though possible, is neglected in our calculation since it is subleading. We overcame this issue by implementing a new version of the collinear remnants aware of the radiation regions (alr in the nomenclature of POWHEG-BOX) that are really present in the calculation, rather than guessing them according to the underlying Born configurations. The alr are in turn determined by the POWHEG-BOX based on the real processes specified by the process-specific routines.
This new mechanism is completely transparent for the user implementing a new process, who needs to provide the Born and real processes only. In addition, we observe that this new implementation is also helpful for debugging purposes. Indeed, it makes it easier to split the calculation in subparts which can be separately tested.

3 Phenomenology

3.1 Inclusive cross sections

The inclusive NLO cross sections for the resonant leptoquark production at the LHC were first computed in [67]. We have validated our Powheg-Box-Res implementation against this reference.5

We then complement the study carried out in [67], which focuses on the LHC phenomenology, and compute the production rates at the FCC-hh ($\sqrt{s} = 100\,\text{TeV}$). In tables 1 and 2, we show the Powheg-Box-Res predictions for the inclusive resonant leptoquark production cross sections at 100 TeV proton-proton collider. We sum up the two cross sections for particle and antiparticle production. We consider all possible flavour and charge combinations for three different leptoquark masses, $m_{LQ} = 5, 10, \text{and } 15\,\text{TeV}$. The couplings are all set to zero but for a single entry in $y_{Lq}^R$ corresponding to a desired quark-lepton flavour combination. (The same results are obtained for $y_{Rq}^L$ instead of $y_{Lq}^R$.) We also compute theoretical uncertainties associated to missing higher orders by taking the envelop of the customary seven point scale variations, and the error associated with the uncertainty on the pdf which is derived by calculating the symmetric error obtained by averaging the results for all the different replicas.

We make use of the PDF set LUXlep-NNPDF31_nlo_as_0118_luxqed [64] which includes photons and leptons. Before discussing the results, some comments are in order. At these energies, top quarks are substantially produced by QCD radiation and should be considered as a possible initial state. This opens an opportunity to study new quark-lepton combinations not present at the LHC. A consistent description of top-initiated processes would require using a PDF set with $n_F = 6$ flavours. However, a single PDF set that includes both photon/leptons and the top quark is still unavailable. To circumvent this issue, we assume that the presence of top and photon/leptons induces only a slight modification to the dominant partons through DGLAP evolution and affects QCD sum rules, such as the proton momentum conservation, by a tiny amount. Therefore, as a first approximation, we can borrow the top quark density as is from the NNPDF31_nlo_as_0118_nf_6 set [81] and add it to the LUXlep-NNPDF31_nlo_as_0118_luxqed set.6

While performing the comparison, we found differences at the level of $\lesssim 1\%$ with tables 1 and 2 of [67] published by some of us. By further inspection, we could trace these differences to the numerical values of $\alpha_{\text{QED}}$, the use of negative PDFs, and a missing term in the numerical implementation of the plus distribution. We do not report the same tables again since the phenomenological relevance of these differences is negligible. The updated numbers can easily be obtained using the Powheg-Box-Res implementation, a publicly available supplement to this paper.

We have also verified that doing the opposite, namely borrowing the photon and leptons from the LUXlep-NNPDF31_nlo_as_0118_luxqed and adding them to the NNPDF31_nlo_as_0118_nf_6, leads to minor differences at the percent level. Therefore, the uncertainty associated with the above approximation is relatively small and well within the scale uncertainty. Once the appropriate PDF set becomes available, our calculations can easily be repeated using Powheg-Box-Res.
| $m_{LQ}$ [TeV] | Partons | $\sigma_{S/3}$ [pb] | $\sigma_{S/3}$ [pb] |

Table 2. Inclusive cross sections (in pb) at NLO for the resonant leptoquark production $pp \to LQ$ plus $pp \to LQ$ at $\sqrt{s} = 100$ TeV from down-type quarks and charged leptons. For each flavour combination $q \ell$ reported in the second column, the associated Yukawa coupling in eq. (2.1) is $y_{q\ell} = 1$ while $y_{q\ell}^R = 0$. The last two columns are for scalar leptoquarks with electric charges $\pm 2/3$ and $\pm 4/3$, respectively. The two displayed uncertainties are due to the scale variations (first) and PDF replicas (second). See section 3.1 for details.
We, therefore, treat the top quark as an extra initial light parton. Alternatively, given that the top mass acts as the physical regulator of the collinear divergence, one may compute the top process starting from a gluon splitting $g \rightarrow t\bar{t}$, retaining the full mass dependence and taking into account the possibility of having a second resolved top. This is in analogy to the 4FS versus 5FS computations for the processes involving bottom quarks at the LHC.

As for the lepton in the initial state, a similar situation also holds for contributions due to the massive EW gauge bosons, whose relevance grows with the collider energies. One can account for them by including additional subprocesses initiated by an EW gauge boson parton splitting into a lepton pair [82, 83]. We observe that in this case, one can study leptoquark production in neutrino-quark fusion. The account of these effects is beyond the aim of the present work.

