Abstract. After the discovery of space masers based on OH radicals (Weaver et al. 1965) and H2O (Cheung et al. 1969) such microwave lasers have been found to work in more than 100 molecular species (Elitzur 1992; Townes 1997), as well as in highly excited H atoms (Strelnitski et al. 1996). In the IR region (10 µm), the effect of stimulated emission of radiation in the CO2 molecule has been discovered in the Martian and Venus’ atmospheres (Betz et al. 1976; Mumma et al. 1981). We report here on the discovery of laser action in the range 0.9–2 µm in several spectral lines of Fe II, which are associated with transitions from “pseudo-metastable” states populated by spontaneous transitions from Lyα pumped Fe II levels. The intense Lyα radiation is formed in the HII region of gas condensations close to the star η Car. The laser transitions form together with spontaneous transitions closed radiative cycles, one of which includes the extremely bright 2507/09 Å lines. Closed radiative cycles, together with an accidental mixing of energy levels, may provide an explanation of the abnormal intensities of these UV non-lasing lines. Using the complicated energy level diagram of Fe II we present those peculiar features, which are essential for the inverted population and laser effect: the pumping, the level mixing, and the “bottle neck” for spontaneous decay. The laser action is a new indicator of non-equilibrium and spatially non-homogeneous physical conditions as well as a high brightness temperature of Lyα in ejecta from eruptive stars. Such conditions are very difficult to probe by existing methods, and we propose some future experiments. The fact, that the lasing near-IR lines appear in the spectrum with about the same intensity as non-lasing lines is discussed and compared with the situation in masers.

Key words. atomic processes – line: formation – radiation mechanisms: non-thermal – stars: individual: η Carinae

1. Introduction

A gas condensation formed by expelled material in the neighborhood of a bright star is an optimal site for hydrogen atoms to be photoionized by extreme ultraviolet (EUV) radiation under high-vacuum conditions. The central star emits the EUV radiation, and hydrogen is ionized by photons with λ < 912 Å. Collisions with electrons at a low rate yield the characteristic recombination spectrum of atomic hydrogen. The intense Lyα line at 1215 Å, which cannot be observed from Earth because of interstellar absorption, contributes about 70% of the energy radiated by the recombination lines. However, Lyα radiation is observed indirectly through its interaction with atoms and ions of other elements, particularly through resonant photoexcitation due to wavelength coincidences. Such an accidental coincidence of spectral lines (the Bowen (1935) mechanism) is a rare phenomenon. Since the spectral lines of free atoms and ions are very narrow the Bowen mechanism has no practical use in present-day lasers. However, this selective excitation mechanism generates some spectral lines in astrophysical plasmas, which contain a mixture of atoms and ions exposed to intense spectral lines of hydrogen, helium and other abundant light elements. The possibility of laser action in stellar atmospheres based on processes such as the Bowen mechanism was considered fairly long ago (Letokhov 1972; Lavrinovich & Letokhov 1974), but the resulting line emission has been difficult to resolve from the stellar background radiation.

The observational conditions changed radically with the launch of the Hubble Space Telescope (HST) and the High Resolution Spectrograph (HRS). Its successor, the Space Telescope Imaging Spectrograph (STIS), provides high spectral resolution in a broad wavelength range (1150–10400 Å) and a near-diffraction-limited angular resolution (∼0.1 arcsec) (Kimble et al. 1998). Beginning in 1998, the eruptive star η Car became one of the most remarkable targets for this instrument (Gull et al. 1999). It is an exceptionally interesting astrophysical object expelling enormous amounts of material into its surroundings. In the immediate vicinity of the central star at a distance of 100–1000 stellar radii (rs = 3 × 1013 cm), compact gas condensations (GC), called the Weigelt blobs B, C and D, of exceptional brightness have been discovered.
The iron atoms occur in the HI region at a density of about $N_\text{Fe} \approx 10^{4} \times N_\text{H}$, and they are easily photo-ionized by the stellar photospheric radiation in the spectral window 7.9 eV < $h\nu < 13.6$ eV (Fig. 1). The Fe$^+$ ion has a line-rich spectrum, and some lines coincide in wavelength with the wide Ly$\alpha$ line resulting in a selective photo-excitation to high energy levels (Brown et al. 1979; Johansson & Jordan 1984). This is discussed in Sect. 2 as well as a general scheme of the radiative decay routes of the Ly$\alpha$-excited Fe II levels. These radiative pathways are numerous and peculiar because of the complex Fe II energy level diagram, which offers both accidental level mixing (ALM) and the presence of “pseudo-metastable” (PM) high-lying states (Sect. 3). The latter have lifetimes of about 1 $\mu$s–1 ms and they create “bottle-necks” in the chain of spontaneous radiative decays of the Ly$\alpha$-excited Fe II levels.

In Sect. 4 the formation of population inversion in the PM states of Fe II, a basic requirement for lasing effect, is described as well as the size of the amplification coefficient. Two types of “bottle-neck”, occurring in PM states with ms lifetimes, respectively, are discussed separately in great detail in Sects. 5 and 6. The ms-“bottle-neck” (Sect. 5) provides a) a strong radiative cycle in Fe II generated by Ly$\alpha$ pumping, b) lasing in spectral lines at 1.68 $\mu$m and 1.74 $\mu$m, and c) the basis for the explanation of the anomalously bright non-lasing UV lines at 2507/09 Å. The $\mu$s “bottle-neck” (Sect. 6) provides laser effect in several lines in the range 0.9–1.0 $\mu$m, observed in $HST/STIS$ spectra of the Weigelt blobs. For completeness, we are also considering (Sect. 7) the combination of strong and weak radiative cycles, where a ms-“bottle-neck” creates strong lasing lines at $\lambda$9617/9913. For the $\lambda$9617/9931 lines we also observe a peculiar intensity ratio, which is in disagreement with the predicted branching ratio. In Sect. 8 we briefly discuss potential sources of Ly$\alpha$ radiation providing the pumping of the Fe$^+$ ions in the Weigelt blobs.

Sections 9 and 10 contain a qualitative discussion of the differences between astrophysical lasers and masers from an observational point of view. The evidence for astrophysical masers is mostly based on their high brightness and narrow line widths, observed by high-resolution radio telescopes. However, the astrophysical laser lines may not be brighter than ordinary lines, and the high spectral resolution ($\approx 10^3$) of optical telescopes/spectrometers (e.g. $HST/STIS$) is too small to observe their narrow Doppler profiles. The possibility of using laser heterodyne Brown-Twiss-Townes interferometry is proposed in Sect. 10.

