ABSTRACT

**Context.** Understanding the relationship between the formation and evolution of galaxies and their central super-massive black holes (SMBH) is one of the main topics in extragalactic astrophysics. Links and feedback may reciprocally affect both black hole and galaxy growth.

**Aims.** Observations of the CO line at the main epoch of galaxy and SMBH assembly (\(z = 2–4\)) are crucial to investigating the gas mass, star formation, and accretion onto SMBHs, and the effect of AGN feedback. Potential correlations between AGN and host galaxy properties can be highlighted by observing extreme objects.

**Methods.** We targeted CO(3–2) in ULAS J1539+0557, a hyper-luminous quasar (\(L_{\text{bol}} > 10^{48} \text{ erg/s}\)) at \(z = 2.658\), selected through its unusual red colour in the UKIDSS Large Area Survey (ULAS).

**Results.** We find a molecular gas mass of \(4.1 \pm 0.8 \times 10^{10} M_\odot\), by adopting a conversion factor \(\alpha = 0.8 M_\odot \text{ K}\text{ km s}^{-1} \text{ pc}^2\), and a gas fraction of \(\sim 0.4–0.1\), depending mostly on the assumed source inclination. We also find a robust lower limit to the star-formation rate (\(SFR = 250–1600 M_\odot\text{yr}^{-1}\)) and star-formation efficiency (\(SFE = 25–350 L_\odot/(K\text{ km s}^{-1} \text{ pc}^2)\)) by comparing the observed optical-near-infrared spectral energy distribution with AGN and galaxy templates. The black hole gas consumption timescale, \(M(H_2)/M_{\text{accretion}}\), is \(\sim 160\) Myr, similar to or higher than the gas consumption timescale.

**Conclusions.** The gas content and the star formation efficiency are similar to those of other high-luminosity, highly obscured quasars, and at the lower end of the star-formation efficiency of unobscured quasars, in line with predictions from AGN-galaxy co-evolutionary scenarios. Further measurements of the (sub)mm continuum in this and similar sources are mandatory to obtain a robust observational picture of the AGN evolutionary sequence.

**Key words.** galaxies: evolution – galaxies: active – quasars: general – quasars: emission lines

1. Introduction

Understanding the relations between the formation and evolution of galaxies and their central super massive black holes (SMBH) is a major challenge of present-day astronomy. Most galaxy assembly and accretion activity occurs at \(z = 2–4\), so it is crucial to study SMBH-galaxy relationships at this epoch. The two main open questions are a) what is the mechanism triggering nuclear accretion and star-formation? and b) are active galactic nuclei (AGN) outflows truly able to regulate star-formation in their host galaxies? Observations of molecular gas are useful to addressing both questions. So far, molecular gas has been detected in a few tens of \(z > 2\) quasars, with typical masses \(1–10 \times 10^{10} M_\odot\), indicating gas-rich hosts. However, most of these observations have been done either on lensed objects (where the intrinsic luminosity is magnified by factors of up to \(\sim 100\)), or on \(z = 5–6\) quasars (Riechers 2011, and references therein).

There is a growing evidence for two modes of star-formation which may also be relevant for triggering nuclear activity: a quiescent one, taking place in most star-forming galaxies, with gas conversion time scales of \(\sim 1\) Gyr, and a less common star-burst mode, acting on much shorter time scales (\(\sim 10^7–10^8\) yr; Rodighiero et al. 2011; Lamastra et al. 2013a and references therein). The star-burst mode is likely related to the powering of high luminosity quasars. In fact, bolometric luminosities of the order of \(10^{47}–10^{48}\) erg/s imply mass accretion rates of tens to hundreds of \(M_\odot\text{yr}^{-1}\) onto \(10^8–10^{10} M_\odot\) SMBHs (assuming a radiative efficiency of 0.1). If the accretion lasts for a few tens of Myr (Salpeter timescale), this in turn implies gas reservoirs of...
10^9–10^{10} M_\odot funneled towards the central ~kpc region. Galaxy interactions seem to be the best (if not the only) mechanism capable of destabilizing large fractions (\Delta M_{\text{gas}} \sim M_{\text{gas}}) of the gas reservoirs towards the central ~kpc region on short time scales (Cavaliere & Vittorini 2000; Tacconi et al. 2006). This naturally produces powerful AGNs hosted in star-burst galaxies (Lamarrstra et al. 2013b). In principle, from the gas consumption timescale (or its inverse, the so-called star formation efficiency (SFE)) i.e. the ratio between the star-formation rate and the gas mass, one can directly derive information on the AGN and star-formation triggering mechanisms.