The results obtained in tables 1 and 2 indicate promising prospects at the FCC-hh given the luminosity target is up to $30\text{ ab}^{-1}$ [69]. As expected from the PDF, the cross sections for heavier quark generations are hierarchically smaller but comparable for different lepton generations. As anticipated, the top-induced cross sections are sizeable, offering unique opportunities for leptoquarks exclusively coupled to top quarks. Given these results, it is interesting to analyze the potential offered by FCC-hh in more detail. We relegate further discussion to section 3.4 where we perform a simplified sensitivity study based on the total cross section to chart the parameter space for which one expects to produce more than 100 events.

3.2 Differential distributions

The main advantage of the POWHEG-Box-RES implementation with respect to [67] is the flexibility to study arbitrary differential distributions. This can be done at any simulation stage (before and after leptoquark decay or parton shower) at the LO and NLO accuracy. In this section, we comprehensively study the resonant leptoquark production kinematics.

We investigate three benchmark scenarios where the scalar leptoquark is exclusively produced from $b + e$, $b + \mu$, and $d + e$ fusion. In all cases, the leptoquark charge is set to $\pm 2/3$, while the leptoquark mass is set to $m_{LQ} = 2\text{ TeV}$ for illustration. The Yukawa couplings in eq. (2.1) are all set to zero except for the desired quark-lepton flavour combination $y_{q\ell}^T = 1$. The leptoquark is therefore decayed to the same quark-lepton pair. The code automatically computes the total leptoquark decay width using eq. (2.15). The energy of the proton beams is set to $6.5\text{ TeV}$ each ($\sqrt{s} = 13\text{ TeV}$) and the PDF set is LUXlep-NNPDF31_nlo_as_0118_luxqed (central) [64].

When running the reconstruction analysis, a perfect detector is assumed with no smearing effects. The high-level objects of interest are the leading-$p_T$ jet and lepton, which typically originate from the leptoquark decay. The jets are built using the anti-$k_T$ algorithm [84] with $\Delta R = 0.4$ as implemented in Fastjet [85]. The cuts on the transverse momentum ($p_T > 500\text{ GeV}$) and the pseudorapidity ($|\eta| < 2.5$) are applied, and the hardest

---

7 The code provided in the POWHEG-Box repository http://powhegbox.mib.infn.it allows studying other benchmarks efficiently.
jet and lepton are then selected. We also require the total invariant mass of the jet-lepton system to be above 1 TeV and below 4 TeV. Bremsstrahlung recombination was considered for the lepton by adding photons that lie inside a cone of $\Delta R < 0.2$. We see no appreciable difference between the muon and the electron case. This is consistent with the fact that for high-mass objects the quark-electron and quark-muon luminosities are very similar (see figure 8 in ref. [64]), and thus the only substantial difference between muons and electrons is the more significant QED radiation of the latter. So, after recombination, no relevant difference remains. Thus, the $b\mu$ case is not shown in the figures since it is indistinguishable from the $b\mu$ case. Finite width effects are turned on (see section 2.2).

Two million LO and NLO events were processed to generate the plots shown in the figures 2 and 3. The upper box in each plot displays four lines. The bands show the customary 7-point scale variation uncertainty. The lines labeled LO (LHE), and LO+PS (HW7) are obtained by restricting the event generation with POWHEG to leading order and running the analysis before (blue) and after (orange) the parton shower using HERWIG. Similarly, the NLO simulations were used for the purple (before PS) and the green (after PS) lines. The two smaller boxes below the main box show the ratio of NLO to LO before and after showering. As illustrated by the plots, the NLO order corrections are sizeable and depend on the kinematics.

The invariant mass and rapidity of the jet-lepton system are shown in figure 2 in the left and right columns, respectively, for the benchmark scenarios: $b + \mu$ (top), and $d + e$ (bottom). The jet-lepton system’s invariant mass distributions ($m_{ll}$) show a resonance peak at $m_{LQ} = 2$ TeV. The width of the peak before the parton shower is narrow and meets the expectation from the intrinsic leptoquark width in eq. (2.15). The effect of the parton shower can be observed as well — the peak position is shifted to a slightly lower value of ($m_{ll}$), the peak is smaller and considerably broader for the distributions of showered events both at LO and NLO and leans towards lower masses. It is helpful to remark that this effect is mostly due to the fact that, in our NLO calculation, we do not include radiative corrections to the leptoquark decay. Under these circumstances, the final state radiation generated by the Monte Carlo in the leptoquark decay becomes very relevant since it is the only source of jet momentum degradation due to final state radiation outside the jet cone. This causes a sizeable raise of the backward tail and a slight lowering of the forward tail in the invariant mass spectrum. By investigating further this effect, we have found that another contributing factor is the presence of events such that the selected jet is not the one arising from the leptoquark decay. This is more likely to happen in the showered events, since there are more jets in that case. These events tend to inflate the differential distribution below the peak.

When comparing the jet-lepton system’s rapidity plots in figure 2 (right column), it is worth noticing a broader distribution for the down quark compared to the bottom quark. This behavior stems from the down quark being a valence quark and having a higher probability of carrying a more significant fraction of the proton’s total momentum. Therefore, leptoquarks produced from valence quarks tend to carry more momentum along the beam axis, broadening the shape of the rapidity distribution towards larger values.
Figure 2. Differential distributions for the benchmark points defined in section 3.2. The left (right) panel shows the jet-lepton system’s invariant mass (rapidity).

