Abstract

Background

Biopsy is considered the gold-standard technique for prostate cancer diagnosis and is recommended in patients with a high clinical indication of prostate cancer. In this study, we aimed to determine the diagnostic efficacy of a novel positron emission tomography (PET)/computed tomography (CT)-guided percutaneous trans-pararectal space-based approach to targeted prostate biopsy.

Methods

PET/CT-guided percutaneous trans-pararectal space prostate biopsies were performed in 14 consecutive patients with indications of prostate cancer. Whole-body 18F-FDG PET/CT indicated the presence of 18F-fluorodeoxyglucose (FDG)-avid focal prostate lesions. Two tissue specimens were obtained from each patient. The final diagnoses were established based on the results of a histopathological analysis and clinical follow-up, and these findings were used to verify the diagnostic accuracy of 18F-FDG PET/CT for prostate cancer.

Results

The diagnostic accuracy of 18F-FDG PET/CT for prostate cancer was 81.8%. Further analyses of the two biopsied samples per patient led to confirmed histopathological and immunohistochemical diagnoses of prostate cancer in all 14 patients. Consequently, the success rate of PET/CT-guided percutaneous trans-pararectal space prostate-targeted biopsy for the diagnosis of prostate cancer was 100.0% (14/14). Regarding safety, the average duration of biopsy was 20 min, and no serious complications occurred.

Conclusions
PET/CT-guided percutaneous trans-pararectal space prostate biopsy may yield a new approach to targeted prostate biopsy for the diagnosis of prostate cancer. Moreover, this biopsy procedure can be performed safely without complications, and is more cost-effective than conventional trans-rectal and trans-perineal prostate biopsy methods.

Background

Prostate cancer is an important cause of morbidity and mortality in men worldwide [1]. In China, the incidence of prostate cancer has been increasing by approximately 12% annually. However, approximately 70% of patients present with locally advanced or extensively metastasised prostate cancer at the time of diagnosis [2–3]. Historically, trans-rectal ultrasonography (TRUS) of the prostate has remained the cornerstone of prostate cancer diagnosis since the period of systematic ‘sextant’ biopsy of suspected prostate malignancy, wherein 3 cores are obtained from each side of the prostate [4–6]. In men undergoing an initial prostate needle biopsy consequent to an elevated serum prostate-specific antigen (PSA) level, systematic 12-core TRUS-guided prostate biopsy yields cancer detection rates of 28–52% [7–13]. The systematic sampling of all prostatic quadrants improves the accuracy of sampling. However, this method has been criticised for its oversampling of insignificant tumours, the risk of additional morbidity and the need for general anaesthesia.

Compared with traditional biopsy protocols such as systematic 12-core TRUS-guided biopsy, multiparametric magnetic resonance imaging (MRI)/ultrasonography-guided biopsy yields more refined diagnostic information [14–16]. The minor complications of the trans-rectal and trans-perineal biopsy procedure include haematuria, rectal
haemorrhage, haemospermia, vasovagal attack, and pathogenic infection. TRUS-guided prostate biopsy is associated with additional major complications, including sepsis, bleeding or other complications requiring hospitalisation. More importantly, an increased risk of life-threatening septic shock was reported with trans-rectal biopsy [17].

Therefore, a safer and more effective algorithm for the diagnosis of prostatic diseases should be explored. Recent advancements in molecular imaging techniques (positron emission tomography [PET]/computed tomography [CT], PET/MRI) have led to the development of several new high-specificity probes for the diagnosis of prostate cancer and may play a crucial role in facilitating the management of prostate cancer at all clinical stages [18–20]. In our previous study, we proved the efficacy of PET/CT-guided targeted biopsy for the evaluation of advanced lung cancer with metastatic bone lesions, for surveilling the surveillance of molecular subtype switching of in metastatic breast cancer cells and identifying the identification of bone marrow involvement in newly diagnosed cases of lymphoma [21–22]. However, no studies have examined the utility of PET/CT-guided targeted biopsy for prostate pathologies. In this study, therefore, we evaluated the safety and efficacy of PET/CT-fusion-guided percutaneous trans-pararectal space prostate biopsy for the diagnosis of prostate cancer.