The SFE also depends on the SMBH gas consumption timescales and on the energy injected in the interstellar medium by the AGN (feedback). High SFE may be the outcome of a small cold gas reservoir that was reduced by on-going SMBH accretion and consequent AGN feedback. For this reason, to have information on AGN feedback is crucial for addressing both questions. There is both theoretical and observational evidence that high-luminosity quasars drive powerful outflows. Theoretically, physically motivated models predict strong winds from AGNs with SMBH larger than 10^8 M_\odot (Zubovas & King 2014, and references therein). These models in general predict mass flows proportional to the AGN bolometric luminosity to some power (\dot{M}_{\text{gas}} \propto L_{\text{bol}}^{1/2} in the Menci et al. 2008 model). For these reasons, the most luminous quasars in the Universe are ideal and unique targets with which study AGN/galaxy feedback mechanisms regulated by powerful outflows. Powerful and massive AGN-driven outflows of molecular gas were recently discovered in luminous quasars (Maiolino et al. 2012; Feruglio et al. 2010; Cicone et al. 2013). Broad absorption lines (BALs) with outflow velocities up to several thousand km s^{-1} are common in high-luminosity quasars (Borguet et al. 2013); BALs are found in 40% of mid-infrared selected quasars (Dai et al. 2008) and in 40% of the WISE selected luminous quasars (Bongiorno et al., in prep.). Powerful, galaxy-wide outflows have also been found in ionised gas using the broad [OIII] emission line (Cano-Diaz et al. 2012).

In this paper we present results from the first Plateau de Bure Interferometer (PdBI) observation of a hyper-luminous quasar, selected from the UKIDSS Large Area Survey (ULAS) and the VISTA (J, K bands) Hemisphere Survey: ULAS J1539+0557 at z = 2.658 (RA:15:39:10.2, Dec: 05:57:50.0, Banerji et al. 2012). The source ULAS J1539+0557 is heavily reddened (rest frame A_V ~ 4) and has a bright 22 μm flux of 19 mJy in the WISE All-Sky Survey, corresponding to \lambda L_\lambda(7.8 μm) = 10^{46} erg/s, and a bolometric luminosity of L_{\text{bol}} \sim 10^{46} erg/s. The black hole mass is as large as 7.4 \times 10^8 M_\odot. As detailed in Banerji et al. (2012), these hyper-luminous quasars are unlikely to be lensed, and therefore they truly trace an extremely luminous population.

In the following we present the results of 3 mm observations of ULAS J1539+0557, targeting the CO(3–2) transition. We derive the gas mass, dynamical mass, and star-formation rate (SFR) of the host galaxy through the comparison of the observed UV-mid-infrared spectral energy distribution (SED) with galaxy templates. We compare the observed gas masses, gas fraction and gas consumption timescale with those of the other quasars and galaxies at similar redshift. We finally discuss future desirable developments in this topic. A H_0 = 70 km s^{-1} Mpc^{-1}, \Omega_M = 0.3, \Omega_\Lambda = 0.7 cosmology is adopted throughout.