Notice also the large difference in the signal rate between the $d$ and the $b$ case, due to the sea versus valence quark PDF, and to larger NLO corrections in the latter. These features are expected since, as shown in figure 8 of ref. [67] for the LQ of charge $\pm 2/3$, the NLO QCD K-factor is close to unity for bottom initiated processes and it does not compensate the negative NLO QED one, which is similar for all quark cases.

Figure 3 shows the azimuthal angle $\Delta \phi$ between the lepton and the jet in the left column, and the transverse momentum $p_T^{\ell j}$ of the jet-lepton system in the right column. The $\Delta \phi$ between the jet and the lepton in figure 3 (left column) shows that the two objects are mostly back to back in the azimuthal plane. At LO without parton shower, all events exactly have $\Delta \phi = \pi$. The radiation at NLO opens up smaller angles to the distribution. The parton shower populates even smaller angles, but the rate still clearly peaks around $\pi$ as expected. The rapid fall of the LHE band in the $\Delta \phi$ plot, near $\delta \phi = 1$, can be understood as a kinematic effects. As $\delta \phi$ decreases, the transverse momentum of the jet balancing the leptoquark must increase, up to the point when it becomes the hardest jet,
and is thus selected as such. The presence of more jets in the shower case can allow instead for a larger boost of the leptoquark, not associated with a single hard jet in acceptance.

The transverse momentum of the jet-lepton system $p_{T}^{\ell j}$ in figure 3 (right column) is zero for all LO events before the shower. We notice the feature of the distribution for transverse momenta between 200 and 500 GeV, where the showered events have larger cross section, and smaller cross section above 500 GeV. First of all, we have verified that such feature is not present in the distribution of the leptoquark at the “Monte Carlo Truth” level (i.e. the leptoquark in the Monte Carlo just before decay), where a perfect agreement is found between the NLO(LHE) and NLO+PS(HW7) distributions. This is due to the fact that *Herwig* preserves as much as possible the four momentum of resonances. A good fraction of the effect can be tracked back to the final state radiation from the quark, that as remarked previously, is included only by the shower. Another contribution arises if the hardest jet or the hardest lepton in acceptance are not the ones coming from the leptoquark decay. Of course this happens more easily in showered events.

---

**Figure 3.** Differential distributions for the benchmark points defined in section 3.2. The left panel shows $\Delta \phi$ between lepton and jet, and the right panel shows the jet-lepton system’s transverse momentum $p_{T}^{\ell j}$. 

---

"JHEP11(2022)129"
The plots show that the uncertainty band of the LO predictions vastly underestimates the size of the NLO corrections. There can be considerable shape differences between results at LO and NLO. The NLO corrections are crucial for an accurate description of these distributions. The $p_T^{\ell j}$ is helpful to discriminate the resonant leptoquark from the single leptoquark plus lepton production [50] which features a hard lepton in the production already at tree-level.

The transverse momentum and the pseudorapidity distributions of the leading jet and lepton are shown in figure 4 and figure 5. In all plots, higher-order corrections to the pseudorapidity distributions are slightly flatter than the corresponding ones to the rapidity distribution of the lepton-jet system. Otherwise, they display a similar pattern, and similar comments are in place. As expected, the $p_T$ distributions show a jacobian
Figure 5. The transverse momentum (left column) and the pseudorapidity (right column) distributions of the leading-$p_T$ lepton. See section 3.2 for details.

peak at $m_{LQ}/2$. The region above the kinematic limit $p_T = m_{LQ}/2$, strictly forbidden at LO in the NWA, is populated by finite-width effects. Starting from NLO, this region also becomes accessible because of extra radiation. This explains the fact that LO (LHE) predictions for $p_T > m_{LQ}/2$ are much softer than the other three predictions. Notice that the NLO (LHE) results' smooth behavior is generated according to the POWHEG Sudakov factor. Showered predictions feature a softer spectrum than NLO (LHE) ones due to final-state radiation. The effect is more pronounced in the case of the leading jet since the radiation probability for additional QED emissions is suppressed by the lower coupling $\alpha_{\text{QED}}$. This explains the rise toward smaller $p_T$ values. Comparing the tail of the leading jet $p_T$ above the peak for the $b + \mu$ and $d + e$ cases, we observe that, in the latter, NLO+PS(HW7) results present a harder spectrum than LO+PS(HW7) ones, while they
overlap in the former. This different behavior can be traced back to the interplay between the initial-state radiation’s hardness and a valence quark’s presence. In fact, in events initiated by a valence quark (that carries a larger fraction of the proton momentum), the first emission is, on average harder, and the NLO+PS generator describes this radiation with higher accuracy than a LO+PS one. On the other hand, in the case of a sea quark, the same configurations feature a softer initial-state radiation and a LO+PS description is sufficient to capture the main effects. For the leading lepton $p_T$ the situation is inverted, with NLO+PS predictions displaying a harder spectrum than LO+PS ones in the $b+\mu$ case. The physical mechanism is the same described above with the difference that, this time, the initial-state lepton colliding with a sea quark is, on average, more energetic than the one colliding with a valence quark.