2. Radiative excitation and relaxation of Fe II levels populated by absorbed Ly$\alpha$ radiation

A large number of observed as well as predicted absorption lines of Fe II fall within a spectral width of 3 Å around Ly$\alpha$. The transitions start from low metastable states as illustrated in Fig. 2 (see Johansson & Jordan 1984). There are about 15 emission lines/Å observed in the laboratory spectrum of Fe II in the wavelength region around Ly$\alpha$. The number is probably even higher for absorption lines, some of which could be pumped by Ly$\alpha$ in astrophysical plasmas. Consequently, numerous Ly$\alpha$ pumped fluorescence lines of Fe II have been...
Three types of radiative decay schemes of high-lying Fe II levels photoexcited by Lyman continuum radiation are presented in this image. These decay schemes are identified in spectra of various emission line sources, such as chromospheres of the sun and cool stars, symbiotic stars, AGNs, and AGNLs. The Weigelt blobs outside η Car are rather special because of their high optical density for Lyα, with τα ≈ 10⁸, and their short distance to the central star. The ratio of the Einstein coefficients for Lyα and the pumped transition Fe II excited states is approximately 10², and since all Fe atoms in the HI region are ionized, the abundance ratio NFeII/NH < 10⁻⁴. Since the optical density for the Fe II absorption lines in the range f ≤ 10⁻¹⁰, the resonant intervals within the wide Lyα profile are fully absorbed. A significant density of absorption lines should result in a total absorption of Lyα in the H I region of the blob.

The photoselective excitation rate of state 4 is defined by

\[ W_{\text{exc}}^{14} = A_{44} \frac{g_4}{g_1} \left( \frac{h \nu_{14}}{kT_\alpha} \right)^{-1} \],

(1)

where the indices 1 and 4 correspond to the level notations in Figs. 2b,c. The Einstein coefficient for spontaneous decay is A_{41} = 1.2 × 10⁷ s⁻¹ (Kurucz, 2003), and T_α = T(Lyα) is the brightness (or effective) temperature of Lyα inside blob B. According to the qualitative picture given above the stellar Lyman continuum radiation is transformed into intense Lyα radiation. A more detailed analysis of this “spectral compression” effect is presented in (Johansson & Letokhov, 2004), and it shows that T_α is comparable with the effective temperature of the stellar photosphere. In the case of η Car, we adopt kT_α ≈ 1.0–1.5 eV (T_α ≈ 12–18 × 10³ K), which means a photoselective excitation rate of W_{\text{exc}}^{14} ≈ 10³–10⁴ s⁻¹. Let us emphasize that without compensation for the dilution factor by the “spectral compression” effect the value of W_{\text{exc}}^{14} will be about 1 s⁻¹, making it impossible to provide an inverted population in the 3→2 transition.

The numerous possible pathways of the radiative relaxation (decay) of the Lyα-excited Fe II levels can be grouped in two categories as illustrated in Fig. 2:

- a spontaneous decay back to the low metastable states without any accumulation in higher states (Fig. 2a);
- spontaneous decay via long-lived higher states (“bottle neck”), which cause an inverted population with an associated stimulated emission (Figs. 2b,c).

The first type of pathway (Fig. 2a) is dominating for all photoexcited states, and the type illustrated in Fig. 2b occurs as a result of ALM, discussed in Sect. 2. The general case is a combination of (1) and (2), where the branching fractions from level 4 determine the population in J. The branching fractions for the decay feeding the long-lived states are thus determined by the strength of the level mixing. In this paper we focus on case (2), i.e. those Lyα pumped Fe II levels having large branching fractions to feed the PM states. It should be pointed out that the continuum pumping, shown by Verner et al. (2002) to increase the population of the low metastable states through cascading, cannot directly populate the PM states due to parity considerations.

If level 2 in case (2) decays to the initial state, i.e. the level being pumped, we obtain a closed radiative cycle (Johansson & Letokhov, 2003). This is determined by the possible decay channels of state 2 and their branching fractions, which may vary among the set of short-lived states (lifetime of a few ns) fed by the decay from the PM states. The distribution of the decay of state 2 is also important for permanent pumping of the low-lying metastable states, with lifetimes of the order of one second. Two examples of pathways containing radiative “bottlenecks”, according to the scheme in Figs. 2b,c, are discussed in detail in Sects 5–6 and a combination of them in Sect. 7. They represent closed radiative cycles, but with different
efficiencies, as the branching fractions differ considerably in those transitions, that bring them back to the initial level. These two pathways of radiative decay have also different lifetimes of the “bottle neck” levels 3′ and 3′′: a ms-lifetime for level 3′ and a ms-lifetime for 3′′ (Figs. 2b.c). The branching fractions for the weakly closed cycle (0.1%) and for the strongly closed cycle (85%) are indicated in Figs. 2b,c.

The rate of collisions between excited Fe⁺ ions and H atoms, with a maximum density of \(10^{10}\) cm\(^{-3}\), is less than one per second. The presence of forbidden lines from the long-lived metastable states (lifetime of about 1 s) verifies that the relaxation of the excited Fe⁺ ions is purely radiative (Fig. 3). Most important are the “closed” radiative pathways including Lyα pumping, spontaneous decays and stimulated emission, since they provide a collision-free and pure radiative conversion of intense Lyα radiation into the intense and anomalous \(\lambda\lambda 2507/09\) UV lines of Fe II (Johansson & Letokhov 2003).

3. Spectral peculiarities in Fe II

Two properties, one atomic and one astrophysical, make the spectrum of Fe II very dominant in spectra of cosmic sources. A complex atomic structure with a large density of energy levels and the high cosmic iron abundance result in numerous lines in ultraviolet and optical spectra – absorption lines in stellar atmospheres and emission lines in nebular regions. Although Fe II has been thoroughly studied in the laboratory and more than 1000 energy levels have been found, ultraviolet stellar spectra still contain unidentified lines of Fe II.