2. Millimetre observations and results

The quasar ULAS J1539+0557 was observed at a frequency of 94.5 GHz with the PdBI array in the most compact (D) configuration in September 2013. The system temperature was between 80 and 120 K, and water vapor about 5 mm. The quasar 1546+027 (1.8 Jy at 94.5 GHz) was used as a phase and amplitude calibrator. The quasar 3C 454.3 (10.1 Jy) was used for bandpass and absolute flux calibration. We estimate a 10% error on the absolute flux calibration. Calibration and mapping were done in the GILDAS environment. The flagging of the phase visibilities was fixed at 35% rms in order to maximise the signal-to-noise ratio (S/N) of the detection. This flagging yields a 1σ sensitivity of 0.21 mJy/beam in 20 MHz channels, and a total 6-antenna equivalent on-source time of 3.2 h With natural weighting, the synthesised beam is 8.9 by 5.0 arcsec.

Figure 1 shows the spectrum and collapsed map of ULAS J1537+0557. The best S/N for the line detection is

![Figure 1](image-url)
The dynamical mass can then be estimated as dividing the FWHM of the CO line by 2.4 (Tacconi et al. 2006). (Carilli & Walter 2013), we derive a total molecular gas mass of $\sim 1 \times 10^{10} M_\odot$, based on the fit of the visibilities with an unresolved source.

The large FWHM of CO(3–2) of ULAS J1539+0557 suggests a non-negligible inclination. If $i = 20$ deg, as in SBSJ1408+567 (Coppen et al. 2008), $M_{\text{dyn}} \sim 5 \times 10^{11} M_\odot$; if $i = 45$ deg, $M_{\text{dyn}} \sim 10^{11} M_\odot$. The ratio between the gas mass and the dynamical mass $M_{\text{H2}}/M_{\text{dyn}}$ is therefore likely to be in the range 0.4–0.1. The assumption of a disk geometry in CO-based estimates of high-$z$ quasar host galaxies may lead to a bias if these are actually undergoing major mergers (Aravena et al. 2011).

nuclear emission is substantially obscured, consistent with the colour selection of this source in the UKIDSS survey (Banerji et al. 2013). The SED below 3000 Å is probably dominated by starlight from the host galaxy. Translating the observed 1500 Å luminosity into a SFR, assuming the Madau (1998) conversion and zero galaxy extinction, provides a firm lower limit to the host galaxy SFR of 70 $M_\odot$/yr. The real SFR is probably much higher than this value, if the galaxy is substantially obscured by dust, but difficult to constrain because of the lack of far-infrared data.

To obtain a better SFR estimate, we modelled the broadband, 0.1–6 μm SED by using a library of AGN and galaxy templates (Bongiorno et al. 2012). For the AGN component, we used the mean quasar SED from Richards et al. (2006), while for the galaxy component, a library of synthetic spectra generated using the stellar population synthesis models of Bruzual & Charlot (2003) has been adopted. Both the AGN and the galaxy templates can be affected by dust extinction. For a given galaxy template, the free parameters in the fit are thus normalisation and extinction of both AGN and galaxy templates. We accepted solutions with galaxy stellar masses smaller than $10^{12} M_\odot$ and SFR × duration of the starburst ≤ total stellar mass. The best-fit values are $400 M_\odot$/yr and $3 \times 10^{10} M_\odot$ for the stellar mass. The 1σ confidence intervals for SFR and stellar mass are 250–1600 $M_\odot$/yr and $3 \times 10^{10}–3 \times 10^{11} M_\odot$, respectively.

The best-fit extinction for the AGN and the galaxy is $E(B-V) = 1.1$ and 0.2, respectively.

4. Discussion

The quasar ULAS J1539+0557 is an extreme object, with a bolometric luminosity of $L_{bol} = 1.6 \times 10^{48}$ erg/s (derived from the 5100 Å continuum), and a SMBH mass, estimated from the Hα emission line, as large as $7.4 \times 10^{9} M_\odot$ (Banerji et al. 2012). This implies that the SMBH is accreting at the Eddington limit, $\dot{M}_{acc}$, would be only $\sim 160$ Myr.