3.3 Impact on the projected LHC bounds

The phenomenological studies performed in [65, 66] disclosed the potential of the resonant leptoquark production through lepton-quark fusion as a competitive search strategy at the LHC, especially for the region of large leptoquark couplings and masses. In that work, the modeling of signal events was based on an approximate LO+PS prediction. The approximation is related to using Pythia8 to shower the LO events. Indeed, Pythia8 does not handle lepton-initiated processes. On the other hand, it supports photons in the initial state. Hence, in that work, the particle labels were suitably manipulated to recognize the process as originating from a photon-quark scattering. In this way, the first radiation generated by the shower is likely to be a colored parton most of the time. At the same time, for a lepton-quark scattering event, the photon splitting process $\gamma \rightarrow \ell\ell$ competes with QCD radiation in the backward evolution. The resulting mismodeling of the hadronic activity in the event was estimated to have only a mild impact, affecting the prediction for the reconstructed leptoquark mass by roughly 20\% [65].

In the present work, we have improved the simulation of the signal events in two ways: first, we include the full set of NLO corrections to the leptoquark production process, from now on NLO$_P$, and, second, we match à la POWHEG the NLO$_P$ corrections to a modified version of the Herwig7 parton shower [74] that handles lepton initiated processes [76]. In the following, we assess the relative impact of these improvements. We consider as a benchmark point a scalar leptoquark of nominal mass $m_{LQ} = 3$ TeV, charge $Q_{LQ} = \pm 1/3$ and which couples only to electrons and up quarks.

Our main focus is on the reconstructed jet-lepton invariant mass where the leptoquark shows up as a resonance. Additional selection cuts are crucial to tame the SM background. However, they largely affect the shape of the resonant peak and the acceptance of signal events. We consider a simplified version of the fiducial volume defined in [65] to analyze the main radiative effects. As a basic requirement, dubbed as cut $A$, we select events with at least one lepton and one jet in the central region of the detector, $|\eta_{\ell,j}| < 2.5$. We then impose the following set of cuts on leading and subleading leptons/jets, collectively referred

\[ f_{\gamma}/f_{\ell} \sim \alpha_s/\alpha \] compensates for the factor of $\alpha$ arising from the photon splitting.

---

---
to as cut $B$: $p_T^{ℓ, j_1} > 500$ GeV, a veto on secondary leptons with $p_T^{ℓ, j_2} > 7$ GeV and $|η^{ℓ, j_2}| < 2.5$, a veto on secondary jets with $p_T^{j_2} > 30$ GeV and $|η^{j_2}| < 2.5$.

In figure 6, we compare different predictions for the invariant mass distribution of the system composed of the hardest lepton and hardest jet, obtained with samples of signal leptoquark events at different accuracy: LO (blue), LO+PS (HW7) showered with HERWIG7 (orange), NLO$_P$ Les Houches events as generated with POWHEG (gray), NLO$_P$+PS (HW7) the same events showered with HERWIG7 (green). The bands correspond to the customary 7-point scale variation. We also report in black the LO+PS$_{γq}$ (PY8) prediction obtained showering the events with PYTHIA8 after performing the replacement of the initial lepton with a photon as done in [65]. We leave out multiparton interactions (MPIs) and detector effects from these comparisons to facilitate the discussion. Furthermore, we do not apply any recombination of photons with a close-by lepton.

Let us remind the reader that we computed NLO radiative corrections only to the leptoquark production process, leaving to the parton shower the full description of the radiation from the decay products. For this reason, it is interesting to consider first the case in which we switch off final-state radiation (FSR) in the parton shower, which more closely resembles the radiative content of our NLO$_P$ prediction. We start focusing on the plots of the left-hand side of figure 6, where we apply only the essential requirement cut $A$. Comparing top and bottom, we observe that the exclusion of FSR leads to much milder parton shower effects. Indeed, the distinctive radiative tail in the bottom plot is entirely due to QCD FSR, which forms a separate second jet softening the leading jet, originated by the quark in the leptoquark decay. Furthermore, we have explicitly verified that photon-to-lepton recombination has a minimal impact on the distribution, confirming that the FSR effects due to QED radiation are less important. When FSR is not included, all predictions are close-by among each other within $15−20\%$, except for the one obtained with LO+PS (HW7) generator. This might be due to different shower mechanisms and recoil prescriptions in PYTHIA8 and HERWIG7, whose impact becomes less prominent after performing the matching to the NLO$_P$ computation. While this is an interesting topic, its investigation is beyond the aim of the present work, and it is left for a future study.

We turn to the more interesting situation in which we apply the combination of cuts cut $A+B$. The results are shown in the plots of the right-hand side of figure 6, excluding (top) or not (bottom) FSR radiation. Since the cuts are tailored to enhance Born-like configurations, the LO prediction remains in practice untouched. On the other hand, the veto on secondary leptons and jets vastly reduces all the other predictions, see Tab 3. In addition, the radiative tail seen in the more inclusive setup is effectively cut out. In particular, when FSR is excluded (top right), we observe that the result obtained with the NLO$_P$+PS (HW7) generator only mildly differs from the NLO$_P$ one, meaning that only the first few emissions are relevant for the computation of the acceptance. The radiation from the decay products further reduces the acceptance. Since the NLO$_P$ computation does not contain such effects, it fails to describe the total result. Instead, the LO+PS predictions and the more accurate NLO$_P$+PS one includes radiative effects from the decay as modeled by FSR of the parton shower (bottom right).
Figure 6. Invariant mass distribution of the leading-$p_T$ lepton and jet system, $m_{\ell j}$, in a model of resonant $s$-channel leptoquark production through lepton-quark fusion at the LHC. In each figure, the various predictions correspond to generators at different accuracy, as explained in the main text, while the bottom panel contains the ratio to the LO+PS (HW7) one. We display results for the number of events requiring only cut A (left) and the combination cut A+B (right). Radiation from the decay products is disabled in the two top figures.