The specific atomic astrophysics problem discussed in the present paper involves two special features that are extremely rare in simple spectra but characteristic for complex spectra: accidental level mixing (ALM) and the presence of “pseudo-metastable” (PM) states. Level mixing is a well-known effect, which in its simplest form depends on deviations from a pure coupling scheme for the electrons, and a final state is described as a linear combination of, for example, pure LS states. Such mixing of levels may be well predicted by theory even for complex systems. Perturbation and level mixing as a result of configuration interaction are also in general taken care of by detailed calculations. However, two energy levels having the same parity and J-value may also mix if they accidentally fall very close to each other in energy. They can have completely different LS character and belong to different configurations. Such an ALM is very difficult to predict in quantum mechanical calculations.

The presence of PM states is the crucial feature in the radiative processes discussed in this paper, but before we define the concept “pseudo-metastable” we give a brief description of metastable states. A metastable state in an atom(ion) is a state that cannot decay to a lower state by electric dipole (E1) radiation, i.e. obeying the selection rules for parity and J-value. Hence, all states of even parity that are located below the lowest state of odd parity are by definition metastable, and they have radiative lifetimes of the order of 1 s. Metastable states are generally collisionally deexcited but in low-density astrophysical plasmas the probability for collisions is very low. Under such nebular conditions the metastable states decay radiatively in electric quadrupole (E2) or magnetic dipole (M1) transitions observed as forbidden lines. There are 62 metastable states in Fe II belonging to the three configurations \(3d^64s\), \(3d^7\) and \(3d^84s^2\). One of the three low even-parity configurations containing the metastable states is the ground configuration \(3d^74s\). In Fig. 4 we show a condensed energy level diagram for Fe II, arranged according to the “branching rule” for the
build-up of the structure of complex spectra. Thus, by starting with the next higher ion, Fe III, we add a 4s-electron to each \( LS \)-term (the parent term) of the ground configuration \( 3d^6 \). The resulting \( LS \) terms in Fe II are represented by one box for each parent term. All 4s boxes are connected by a dotted line in Fig. 4. Since the 4s binding energy is independent of the parent term the pattern of connected 4s boxes mimics the pattern of the parent terms. The next higher configuration in the diagram is the odd-parity 4p configuration, represented by grey boxes. Thus, according to the definition all levels in the boxes located below the lowest grey 4p box are metastable. These are placed in a marked box in the diagram.

Due to the extended structure of the parent terms the 4s configuration extends above 4p, i.e. the highest 4s boxes are located above the lowest 4p box (see Fig. 4). This is a special feature of the transition elements. In Fe II six observed (and two unknown) \( LS \)-terms of the \( 3d^64s \) configuration are located above the lowest \( LS \) terms of \( 3d^64p \), which means that a 4s electron can make a \textit{downward} transition to a 4p state. The lifetime of these high 4s states is of the order of 1 ms, three orders of magnitude shorter than for pure, metastable states but six orders of magnitude longer than for ordinary, excited states. Because of their long lifetimes we call them \( PM \) states, and they are marked in a dashed box in Fig. 4. It looks like the \( PM \) states keep a fraction of the metastability of their sister \( LS \) terms in the same configuration, even if \( LS \)-allowed decay channels become available. Without looking at the spectroscopic origin of these \( PM \) states, but just their \( LS \) assignment, it is not possible to distinguish them from other \( LS \) terms. However, the transition probability of their decay to 4p is six orders of magnitude smaller than for normal allowed transitions. It turns out that this is the crucial feature behind the explanation of the laser action in Fe II observed in \( \eta \) Car and discussed in detail in this paper.

The two cases of four-level schemes in Fe II involved in the radiative processes discussed in the forthcoming sections of this paper are shown in Figs. 5a and 5b. The low 4s box (at 1 eV) in Fig. 5a is the \( a^D \) term in the lowest 4s box in Fig. 4. It can be pumped by \( \text{Ly}_\alpha \) to several 5p levels around 11 eV, which is discussed in detail in Sect. 3. Due to a near coincidence in energy there is an \( ALM \) between some of the lowest 5p levels and some high 4p levels, as indicated in Fig. 4, and a mixing of states from two consecutive members (4p and 5p) in a Rydberg series is very rare. The \( ALM \) means that the high 4p levels (denoted \( 4p'' \) in Fig. 5a), which belong to \( LS \) terms of the \( (b^3F)4p \) and \( (b^3P)4p \) subconfigurations, are also radiatively populated by \( \text{Ly}_\alpha \). The fast decay from 5p is to 5s (in the near-IR) and back to 4s via 4p. The fast decay from 4p'' is down to 4s'' in Fig. 5a, i.e. along the vertical line down to \( (b^3F)4s \) and \( (b^3P)4s \) in Fig. 4. As all other strong 4s–4p transitions the corresponding lines fall around 2500 Å. These 4s'' levels are the \( PM \) states discussed above, and they can decay in slow transitions to the low 4p states at 5 eV (40 000 cm\(^{-1}\)). The 4p levels have fast decays back to the metastable 4s levels, as shown in Fig. 5a.

The case outlined by the scheme in Fig. 5b starts from a higher metastable 4s level (marked 4s'), which is excited up to a 4s4p state by \( \text{Ly}_\alpha \) radiation. The natural decay for this pumped state is down to a 4s'' state at about 7 eV. This level belongs to the \( 3d^44s^2 \) configuration, which is not included in Fig. 4. It has about the same properties as the \( PM \) states discussed in the first case above, but the lifetime is about three orders of magnitude smaller, or about 1 \( \mu s \). The 4s'' state decays in a "two-electron jump" to 4p, i.e. to the same 4p levels as for the 4s' state in the first case. The 4p level has a branch to the metastable 4s' level and even in this case we can find a closed cycle for the radiative excitation and deexcitation.