Methods

Patients

A retrospective review of our electronic database comprising 14 patients (age range, 52–78 years; mean age, 69.0 years) identified who were retrospectively enrolled in our study. Among which, 13 patients had indications of prostate cancer
based on an elevated PSA level, abnormalities detected during a digital rectal examination (DRE), abnormal imaging findings or a combination thereof. One patient underwent prior treatment for prostate cancer. All 14 patients underwent 18F-fluorodeoxyglucose (FDG) PET/CT scans. The diagnoses of prostate cancer were confirmed via histopathological examination or evidence of prostate cancer detected during a clinical and imaging follow-up 12 months after the initial PET/CT examination.

**PET/CT and image interpretation**

The patients were asked to fast for at least 4 hours before undergoing 18F-FDG PET/CT to ensure a normal blood glucose level (70–120 mg/dL) before the intravenous injection of 18F-FDG. Each patient received an intravenous injection of 370–666 MBq (10–18 mCi) of 18F-FDG. Data were acquired using a PET/CT system (Discovery STE; GE Medical Systems, Milwaukee, WI, USA) at 45 min post-injection. The following procedure was used to acquire data First, a CT scan was performed from the head to the pelvic floor, using the following settings: 110 kV, 110 mA, tube rotation time of 0.5 s, and 3.3-mm scan section thickness. These settings were matched to the PET settings. Immediately after the CT scan, a PET scan was performed to obtain a transverse field of view identical to that obtained by CT. The acquisition time was 3 minutes per table position.

Based on our previous knowledge of the normal biodistribution of 18F-FDG, the malignant prostate cancer lesions were identified as foci exhibiting increased tracer accumulation relative to the cancer-free contralateral structures and surrounding soft tissues. The lesions were graded qualitatively as definitely or probably abnormal (i.e., representative of a tumour) if a moderate to marked increase in the
accumulation of $^{18}$F-FDG was observed. A diffused, mild increase or no increase in tracer accumulation (i.e., abnormalities identified by CT for which no corresponding abnormality was visualised by PET) was indicative of pathologically normal or benign tissue.

**PET/CT-fusion-guided percutaneous trans-pararectal space prostate biopsy**

On the day after the whole-body PET/CT scan, a board-certified interventional radiologist and nuclear medicine physician performed the prostate biopsies in a PET/CT suite dedicated to biopsy procedures. PET/CT-guided prostate biopsies were performed in a stepwise manner under aseptic conditions, with the patient in a prone position. A local anaesthetic agent, lidocaine, was administered subcutaneously via the buttocks. An 18-gauge biopsy needle (Magum, Bard, AZ, USA) was introduced in a stepwise manner under the guidance of PET/CT fusion and CT imaging via a percutaneous trans-pararectal space approach, without damaging the rectal wall or skin of the perineum. Two prostate tissue specimens was obtained from each patient and were subjected to subsequent histopathological and immunohistochemical examinations. The PET/CT-fusion-guided percutaneous trans-pararectal space prostate biopsy approach is shown in detail in Figure 1. Representative $^{18}$F-FDG PET/CT images of patients undergoing prostate needle biopsy are shown in Figures 2 and 3.

**Synchronised multiple organ biopsy**

Of the 14 patients in the electronic database, synchronous pulmonary lesions were detected in 3 patients, hypermetabolic bone lesions were observed in 3 patients, a retroperitoneal mass was detected in 1 case, and an renal mass was found in 1 patient incidentally. These 8 patients underwent PET/CT-guided percutaneous
biopsies targeting the $^{18}$F-FDG-avid regions.

**Clinical and imaging follow-up of the prostate lesions**

All biopsy results were confirmed histologically or clinically, and a final diagnosis was made for all patients. For prostatic lesions which were pathologically not indicative of malignancy, clinical and imaging follow-ups were performed for at least 12 months after the PET/CT examination.

**Statistical analysis**

The diagnostic accuracy rate of PET/CT and the diagnostic success rate of prostate biopsy were determined based on the number of confirmed cases, rather than the number of lesions.

**Results**

**Diagnostic accuracy of $^{18}$F-FDG PET/CT for identifying malignant prostatic lesions**

The diagnostic accuracy of $^{18}$F-FDG PET/CT was determined by histopathological examination or based on other clinical evidence. The $^{18}$F-FDG PET/CT scans of 14 patients of prostatic lesion led to the identification of 9, 0, 3, and 2 cases with true positive, false negative, true negative, and false positive results, respectively. The latter 2 cases were subsequently identified as chronic prostatitis and granulomatous prostatitis. The diagnostic accuracy of $^{18}$F-FDG PET/CT for the detection of prostate cancer was 81.8% (9/11; Table 2).