The main results regarding the A+B cuts can be summarised as follows:

- NLO$_P$ provides an estimate of the acceptance that, however, misses the effects due to radiation from the decay products;
Table 3. The cut flow analysis. The table shows the acceptance $A = \sigma_{\text{cut}}/\sigma_{\text{nocuts}}$ associated to cut A and cut A+B. See section 3.3 for details.

|              | cut A (noFSR) | cut A+B (noFSR) | cut A   | cut A+B  |
|--------------|---------------|-----------------|---------|----------|
| LO          | 0.96          | 0.89            | 0.96    | 0.89     |
| LO+PS (HW7) | 0.98          | 0.48            | 0.98    | 0.28     |
| NLO         | 0.97          | 0.42            | 0.97    | 0.42     |
| NLO+PS (HW7)| 0.98          | 0.37            | 0.99    | 0.20     |
| LO+PS$_{\gamma q}$ (PY8)| 0.97 | 0.51            | 0.98    | 0.29     |

- LO+PS$_{\gamma q}$ (PY8) and LO+PS (HW7) give results in reasonable agreement among each other, with very mild differences of about 15%. Nonetheless, we notice that this result might be accidental given that we observe substantial differences in the mass spectrum predicted by the two generators when FSR is turning off. This issue seems alleviated after the NLO matching, as the NLO$_P$+PS(HW7) and LO+PS$_{\gamma q}$ (PY8) display an overall better agreement in shape. We believe that this is a further motivation for the experts in parton showers to pursue the study of lepton initiated processes in proton-proton collisions;

- by comparing with the NLO$_P$, FSR radiation contributes to the reduction of the acceptance of a further 50%, see also table 3;

- the most accurate NLO$_P$+PS prediction leads to a further reduction of the acceptance of about 30% with respect to LO+PS ones. This can be explained by the fact that the former includes the exact matrix element for the first emission in production. As a result, we expect the limits on the leptoquark couplings shown in figure 3 of [65] to relax by about 15%.

It is well known that parton showers usually provide a better description of FSR radiation than ISR. Therefore, one may expect that the NLO$_P$+PS description computed in this work already captures the main radiative effects. Nonetheless, given the importance of FSR in computing the acceptance, a natural extension of the present work would be to match the NLO computation for all possible resonant and non-resonant $2 \rightarrow 2$ quark-lepton processes to the parton shower, thus including radiation from all legs and (or) resonant intermediate states.

In the above comparative study, we have focused on a leptoquark which couples to first-generation quarks and leptons in order to have a more direct comparison with the benchmark used in ref. [65]. Given the relevance of second- and third-generation leptoquarks in flavour physics, we show in figure 7 analogous results for a leptoquark of mass $m_{\text{LQ}} = 2 \text{TeV}$, which is closer to the current LHC bounds, charge $Q_{\text{LQ}} = \pm 1/3$ ($\pm 2/3$) and which couples only to muons and charm (bottom) quarks. While the qualitative behavior of the different predictions is similar to that observed in the previous case, we see a larger reduction of the signal rate at the NLO$_P$+PS level, about 50% compared to the LO+PS result. This effect can be related to the differences in the NLO corrections among
Figure 7. As in figure 6 for the combination cut A+B. The left (right) panel displays the result for a leptoquark $m_{LQ} = 2$ TeV, charge $Q_{LQ} = \pm 1/3$ $(\pm 2/3)$ and which couples only to muons and charm (bottom) quarks.

valence and sea quarks, as already outlined in the previous section. It clearly highlights the importance of using the more advanced generator, which includes higher-order radiative corrections, developed in this work.

3.4 The case study: $S_3$ leptoquark

To illustrate the usage of the code for a particular UV model, we add to the SM an additional scalar field transforming in the anti-fundamental of $SU(3)_{C}$ and the adjoint of $SU(2)_{L}$ with the hypercharge $Y = 1/3$, known as the $S_3 \sim (\bar{3}, 3)_{1/3}$ leptoquark [4]. In the unbroken phase, the renormalisable Lagrangian describing the couplings of $S_3$ to the SM fermions reads

$$- L \supset \lambda_{q\ell} \bar{Q}^{C}_{L} e^{ab}(\sigma^{k} S_{3}^{k})^{bc} L_{L} + \lambda_{qq} \bar{Q}^{C}_{L} e^{ab}((\sigma^{k} S_{3}^{k})^{\dagger})^{bc} Q_{L} + h.c.,$$

(3.1)

where $\sigma^{k=1,2,3}$ are the Pauli matrices, $e^{ab} = (i\sigma^{2})^{ab}$, $C$ stands for charge conjugation, and $S_{3}^{k}$ are leptoquark components in the $SU(2)_{L}$ space. The matrices $\lambda_{q\ell}$ and $\lambda_{qq}$ are generic $3 \times 3$ matrices in flavour space. The summation over flavours is assumed. It is easy to argue that dangerous diquark couplings $\lambda_{qq}$ are absent due to an (approximate) baryon number conservation.