4. Population inversion and amplification coefficient in the "bottle-neck" 3\( \rightarrow \)2 transition

There are a number of decay schemes in Fe II creating an inverted population due to a radiative "bottle neck". The main
schemes are shown in Figs. 5a,b, where few selected energy levels and radiative transitions from the level- and line-rich spectrum of the complex system of Fe II illustrate a photo-selective excitation by Lyα and a subsequent cascade of radiative decay channels. A remarkable feature in the decay schemes is the existence of PM states. They decay relatively slowly (radiative lifetimes from 10 μs to 1 ms) in permitted transitions to lower, rapidly decaying states (lifetimes of a few ns). However, the time elapsing between successive collisions between excited Fe⁺ ions and H atoms, the main component of the GC, is characterized by a peculiar time hierarchy as illustrated in Fig. 5), which acts as a “bottle-neck” for radiative decay of the Lyα pumped states results inevitably in an inverted population of level 3 (the 3→2 transition in Fig. 5), which forms a cold HI region in the blob (Johansson & Letokhov 2001a,b). Thus, the amplification coefficient may be estimated by the expression

\[ \alpha_{32} = \sigma_{32} W_{\text{exc}} \beta N_{\text{Fe}}. \]  

where \( \beta \) is the fraction of the Fe⁺ ions in state 1 relative to all Fe⁺ ions (all iron atoms in the HI region of the blob are supposed to be ionized).

The fraction \( \beta \) is governed by the excitation rate of level 1 and its radiative lifetime \( \tau_1 \). The excitation rates for collisional population of level 1 (i.e., by recombination of Fe III and electron collisions) are negligible in comparison with the radiative decay rate \( 1/\tau_1 \) because of the low electron density \( n_e \approx 10^5-10^6 \text{ cm}^{-3} \) in the HI region. The electrons are generated in the photoionization process of iron as well as other elements having an ionization potential of IP < 13.6 eV. However, the most important channel for populating the metastable state 1 is the radiative decay of the high Fe II states selectively excited by Lyα or other intense lines. These excitation channels can provide an excitation rate \( >1/\tau_1 \approx 1 \text{s}^{-1} \) and hence sustain the relative population of state 1 at a level of \( \beta \approx 10^{-2} \). This would correspond to an approximately equal distribution of the Fe⁺ ions among the 60 metastable states, including state 1. Leaving the calculation of a more accurate value of \( \beta \) for future modeling, we adopt here a qualitative estimate of \( \beta \approx 10^{-2} \). An evidence for a substantial population in the metastable states is provided by the observation of strong, forbidden lines, e.g., from state 1, in the optical region of HST spectra of the blob (Zethson 2001).

With these assumptions, we can use Eqs. (1) and (6) to estimate the amplification coefficient for the 3→2 transition to \( \alpha_{32} \approx (3 \times 10^{-18}-10^{-16})N_{\text{Fe}} \text{ cm}^{-2} \), where \( N_{\text{Fe}} \approx 10^4 - 10^5 \text{ cm}^{-3} \) (Johansson & Letokhov 2001a,b). Thus, for \( \alpha_{32} \geq (3 \times 10^{-14}-10^{-12}) \text{ cm}^{-1} \) and a blob diameter of \( D \approx 10^3 \text{ cm} \), which can be regarded as the size \( L \) of the amplifying region, \( \alpha L = (30-100) \) at an effective blob temperature of Lyα of \( T_{\alpha} \approx (12-18) \times 10^3 \text{ K} \). The amplification coefficient \( \alpha_{32} \) is, according to Eq. (7), sensitive to the spectral width of the amplified line. From this point of view the cold HI region is more suitable as a lasing medium than the hotter HI region, causing a higher Doppler width in the 3→2 transition.

Let us emphasize that the amplification coefficient \( \alpha_{32} \) for future work.
Einstein coefficient $A_{32}$, since $A_{32} \approx 1/\tau_3$ as long as the branching fraction for the $3 \to 2$ transition is dominating in the decay of state 3. The $(aL)$-values obtained correspond to fairly high values of the linear (non-saturated) amplification coefficient $K = \exp(aL)$. In the saturation regime, however, the intensity of the weak line $\lambda_{32}$ (in photons/cm$^2$ s) approaches that of the strong line $\lambda_{33}$. Thereafter, the amplification regime becomes saturated. This means that the rate of stimulated transition approaches the pumping rate of level 3 provided by the spontaneous $4 \to 3$ decay. Under such conditions the intensities of both these lines grow in proportion to the propagation length $L$.

5. A radiative millisecond “bottle neck” and strong radiative cycling

Many of the radiative decay schemes of Ly$\alpha$ pumped Fe II levels contain three spontaneous transitions before the electron ends up in a low-lying metastable state. In some of these schemes there is a high probability that the final state of the electron is the same as the initial state, i.e. there is a high branching fraction of the final transition connecting states 2 and 1. This is the case illustrated in Fig. 5a.

First we discuss the closed cycle containing Ly$\alpha$ absorption, spontaneous decay with emission of the bright UV $\lambda_{12507/2509}$ lines, stimulated emission at 1.74 and 1.74 $\mu$m, and a fast UV transition to the initial state. The diagram in Fig. 6 includes a few of the known energy levels of Fe II, which together with the inserted transitions and atomic data are relevant in the present study of a strong radiative cycle. The broad (a few hundreds cm$^{-1}$) Ly$\alpha$ line almost coincides in wavelength with two Fe II transitions from the low level $\alpha^1\Delta g_{1/2}$ (level 1 in Fig. 6) to the close levels $(^3D)5p \ ^6G_{9/2}$ and $(b^3F)4p \ ^4G_{9/2}$ (marked 4 in Fig. 6), the frequency difference (detuning) being $\Delta \nu = -160$ cm$^{-1}$ and $-185$ cm$^{-1}$, respectively. The detuning is compensated by the Doppler shift or the broadening of Ly$\alpha$ (see Sect. 8). The line at 2509.1 Å to state $3 (c^3F_{1/2})$ is the main decay channel from $(b^3F)4p \ ^4G_{9/2}$ (state 4) with a branching fraction of about $\gamma \approx 0.9$. Due to the small energy difference there is an ALM between the two energy levels in state 4, $(^3D)5p \ ^6F_{7/2}$ and $(b^3F)4p \ ^4G_{9/2}$, resulting in similar decay schemes (Johansson 1978). As discussed above level 3 is a PM state, with a lifetime of 1.5 ms, but in contrast to a pure, metastable state it can decay slowly by electric dipole radiation to the short-lived states 2 ($\alpha^1\Delta g_{1/2}$ and $\alpha^3\Delta g_{1/2}$). To get strong radiative cycling it is important that state 2 decays by returning a large fraction of the Fe$^+\alpha$ ions to the initial state 1, which is metastable with a radiative lifetime of one second. Assuming the blob conditions discussed in the previous section ($N_H \approx 10^9 - 10^{10}$ cm$^{-3}$) the time scale for collisions is much longer than the time scale for radiative decay of state 3. Under these conditions the closed radiative cycle 1 $\to$ 4 $\to$ 3 $\to$ 2 $\to$ 1 has a “bottle neck” in the 3 $\to$ 2 transition.