In the following we discuss the source properties in comparison with other known luminous systems. A clean estimator for the intrinsic AGN power is its mid-infrared luminosity, since it guarantees little bias against dusty objects and little extinction (or absorption) corrections. Recently, the WISE satellite has performed the deepest all-sky survey at 22 μm, which samples the rest frame 4–8 μm band at $z = 2–4$ (where AGN heated warm dust is the main component to the total flux), finding the most luminous AGN in the sky at $z < 4–5$. It is therefore convenient to use the 7.8 μm luminosity ($L_{7.8}(\lambda 7.8 \mu m)$) as a reliable proxy for the AGN power. By measuring $L_{7.8}(\lambda 7.8 \mu m)$ of all quasars with CO detections, we find that only three of these sources at $z < 5$ have extreme intrinsic luminosities ($L_{7.8}(\lambda 7.8 \mu m) \gtrsim 10^{47}$ erg/s). Other six quasars with CO detection have $10^{46} < L_{7.8}(\lambda 7.8 \mu m) < 10^{45.5}$ erg/s, including the two highly obscured SWIRE quasars of Polletta et al. (2011).

To characterise quantitatively the unique population of hyperluminous quasars we need to substantially increase the sample with gas mass, dynamical mass, and SFR detections.

Figure 3 plots L’CO against $L_{7.8}(\lambda 7.8 \mu m)$ for a compilation of both unobscured and highly obscured AGN. The luminosities of lensed objects have been corrected for the published lens amplification factor. A rough correlation between the AGN luminosity and the CO luminosity is present. We note that the scatter in the correlation is higher for the lensed objects, probably because both luminosities have been corrected for the same amplification factor, but the source of the 7.8 μm luminosity is most likely very compact (pc scale), while the source of the CO luminosity could be more extended (a few kpc), implying an amplification pattern more complex than the assumed one. The 7.8 μm luminosities of highly obscured (Compton thick, $N_H > 10^{24}$ cm$^{-2}$, two are from Polletta et al. 2011, and Mrk 231) have been computed using the 6.5–22 μm fluxes, not corrected for extinction, which however may be relevant in highly obscured objects even at such long wavelengths. AGNs at $z > 5.8$ are found at the lower part of the correlation. Non-lensed quasars at $z = 1.5–5$ with $L_{bol}(\lambda 7.8 \mu m) > 10^{46}$ erg/s have high L’CO, in the range $3–8 \times 10^{10}$ K km s$^{-1}$ pc$^2$.

To convert L’CO into gas mass we again adopt a conversion factor $X_{CO} = 0.8$, as in most studies of AGN, ULIRGs, and SMGs (see Carilli & Walter 2013). The molecular gas mass of ULAS J1539+0557 and three other hyper-luminous quasars (Table 1) are in the range $3–6 \times 10^{10} M_\odot$. We evaluate the dynamical mass of ULAS J1539+0557 under admittedly major assumptions (the FWHM estimated from the core of the CO(3–2) line, the size of the molecular gas disk of 2 kpc and its inclination angle). We find that the gas mass is 0.1–0.4 of the dynamical mass. This suggests that the host galaxy of this hyper-luminous quasar is not deprived of gas, and it is likely forming stars actively, in agreement with the prediction of semi-analytic models for AGN/galaxy co-evolution (Lamastra et al. 2013b).

The SFE is usually computed as $SFE = L_{FIR}/L’CO$. Since ULAS J1539+0557 has never been observed at far-infrared (FIR) or submm wavelengths, we do not have a direct measure of $L_{FIR}$. We can, however, estimate $L_{FIR}$ from the SED fitting, using the conversion $SFR = 2–1.2 \times 10^{-10} (L_{FIR}/L’CO) M_\odot$/yr (Scoville 2012). We find SFE in the range 25–350 $L_\odot/$(K km s$^{-1}$ pc$^2$), which correspond to gas consumption timescales from 25 Myr to 160 Myr, smaller than or equal to the black hole gas consumption timescale computed above (assuming that AGN feedback has not yet been able to significantly modify its environment and reduce the total host galaxy cold gas mass).