This can be achieved, for example, in some GUT models where $S_3$ is embedded in SO(10) or SU(5) irreducible representation [86, 87]. Another example is to gauge a lepton flavour non-universal $U(1)$ under which $S_3$ is charged such that $\Delta B = 0 \,(\text{mod} \, 3)$ completely forbids proton decay [88].
The left-handed quark and lepton SU(2)_L doublets, Q_L and L_L, are assumed to be in the down-quark and charged-lepton mass basis, respectively. After the electroweak symmetry breaking, the relevant interactions of the electromagnetic charge eigenstates

\[ S_{-2/3} = (S_3^1 + i S_3^2)/\sqrt{2}, \quad S_{1/3} = S_3^3, \quad \text{and} \quad S_{4/3} = (S_3^1 - i S_3^2)/\sqrt{2}, \]

in the notation of eq. (2.1), read

\[ -\mathcal{L} \supset y_{U_L}^L U_L^C \nu L S_{-2/3} + y_{U_L}^\ell U_L^C \ell L S_{1/3} + y_{D_L}^L D_L^C \nu L S_{1/3} + y_{D_L}^\ell D_L^C \ell L S_{4/3} + \text{h.c.}, \quad (3.2) \]

where U and D stand for the three up- and down-type quarks, while \( \ell \) (\( \nu \)) stands for the three charged leptons (neutrinos), and

\[ y_{U_L}^\nu = \sqrt{2} V_{\text{PMNS}}^T \lambda_{q\ell} V_{\text{PMNS}}, \quad y_{U_L}^{\ell} = -V_{\text{CKM}}^T \lambda_{q\ell}, \quad (3.3) \]

\[ y_{D_L}^\nu = \lambda_{q\ell} V_{\text{PMNS}}, \quad y_{D_L}^{\ell} = -\sqrt{2} \lambda_{q\ell}, \quad (3.4) \]

where \( V_{\text{PMNS}} \) is the Pontecorvo-Maki-Nakagawa-Sakata mixing matrix, and \( V_{\text{CKM}} \) is the Cabibbo-Kobayashi-Maskawa mixing matrix. The SU(2)_L gauge symmetry predicts the three states to be nearly mass-degenerate. Potentially significant contributions to the mass splitting are constrained by the electroweak precision tests \([4]\). This is, of course, very important for the direct searches at the LHC, predicting multiple degenerate resonances.

Since the neutrino PDF in the proton is vanishing (at the order in perturbation theory we are working at)\( ^{10} \), proton collisions can produce only the states with charges 1/3 and 4/3 in the quark-lepton fusion. However, various decay channels are generally open (including neutrinos), and the branching ratios depend on the flavour structure of \( \lambda_{q\ell} \).

When the leptoquark flavour matrix \( \lambda_{q\ell} \) has an anarchic structure, the low-energy flavour physics observables set a lower limit on \( m_{LQ} \) to be far above the TeV scale, see \([4, 89]\). A consistent scenario should therefore exhibit flavour protection. For simplicity, we assume that the leptoquark carries a global U(1)_j \times U(1)_\beta quark and lepton charges, where \( j \) and \( \beta \) denote a particular quark and lepton flavour combination, such that the only allowed coupling becomes

\[ \lambda_{q\ell} \frac{U(1)_j \times U(1)_\beta}{\lambda} \delta_{qj} \delta_{\ell\beta}, \quad (3.5) \]

where \( \lambda \) is a complex number. For example, the case in which the leptoquark is charged under the global U(1)_1 \times U(1)_2 symmetry implies that the only non-vanishing entry in \( \lambda_{q\ell} \) is the 1 \(-\) 2 entry, \( \lambda_{12} = \lambda \). Neglecting neutrino masses, which is an excellent approximation at relevant energies, this symmetry is broken only by the CKM mixing matrices. In this limit, the flavour-changing contributions in the quark sector are suppressed by the smallness of the off-diagonal CKM elements while charged lepton flavour is exactly conserved. For the direct searches at the LHC, the CKM can safely be approximated with the unit matrix.

The bottomline of these assumptions is that the leptoquark interacts dominantly with a single generation of quarks and a single generation of leptons. In the following, we

\( ^{10} \)It can be generated with a mechanism similar to the lepton PDF, going through a Z/W rather than a photon, but, unlike the lepton case, the logarithmic enhancement is missing.
Figure 8. Contours in the \((m_{LQ}, \lambda)\) plane for producing 100 events at the FCC-hh for \(\pm 1/3\) (left plot) and \(\pm 4/3\) (right plot) charge components of the \(S_3\) scalar leptoquark model from section 3.4. The solid black line is for the QCD pair production, while the red, blue, and orange are for the resonant leptoquark production, assuming couplings to the first, second, or third generation of quarks, respectively. The grey shaded region shows the regime of a broad resonance.

will study all six quark flavour cases separately. Since the lepton PDF are similar across different flavours, we will consider only the coupling to muons for simplicity.\(^{11}\)