The linear amplification coefficient for the $3 \to 2$ transitions at 1.74 $\mu$m and 1.68 $\mu$m (Fig. 9) is defined for $W_{14}^{\text{exc}} \ll \tau_3^{-1}$ (a rather moderate requirement) by Eqs. (4) and (8), rewritten as:

$$\alpha_{32} = \left[ \frac{A_{32}^2}{2\pi L} \left| A_{32} \right| \right] \tau_3 (\beta N_{\text{Fe}}).$$

From Eq. (9) we get that the amplification coefficient $\alpha_{32}$ (cm$^{-1}$) for the scheme in Fig. 6 is largely determined by the factor $(A_{32} / \tau_3)$. Its maximum value is $A_{32} / \tau_3 = 1$ in the ideal case, i.e. when there is only one radiative channel of spontaneous decay from state 3. In the real case (see Fig. 6) discussed here the factor $A_{32} / \tau_3 \approx 0.15$. Rough estimates of $\alpha_{32} L \gtrsim 10$, where $L \approx 10^{15}$ cm is the length of the amplifying medium, can be obtained for $T_{\alpha} > 10000$ K and $N_{\text{Fe}} \approx 10^9$ cm$^{-3}$ or $T_{\alpha} > 8000$ K and $N_{\text{Fe}} \approx 10^9$ cm$^{-3}$.

For an ensemble of atoms with sufficient density and size the channel 3 $\to$ 2 will open for a fast stimulated decay, and the duration of the whole radiative cycle is determined by the rate of the slowest excitation channel rather than by the $W_{14}^{\text{exc}}$ rate of the slowest spontaneous decay $A_{32}$. For a high brightness temperature of Ly$\alpha$ in the range $T_{\alpha} \approx 15000$ K the excitation rate is $W_{14}^{\text{exc}} \approx 5 \times 10^3$ s$^{-1}$ giving a duration of the total radiative cycle in Fe II of $\tau_{\text{cycle}} \approx 2 \times 10^{-4}$ s. Hence, the Fe ions can undergo a maximum number of cycles ($\tau_1 / \tau_{\text{cycle}} \approx 3.5 \times 10^3$) during the lifetime of the initial state ($\tau_1$).

A large number of radiative cycles containing a stimulated channel provide a large intensity enhancement of the
\(\lambda\lambda2507/2509\) fluorescence lines \((4 \rightarrow 3)\) due to the suppressed accumulation of Fe\(^{+}\) ions in the \(PM\) state \(3\) and the corresponding depletion of the initial state \(1\). If the density \(N_{\text{Fe}}\) and the size \(L\) are not sufficiently large for the ensemble of atoms the amplification will be small and the stimulated channel will not operate. In such a case the radiative “bottle neck” limits the rate of the radiative cycling in Fe II to the time \(\tau_{\text{1}} = 1.5\) ms and the intensities of the two UV lines \(\lambda_{\text{3}}\) become normal.

High-resolution spectra of the blobs outside \(\eta\) Car, spatially resolved from the central star, show the anomalous brightness of the two \(\lambda\lambda2507/2509\) lines. Further observational evidence in the blob spectrum for the radiative cycle is the presence of one “bottle neck” line at 8674.7 Å (Zethson 2001), which is an intercombination line with an extremely low transition probability \(A_{32} \approx 13\) \(\mu\text{m}^{-1}\) (Raassen 2002). The “bottle neck” transitions around 1.7 \(\mu\text{m}\) indicated in Fig. 6 have been observed in ground-based spectra of \(\eta\) Car (Hamann et al. 1994). The \(3\rightarrow2\) transition from \(c^{4}F_{7/2}\) at \(J = 1.74\) \(\mu\text{m}\) and 1.68 \(\mu\text{m}\) appear relatively stronger than lines from the other fine structure levels of \(c^{4}F\). Since the ground-based spectra of \(\eta\) Car contain integrated light from a larger region than the Weigelt blobs discussed here the absolute intensities cannot be compared with the intensities measured in the \(HST\) spectra.

Moreover, according to the observations made in (Gull et al. 2001), the UV lines of the \(2\rightarrow1\) transition at 2740 and 2756 Å have an integrated intensity comparable with that of the bright lines of the \(4\rightarrow1\) transition. The width of these spectral lines is great because of the substantial optical density in the \(4\rightarrow1\) transition and the corresponding resonance transfer radiation broadening. Resonance radiation trapping increases the effective lifetime of level 2, but still it remains much shorter than the long lifetime of level 3 and does not prevent the formation of an inverted population in the \(3\rightarrow2\) transition.

### 6. Radiative microsecond “bottle-neck” and weak radiative cycling.

In some of the schemes of Ly\(\alpha\) pumped Fe II levels there is a low probability that the final state of the electron is the same as the initial state, i.e. there is a low branching fraction of the final transition connecting states 2 and 1. Such a case is illustrated in Fig. 5b. The primary spontaneous decay of state 2 is to the metastable state \(1a\) at 1 eV, and a weaker branch populates the initial state \(1b\) at about 3 eV) of the closed radiative cycle. In the case studied here state \(1a\) is the same as state \(1\) in the millisecond “bottle-neck” discussed in Sect. 5, which gave a strong radiative cycling. The low branching fraction of 0.1% for the \(2\rightarrow1b\) transition at 5116 Å produces a closed cycle but a weak radiative cycling. Some feeding of the initial level, state \(1b\), is provided by the radiative cycle discussed in Sect. 5, which means that there is only need for an initial population in state \(1a\) to start the pumping processes of both the ms- and \(\mu\)-“bottle-neck” cycles.