For a SFR in the range 250–1600, the ratio $M_{acc}/SFR$ is in the range 0.1–1, which is $\sim 2–3$ orders of magnitude above the mean value $10^{-3}$ found by Mullaney et al. (2012) for AGN.
with star-forming hosts in GOODS-S, thus suggesting that ULAS J1539+0557 is an outlier to the AGN main sequence. The SMBH mass is $\gtrsim 2\%$ of the dynamical mass, so $M_{\text{BH}}/M_*$ is of the order of 0.1 or higher, i.e. 2 orders of magnitude larger than the canonical value. This means that, although ULAS J1539+0557 has an extremely massive SMBH, this SMBH seems to live in an environment that is not that of a typical AGN, which is in agreement with other cases of luminous AGN at z $\gtrsim 2$ (i.e. 2 orders of magnitude larger than the canonical value). This means that, although ULAS J1539+0557 has an extremely massive SMBH, this SMBH seems to live in an environment that is not typical of AGN, which is in agreement with other cases of luminous AGN at z $\gtrsim 2$.

In Fig. 4 we plot the SFE against redshift, for ULAS J1539+0557 and a compilation of AGN and galaxies (samples of Daddi et al. 2007; Genzel et al. 2010; Riechers et al. 2011, and references therein; Krips et al. 2012). The red triangle corresponds to ULAS J1539+0557.

5. Conclusions

We detected CO(3–2) in the hyper-luminous quasar ULAS J1539+0557 at z = 2.658, a source selected for its extremely red colours in the UKIDSS Large Area Survey (ULAS) and brightness at 22 $\mu$m in the WISE Survey. We find a molecular gas reservoir of $4.1 \pm 0.8 \times 10^{10} M_\odot$. The dynamical mass is well constrained, but it could be $2$–$10$ times higher, depending mostly on the gas disk size and inclination. In any case, the host galaxy does not appear deprived of cold gas, suggesting that it is still actively forming stars. From fitting of the UV to mid-infrared SED, we derived a robust lower limit to the SFR and gas consumption time scale. The ratio of SMBH accretion to star-formation rate, $M_{\text{acc}}/SFR$, is significantly higher than that found by Mullaney et al. (2012) for AGN with star-forming hosts. The SFE is similar to that of highly obscured, high-luminosity quasars. This class of quasars is believed to witness the brief evolutionary phase that traces the transition from a heavily enshrouded ULIRG-like phase of black-hole growth to the blue unobscured quasars. Thanks to their high luminosity these exceptional objects are ideal laboratories for investigating the physics of the feedback phenomenon with in situ observations at the peak of galaxy and SMBH assembly. The high luminosity allows the highlighting of the correlation between SFE and other parameters (obscuration, AGN luminosity).

The WISE All-Sky Survey, the UKIDSS survey, and the VISTA Hemisphere Survey have revealed a population of hyper-luminous quasars in the near- and mid-infrared. These selections have already produced reasonably large hyper-luminous quasar samples at z $\gtrsim 1.5$–$4$, the main epoch of galaxy formation and accretion activity in the Universe. Recently, Banerji et al. (2014) presented IR and X-ray observations of a similar source from the same parent sample, ULAS J1234+0907 at redshift 2.5, finding high SFR ($\gtrsim 2000 M_\odot$/yr) and high X-ray luminosity ($\gtrsim 10^{46}$ erg/s), thus confirming that infrared selection is efficient at discovering a population of hyper-luminous quasars in the blowout phase.

It is crucial that we increase the sample of hyper-luminous quasars with good estimates of both gas mass, dynamical mass, $L_{\text{IR}}$, and X-ray luminosity, including both unobscured and highly obscured quasars. These goals can be achieved with the present and future generation of millimetre interferometers, such as the PdBI, NOEMA, and ALMA.