With all this, the LO decay widths of \(S_{1/3}\) and \(S_{4/3}\) states are given as

\[
\Gamma_{S_{1/3}} = \frac{(y_{UL}^L)^* y_{UL}^L + (y_{DL}^L)^* y_{DL}^L}{16\pi} m_{LQ} U(1)_{j \times U(1)_2} \frac{m_{LQ}}{8\pi},
\]

\[
\Gamma_{S_{4/3}} = \frac{(y_{UL}^D)^* y_{UL}^D}{16\pi} m_{LQ} U(1)_{j \times U(1)_2} \frac{|\lambda|^2}{8\pi} m_{LQ},
\]

where we sum over quark and lepton flavour indices. In the case of \(U(1)_j \times U(1)_2\) global symmetry, \(\lambda = \lambda_{2j}\), with \(j = 1, 2, 3\) depending on the quark generation which couples to the leptoquark.

Let us finally discuss the importance of the resonant leptoquark production at the FCC-hh collider operating at 100 TeV proton-proton center of mass energy, with the luminosity of 30 ab\(^{-1}\). We do not aim to derive precise projections since a complete analysis, including the signal and background simulations, is clearly beyond the scope of this work. Instead, a simple comparison with the QCD pair production can already be made using the inclusive cross sections from section 3.1 and predicted branching ratios to determine the parameter space for which one can produce more than 100 events. Even though it is a naive estimate, since the SM background is subleading in the high-energy bins (as proved in \[65\]) and the signal is resonant, we expect 100 events to guarantee a discovery. A detailed projection study for the QCD pair production mechanism \[47\] gives a result very close to this criteria.

\(^{11}\)An example of a particularly motivated flavour structure in the quark sector is \(U(2)^3_q\) flavour symmetry under which the third generation is invariant while the light generations form doublets \[90–92\]. This symmetry is an excellent approximate symmetry of the SM Yukawa sector. In the leptonic sector, the \(U(1)_{\mu-LQ}\) symmetry can result accidentally from a lepton non-universal gauge symmetry \[88, 93–97\]. Thus, in the exact symmetry limit, only the \(3 - 2\) entry, \(\lambda_{32}\), is allowed. Figure 8 shows this case with the orange curve, while the projections at future colliders (in other channels) were also considered in \[98\].
Figure 8 illustrates the main point. The plot on the left (right) side is for the $\pm 1/3$ ($\pm 4/3$) state. The solid black line is for the QCD pair production, while the red, blue, and orange lines are for different quark generations in increasing order. The regions left to the lines is where the FCC-hh can produce more than 100 events. Finally, the grey shaded region predicts a broad resonance ($\Gamma_{LQ}/m_{LQ} > 0.15$). The plots show large portions of parameter space for which the resonant leptoquark production channel offers a unique window for discovery. This finding motivates a comprehensive projection study for future work.

4 Conclusions

Leptoquarks at the TeV scale are predicted in various settings beyond the SM, such as non-minimal composite Higgs models, $R$-parity violating supersymmetric models, extended gauge symmetries, and others. Leptoquark extensions of the SM have recently been under the spotlight as promising candidates to address various flavour anomalies. As a result, ATLAS and CMS collaborations are investing increasingly more resources to search for these particles. Direct discovery of a leptoquark would have profound implications for the paradigm of quark-lepton unification at shorter distances.

Precise determination of lepton densities inside the proton [64] revealed a novel path for leptoquark production at the LHC. Despite the smallness of the lepton PDF, a direct quark-lepton fusion at the partonic level is the most sensitive production channel for large leptoquark couplings, thanks to the resonant enhancement. Indeed, the first phenomenological studies show that large portions of the leptoquark model’s parameter space can uniquely be probed through this channel [65]. This study, however, relies on tree-level calculations and a crude estimate of the lepton shower effects that were not developed at the time. The first calculation at NLO [67], albeit limited to the inclusive cross sections, showed an interesting pattern of QCD and QED corrections which are similar in size. However, the full NLO description of the process, including differential distributions, was still missing.

In this work, we develop the first Monte Carlo event generator for precision studies of the resonant leptoquark production at hadron colliders. In section 2.1 we present the POWHEG-BOX-RES implementation of the process at NLO matched to parton shower, including the lepton shower, which has recently become available in HERWIG. Section 2.2 discusses leptoquark decays and the treatment of the resonance line shape. Our code allows for a full-fledged simulation of the process and is flexible enough to include all renormalisable scalar leptoquark models with arbitrary flavour structures [4]. We leave for future work the implementation of the vector leptoquark models.

We validate the code by reproducing the NLO inclusive cross sections at the LHC [67] and provide new results for the FCC-hh (see section 3.1). The unique advantage of our POWHEG-BOX-RES implementation is the possibility to study arbitrary differential distributions. In section 3.2, we comprehensively investigate the phenomenologically relevant observables, such as the jet-lepton azimuthal distance and the system’s invariant mass, $p_T$, and rapidity. As an illustration, in figures 2 and 3 we show these distributions for three
different benchmark points, at LO or NLO and with or without PS. We conclude that higher-order corrections are kinematics-dependent and should be adequately incorporated. In section 3.3, we study the importance of improved signal predictions on the (HL-)LHC projections reported in [65]. We closely follow the cut flow analysis of [65] to find an over-estimation of the acceptance of up to 30% for first-generation leptoquarks and up to 50% for second- and third-generation ones.