A more detailed scheme of the microsecond “bottle-neck” with relevant atomic data is given in Fig. 7. The Ly\(\alpha\) radiation populates a high-lying state of Fe II from the metastable state \(a^{4}G_{11/2}\). This excitation scheme is operative in various objects, verified by the observation of the spontaneous radiative decay in the primary cascade as a fluorescence line at 1869 Å (Johansson & Jordan 1984) as well as the secondary cascade at 9977 Å, seen in many objects as a prominent feature. Based on the extended laboratory analysis of Fe II (Johansson 1978), the 9977 Å line was first identified (Johansson 1977) in the near-IR- spectrum of \(\eta\) Car (Thackeray 1969). A plausible explanation to its appearance in spectra of some astrophysical objects was ascribed to the excitation scheme shown in Fig. 7 (Johansson 1990).

According to theoretical calculations (Kurucz 2003), the main radiative decay from state 4, \(3d^{3}(a^{2}F)4s4p(4^{1}P)^{0}G_{11/2}\) (hereafter \(sp^{4}G\)), occurs to the fine-structure levels of \(b^{4}G\) with branching fractions of 0.83 to \(J = 11/2\) and 0.04 to \(J = 9/2\). The most natural representative of state 3 in Figs. 5b and 7 is thus \(b^{2}G_{11/2}\) with a radiative lifetime of 11 \(\mu\text{s}\). Hence, it has a relatively slow spontaneous decay, \(A_{32} = 8 \times 10^{4}\) \(s^{-1}\), to level 2 \((a^{4}F_{9/2})\), which has a much shorter lifetime (\(\approx 3\) ns).

Using \(HST/STIS\), Gull et al. (2001) have recorded spectra of blob B in \(\eta\) Car at high angular and spectral resolution. The spectrum contains the intense 9977 Å line (see Fig. 8), which can be excited by Ly\(\alpha\) radiation according to the excitation and decay scheme shown in Fig. 7. The 9977 Å line is thus a transition from a microsecond \(PM\) state, which belongs to a different configuration \((3d^{3}4s^{2})\) than the millisecond \(PM\) state in Sect. 5. Since the lower state of the 9977 Å transition is short-lived (a few ns) an inverted population is built up, and the

![Fig. 7. Diagram showing the creation of population inversion in the \(3\rightarrow2\) transition of Fe II because of a microsecond “bottle-neck”. Since only a small fraction of the Ly\(\alpha\) pumped Fe II ions return to the initial state 1b the closed loop 1b\(\rightarrow4\rightarrow3\rightarrow2\rightarrow1b\) generates a weak radiative cycling.](image-url)
8. Sources of Lyα Radiation Pumping Fe II in the Weigelt blobs

The blobs in \( \eta \) Car are embedded in the photospheric radiation and the wind from the central star. Let us speculate about possible sources for Ly\( \alpha \) radiation capable of pumping Fe II within the blobs. Firstly, the Ly\( \alpha \) radiation emitted by the photosphere of \( \eta \) Car can excite Fe\( ^+ \) ions in blobs located at distances of \( R_b \approx (300–1000) \cdot r_s \), where \( r_s \approx 10^{13} \) cm is the stellar radius. But, even at such a relatively close location of the blob the dilution factor \( \Omega = (r_s/2R_b)^2 \approx 10^{-6}–10^{-5} \), which substantially weakens the intensity of the Ly\( \alpha \) radiation reaching the blob and makes it incapable of producing the bright 2507/2509 Å lines (Johansson & Letokhov 2001).

The stellar wind of \( \eta \) Car is an important characteristic of the star’s surroundings, the mass loss rate of the star being substantial (Davidson & Humphreys 1997). Spherical (Hillier et al. 2001) as well as aspherical (Smith et al. 2003) models of the stellar wind of \( \eta \) Car with a terminal velocity of \( v_t \approx 500–1000 \) km s\(^{-1} \) have been considered. In accordance with models by Lamers & Cassinelli (1999) of the stellar wind its velocity is almost close to the terminal value everywhere between \( \eta \) Car and the GC. The Lyman continuum radiation, Ly\( \alpha \), from the star photoionizes the stellar wind and after the subsequent recombination a wide Ly\( \alpha \) profile is produced. Another potential source of ionizing radiation is a binary companion, but in the discussion below about Ly\( \alpha \) formation inside the blob it is not important to distinguish between the individual components in a binary system. It is possible to consider three cases of irradiation of the blob by radiation from the stellar...
Fig. 9. Partial energy level diagrams of Fe II showing two examples of combined strong and weak radiative cycling due to alternative decay routes for the two “pseudo-metastable” states c^4P_{3/2} (Fig. 9a) and c^4P_{1/2} (Fig. 9b). The “bottle-neck” effect generates inverted population and lasing in the 3→2 transitions to sextet and quartet levels, which have quite different branching fractions (BF) to the initial state I.

Fig. 10. Comparison of HST/STIS spectra of the central star (flux scale on right axis) and the Weigelt blob B (flux scale on left axis) in η Car with the two lasing lines λλ 9617, 9913 generated in the level schemes in Fig. 9 and discussed in Sect. 7.

wind depending on the size of its Strömgren radius, \(~\tilde{R}_{\text{Str}}\) relative to the distance \(R_0\) between the blob and the star as illustrated in Figs. 11a–c.

1) \(~\tilde{R}_{\text{Str}} \gg R_0\) (Fig. 11a). In this case the Lyα radiation reaches the blob without significant attenuation and can photoionize the front part of it. If the hydrogen density in the blob exceeds the critical density \(N_{\text{cr}} = 10^{8} \text{cm}^{-3}\) (Klimov et al. 2002) the Strömgren boundary of the blob, defined by, intersects the blob. The front part of the blob produces an intense Lyα radiation with \(T_{\text{alpha}} > 10000 \text{ K}\). Thus, the dilution of the photospheric Lyα radiation falling on to the blob is to a great degree compensated by spectral compression of absorbed broadband radiation to a \(10^3–10^4\) times more narrow Lyα profile (Johansson & Letokhov 2004). Under these conditions the blob is very different from a typical planetary nebula since the dilution factor \(\Omega = (r_s/2L)^2\) is \textit{many orders of magnitude larger} than for a planetary nebula (\(\Omega \approx 10^{-15}–10^{-12}\)).

2) \(~\tilde{R}_{\text{Str}} \ll R_0\) (Fig. 11b). In this case the Lyman continuum is blocked out for the blob. This means that the entire volume of space between η Car and the blob is an ionized H II region, with the Strömgren boundary for the stellar wind being located between the star and the blob. Since hydrogen is not fully ionized the blob does not have two regions as in the previous case, where the HII and HI zones are adjacent to each other (Fig. 11a). A single-component blob (a HI region) is probably too cold to emit the bright UV Fe II lines. It will therefore make sense to assume that the optical density of the Lyman continuum \(\tau(\lambda_c) \leq 1\) in the region between η Car and the blob.