To illustrate the potential of the FCC-hh, in section 3.4 we study a concrete model, the $\mathcal{S}_3 \sim (\bar{3}, 3)_{1/3}$ scalar leptoquark. Figure 8 shows the leptoquark coupling as a function of mass needed to produce 100 events. We find that the resonant production mechanism can potentially probe uncharted parameter space beyond the reach of QCD pair production for all quark flavours (including the top quark). Our simplified analysis motivates a detailed projections study at the FCC-hh, including the background simulation, which is left for future work.

To conclude, this work paves the way for the first experimental searches and further phenomenological studies of the resonant leptoquark production at the LHC (and beyond). The latest addition to the leptoquark toolbox is made publicly available at the website http://powhegbox.mib.infn.it.

Acknowledgments

We thank Silvia Ferrario Ravasio for clarifying issues with HERWIG. The code for the computation of the running $\alpha_{\text{QED}}$ in the project repository was taken from the Hoppet code [99]. The work of AG has received funding from the Swiss National Science Foundation (SNF) through the Eccellenza Professorial Fellowship “Flavor Physics at the High Energy Frontier” project number 186866. The work of AG and NS is also partially supported by the European Research Council (ERC) under the European Union’s Horizon 2020 research and innovation programme, grant agreement 833280 (FLAY). A Instructions to run the code

The purpose of this appendix is to provide a brief guide to run the code. By the end of this section the reader should be able to reproduce the plots such as the ones in figures 2, 3, 4 and 5. The first step is to download the POWHEG-BOX-RES and then get the process LQ-s-chan from the svn repository svn://powhegbox.mib.infn.it/trunk/UserProcesses-RES/LQ-s-chan. At the time of writing POWHEG-BOX-RES is at revision 3967.

The Makefile may need a few modifications. At the beginning choose the compiler and check that the commands to invoke the compiler (F77, CC and CXX) match your system. On new MacOS gcc and g++ by default point to clang and clang++. This can lead to problems when linking against libraries built with the actual GNU Compiler Collection (gcc).

\footnote{It is possible to run this on the new Apple Silicon processors if all packages are built using homebrews gcc and gfortran.}
LHAPDF is used to access the lepton PDFs \texttt{LUXlep-NNPDF31_nlo_as_0118_luxqed}. Therefore, the \texttt{lhapdf-config} executable should be in the path. Set the variable \texttt{RES} to the path of \texttt{POWHEG-BOX-Res} following the examples in the file. Now it should be possible to build both targets (\texttt{pwhg_main} and \texttt{lhef_analysis}).

In order to shower the events one needs to download the appropriate version of \texttt{Herwig7}. In the folder \texttt{HerwigInstallation} one can find a simple installation script. It can be run directly, or used as a sequence of instructions to install \texttt{Herwig7}. The next step is to build the Herwig interface. To do so edit the Makefile in the folder \texttt{HerwigInterface}. The variable \texttt{PROCDIR} has to be set to the path of the LQ-Res-Prod folder. Again set the path to \texttt{POWHEG-BOX-Res} and check whether the \texttt{herwig-config} and \texttt{thepeg-config} executables are in the path. Also, set the correct path to the \texttt{HepMC2} library. After building the interface return to the project’s main folder. Finally navigate to the folder’s scripts and build the two executables \texttt{mergedata} and \texttt{pastegnudata}. Move them to a directory in the path. Everything needed to compute the histograms should now be compiled.

To quickly check whether the code is yielding results open the script \texttt{run.sh} and adjust the variables \texttt{ncores} and \texttt{nprocesses} to the system. To execute the code create two directories, one for the LO and one for the NLO computation. Copy the content of the folder \texttt{run-master} to both folders. Now the input cards for \texttt{POWHEG-BOX-Res} and Herwig should be present among some scripts to run the code on multiple cores. In the LO folder rename \texttt{powheg.input-save-LO} to \texttt{powheg.input-save}. Among many parameters that control the behaviour of \texttt{POWHEG-BOX-Res} the mass and charge of the desired leptoquark is specified in this file. The mass and the charge of the leptoquark, as well as, the quark and lepton flavours, can be set. The latter is done by enabling the coupling for the corresponding family of quarks and leptons. The flavour of the quarks is determined by the charge of the leptoquark. If the number of events was changed in the \texttt{POWHEG} input card, the corresponding line in the Herwig input card \texttt{Herwig.in} should be modified.

To run the code, modify the lines controlling the number of cores and processes in the \texttt{run-parallel.sh} script and execute it. This script will run multiple instances of \texttt{POWHEG-BOX-Res} and create the Les Houches events files. For the analysis, execute the \texttt{runlhe.sh} script. The parton shower and its analysis is done by running the script \texttt{hw7.sh}. Move the files with the top-extensions from the \texttt{HerwigRun} directory up to the current directory and run \texttt{refine.sh} combine the data from all processes. The same procedure can be repeated for the NLO case. To plot the histograms create a new directory and copy the python scripts to it. Set the variable \texttt{RUNDIRLO} and \texttt{RUNDIRNLO} to the directories containing the tables created with \texttt{refine.sh}. Run the python script \texttt{plots.py} to obtain the histograms.