3) \(~\tilde{R}_{\text{Str}} \geq R_0 + D\) (Fig. 11c). In this case the Strömgren boundary outside the blob is located slightly behind it. This can be considered as an optimal situation for pumping of Fe II in the blob for two reasons. Firstly, the Lyα photons produced in this torus-like zone beyond the blob are red-shifted and \(\Delta \lambda_{\text{w}} = \lambda_0(v_t/c) \cos \Theta\), where \(\Delta \lambda_{\text{w}}\) is the wavelength shift, \(\lambda_0\) is the rest wavelength, \(v_t\) is the terminal stellar wind velocity and \(\Theta\) is the viewing angle as indicated in Fig. 11c. The red-shifted and broadband Lyα radiation irradiates the H I region of the blob without any need for diffusion Doppler broadening. It can penetrate the whole H I region, since its optical density \(\tau(\lambda_0 + \Delta \lambda)\) in the far
A schematic model of a Weigelt blob, located at a distance \( R_b \) from the hot, luminous star \( \eta \text{ Car} \) and subject to the stellar radiation and wind. a) A local Strömgren boundary, \( R_{\text{str}} \), between the \( \text{H II} \) and \( \text{HI} \) regions located inside the blob. Stellar radiation in the Lyman continuum (Ly\( \alpha \), \( h\nu = 13.6 \text{ eV} \)) photo-ionizes hydrogen only in the front part of the blob. Radiation in the range \( 7.6 \text{ eV} < h\nu < 13.6 \text{ eV} \) passes through the \( \text{H II} \) region and photo-ionizes iron atoms, which have a density \( N_{\text{Fe}} \approx 10^{14} \text{ cm}^{-3} \) in the \( \text{HI} \) region. Intense Ly\( \alpha \) radiation from the \( \text{H II} \) region excites Fe II resonantly in the \( \text{HI} \) region (lasing volume). The Strömgren boundary for the stellar wind \( R_{\text{str}} \approx R_b \) b) the stellar wind is optically thick for Ly\( \alpha \) and the blob is a one-component \( \text{HI} \) medium. Only remote blue-shifted Ly\( \alpha \) radiation from the stellar wind can irradiate the \( \text{HI} \) region containing Fe II; c) the Strömgren boundary in the wind lies behind the blob \( (R_{\text{str}} \approx R_b) \), providing intense, red-shifted Ly\( \alpha \) photons for efficient excitation of Fe II.

Wing of Ly\( \alpha \) is not abnormally high, where \( \Delta \lambda = 2.4 \text{ Å} \) is the shift of the Fe II absorption line relative to the center of Ly\( \alpha \).

Secondly, the dilution factor for the Lyman continuum irradiating the stellar wind (see geometry in Fig. 11c) will largely be compensated for by the conversion of Ly\( \alpha \) into narrower Ly\( \alpha \) radiation in the stellar wind in the vicinity of the blob. The optimal case is when the size of \( R_{\text{str}} \) coincides with the distance to the irradiated part of the \( \text{HI} \) region in the blob, which will require a significant density of the stellar wind near the blob. The critical hydrogen density in the stellar wind, \( N_{\text{cr}} \), that can provide \( R_{\text{str}} \approx R_b \), is connected with the critical density of the blob itself, \( N_{\text{cr}} \), required to locate the Strömgren boundary inside the blob, by the approximate expression:

\[
N_{\text{cr}} \approx \left( \frac{D}{R_b} \right)^{1/2}.
\]

For the adopted values of the distance to the star \( R_b = 300-1000 r_s = 10^{16}-3 \times 10^{16} \text{ cm} \) and the size of the blob, \( D \approx 10^{15} \text{ cm} \), \( N_{\text{cr}} \) is some tenths of \( 10^8 \text{ cm}^{-3} \), i.e. a relatively high density of the stellar wind close to the blob. This very approximate estimate of \( N_{\text{cr}} \) in the vicinity of the blob \( (0.15'' \text{ from } \eta \text{ Car}) \) agrees with other estimates, based on observed and modelled spectra of the stellar wind (Hillier 2001, 2003). The evaluation of Eq. (10) agrees with direct measurements of the size and shape of the stellar wind and the blobs in \( \eta \text{ Car} \) (van Boekel et al. 2003). Of course, all these qualitative speculations should be subject of detailed modelling of the stellar wind with the blob included, but that is out of the scope of the present paper.

In Sects. 4 and 5 above, we have used the effective spectral temperature of Ly\( \alpha \) \((T_\alpha > 10000 \text{ K})\), in the treatment of the pumping of absorption lines to achieve a population inversion in some Fe II transitions from \( \text{PM} \) states. This requirement is valid for any possible source of intense Ly\( \alpha \) radiation. The consideration of possible Ly\( \alpha \) pumping from the stellar wind is still preliminary and qualitative, and it needs a future detailed modelling.

9. On the spectral brightness and spectral width of astronomical lasers

We have emphasized that the radiation intensity (photons \( s^{-1} \text{ cm}^{-2} \)) of an astrophysical laser (APL) line cannot be higher than the intensity of the pumping line. In principle the spectral brightness \((\text{photons } s^{-1} \text{ cm}^{-2} \text{ Hz}^{-1} \text{ sr}^{-1})\) of the APL line can exceed that of the pumping line because of two effects: 1) the narrowing of the APL line by resonant amplification of the radiation (both the spontaneous radiation itself and some external radiation); and 2) an anisotropic type of amplification (for example in an elongated amplifying region). Since these effects are interrelated, they can be considered simultaneously. In the regime of linear amplification of spontaneous emission, the line width decreases because of an exponential amplification at the line center. This is described by a simple relation (Casperon & Yariv 1972; Allen & Peters 1972):

\[
\Delta \nu = \frac{\Delta \nu_D}{\sqrt{1 + \alpha L}}.
\]

where \( \alpha \) is the gain coefficient (see Sect. 4) per unit length. The narrowing occurs until the amplified line, which is inhomogeneously Doppler-broadened, gets saturated and its peak “flattens out”. This effect was considered for the APL-saturated amplifier, and it has been shown (Litvak 1970) that the narrowing of the spectrum lines ceases at saturation. The line broadens again to the width of the gain line, which has been confirmed by observational data for astrophysical masers (Reid & Moran 1981; Elitzur 1992).

It would be very interesting to measure the sub-Doppler line width of the 9997 Å line (as well as other laser lines mentioned above) using a spectral resolution \( R > 10^5 \) and an angular resolution better than 0.1 arcsec. This could, for example, be done with spatially separate telescopes using a heterodyne correlation analysis of the Brown-Twiss effect (Johnson et al. 1974). The spectral brightness of APL radiation can grow as a result of the narrowing of the spectrum lines. In order to observe this effect, one will need a detection technique that is
Space lasers with optical pumping operate according to a scheme similar to the one suggested for the first laboratory laser 45 years ago by A. Schawlow and C. Townes (1958). We believe that laser amplification and stimulated emission of radiation is a fairly common and widespread phenomenon, at least in gaseous condensations in the vicinity of bright stars. This is due to the occurrence of two types of processes (fast radiative and slow collisional) in the very rarefied gaseous condensations, whereby the population of energy levels in atoms (ions) can relax. These relaxation processes occur on highly different time scales, radiative relaxation operating on a wide time scale of $10^{-9} - 10^{-3}$ s (sometimes even within $10^{-7} - 1$ s), and collisional relaxation, on a time scale of over seconds (at gas densities $< 10^{10}$ cm$^{-3}$). In the case of photoexcitation of some high-lying electronic levels of an atom or ion with a complex energy-level structure, radiative relaxation can take place as a consequence of downward transitions with spontaneous emission of radiation, in the course of which there develops an inverse population of some pair (pairs) of levels. If the size of a gas cloud is large enough, large amplification on the inverted-population transition automatically switches on the radiative relaxation channel, which leads to faster stimulated transitions until collisional relaxation becomes important. Thus, the laser action is an intrinsic characteristic of the radiative cooling of gas clouds near bright stars by stimulated emission for inverted transitions along with spontaneous emission for normal transitions.

However, the detection of the laser effect is less evident in the optical region of the spectrum than in the microwave region, where it gives rise to strong radiation lines of exceptionally high brightness temperature ($10^{10} - 10^{15}$ K (Elitzur 1992)). In the optical region, the laser effect raises the intensity of weak forbidden lines up to the intensity of those strong allowed lines providing the selective photoexcitation of the upper levels. This is explained by the huge difference ($\approx 10^{15} - 10^{18}$ times) between the spontaneous emission rates and inverse population production mechanisms in the two wavelength regions. This follows from simple qualitative considerations of the steady-state saturation regime of the isotropic maser/laser action.

The stimulated emission of radiation in a space maser occurs as a result of pumping of the upper maser level, which is not associated with any spontaneous emission in radiative microwave transitions. It may therefore have a decay rate much in excess of the spontaneous emission rate, which lies in the region $A_{nm} \approx 10^{-9} - 10^{-7}$ s$^{-1}$. As a result, the intensity of the stimulated radiation can be many orders of magnitude higher than the intensity of the spontaneous radiation and it is only limited by the pumping rate. This is exactly the reason why the brightness temperature of maser microwave lines reaches as high a value as $10^{10} - 10^{15}$ K. The intensity of maser lines is not borrowed from other microwave spectral lines, which are very weak, but from other pumping sources.

In the optical region of the spectrum, the rate of allowed spontaneous transitions is high ($A_{nm} \approx 10^{8} - 10^{9}$ s$^{-1}$), and it is precisely spontaneous transitions that provide for the pumping of the upper level in an optical space laser at a sufficiently high rate to exceed the rates of collisional pumping mechanisms. This is especially true for the case considered here where the space laser is being indirectly pumped by H Lyα in the vicinity of η Car, one of the most luminous stars of our Galaxy. Therefore, the intensity of the stimulated radiation in the optical region generated by the occurrence of an inversion population and significant amplification cannot in the steady-state regime to any substantial extent exceed the intensity of the pumping spectral lines, formed by spontaneous emission in allowed radiative transitions of atoms or ions. This fact presents difficulties in detecting laser action by a large enhancement of the intensity of the radiation, but it should manifest itself in comparatively moderate changes of the branching ratios of spectral lines, having a common source of pumping.

One exception is the case of quantum transitions having a relatively low spontaneous emission probability ($A_{nm} \approx$ a few -- $10^{5}$ s$^{-1}$), and consequently, the spontaneous radiation lines are weak. Once an inverted level population has developed in such a transition with a significant amplification in a properly sized cloud, a stimulated emission channel opens up. The stimulated transition rate cannot be much higher than the spontaneous emission rate, which is limited by the pumping rate of the upper laser level. Thus, the intensity of the laser line should become comparable with the intensity of the lines, which are due to allowed spontaneous emission of radiation and resulting from the optical pumping (direct or indirect) of the upper level. This takes place only in the inverted population volume with size $L \gg 1/\alpha$, where $\alpha$ is the amplification coefficient per unit length. In such a case, a spectral line, expected to be weak, must appear as a spectral line of normal intensity, typical for an allowed transition. This is exactly what we have found to be the case with several spectral lines of Fe II pumped indirectly by the intense H Lyα radiation (1215 Å) in the Weigelt blobs of η Car.

In conclusion, let us emphasize that stimulated emission at optical and near-infrared wavelengths forming non-collisional, radiative cycling of atomic particles in astrophysical media gives a natural explanation to the anomalous behaviour of spectral lines of two types: i) the transformation of a very weak line from a PM state have a low transition probability (line 3→2 in Figs. 1a, 6 and 9) into a strong line with an intensity comparable to that of an allowed transition; and ii) the transformation of a normally intense line into an anomalously bright line (line 4→3 in Fig. 10) due to radiative cycling, which is only possible if stimulated emission drives the weakest link in the cycle.

Before astrophysical spectra at very high resolution can be observed these conclusive facts constitute, at present, the only
proofs of the Fe II astrophysical laser in the Weigelt blobs of \eta Carinae.

Acknowledgements. We thank Dr. John Hillier for sending us data on the density of the stellar wind, and later for providing very useful referee comments on the manuscript.