**Diagnostic accuracy of PET/CT-guided prostate biopsy for identifying malignant prostatic lesions**
The diagnostic accuracy of PET/CT-guided prostate biopsy for prostate cancer was determined according to a histopathological examination or further clinical evidence. The histopathological analysis of PET/CT-guided prostate biopsy specimens confirmed the diagnosis of prostate cancer in 9 cases and of benign lesions in 5 cases.

Of the 5 patients with benign lesions, 1 patient had undergone multiple prostate biopsies at our hospital because of an elevated PSA level since 2013 but received biopsy results that were negative for prostate cancer. Each time, the patient’s PSA level decreased after symptomatic treatment, and eventually a negative result was achieved after 6 years of follow-up. Another patient was infected with human immunodeficiency virus. Because the histopathological analysis of the prostate biopsy yielded negative results, special staining and molecular detection techniques were applied. Acid-fast staining of the specimen revealed bacteria, and a polymerase chain reaction assay indicated the presence of tuberculosis-associated genes. The prostatic lesion was attributed to mycobacterial infection. Although $^{18}$F-FDG PET/CT incidentally detected hypermetabolic nodules in the prostate of the 6th and 7th patients, the serum PSA level and DRE evaluations did not suggest malignancy, and the results were similar to those detected in the second year of follow-up. The 8th patient underwent PET/CT-guided biopsy because of an increased PSA level, but the results were negative for prostate cancer. Similar results were obtained with subsequent TRUS-guided prostate biopsy. The patients were followed for 1 year after biopsy. The diagnostic success rate of $^{18}$F-FDG PET/CT-guided percutaneous trans-pararectal space prostate biopsy was 100.0% (14/14; Table 3).

Multiple primary tumours in patients with
prostatic lesions
Simultaneous PET/CT-guided biopsies of the prostate and other organs were performed in 57.1% (8/14) of the patients with prostatic lesions. The incidence rate of multiple primary tumours was 28.6% (4/14). The patients’ characteristics are summarised in Table 1.

Biopsies of primary prostate and bone lesion
Simultaneous PET/CT-guided prostate and bone lesion biopsies were performed in 28.6% (4/14) of the patients. Histopathological examinations confirmed the presence of metastatic bone lesions in patients with prostate cancer (Table 1).

Complications of targeted prostate biopsy
Each targeted prostate biopsy required an average of approximately 20 minutes. Slight bleeding and pain were experienced by almost all patients who underwent the biopsy. However, no serious complications were noted. Moreover, no complications associated with rectal puncture injury occurred in the patients who underwent prostate biopsy (Table 4).

Discussion
According to the 2015 Annual Report of the National Central Cancer Registry (China), the overall incidence of prostate cancer was 7.1/10^5 individuals in 2011. Accordingly, prostate cancer was the ninth most prevalent cancer overall, and seventh most prevalent among men [23]. However, the majority of patients with prostate cancer were diagnosed at an advanced disease stage. Early diagnosis is a key driver of improved survival among men with prostate cancer in China. Organ-confined prostate cancer at the time of diagnosis is associated with a good prognosis and a favourable response to curative therapy [24]. Conversely,
metastatic prostate cancer is associated with a poor prognosis, and skeletal metastasis is associated with a 5-year survival rate of <30% [25].

In the present study, 13 patients presented with indications of prostate cancer, including an elevated PSA level and/or abnormal digital rectal examination and/or imaging findings. One patient had been treated previously for prostate cancer.

According to the $^{18}$F-FDG PET/CT findings, 6 patients (66.7%) with prostate cancer had skeletal metastases, and 1 patient (11.1%) presented with a tumour that was no longer organ-confined and had invaded the bladder. The incidence rate of multiple primary tumours among patients with prostate cancer was 28.6% (4/14).

Improvements in cancer care have been linked closely to advances in imaging technologies, as these improvements enable a more accurate diagnosis, staging, and surveillance of disease. PET/CT recently emerged as a promising diagnostic imaging platform for both primary and recurrent prostate cancers [26]. In addition to $^{18}$F-FDG, routine clinical imaging procedures use various radiolabelled tracers [e.g., $^{18}$F-choline, $^{18}$F-NaF, $^{68}$Ga-prostate-specific membrane antigen (PSMA), $^{68}$Ga-DOTATATE, $^{18}$F-FACBC] with demonstrated efficacy for cancer diagnosis in various clinical settings [26–27]. Newly developed tracers exhibit increased accuracy for the detection of small, incipient metastatic foci [28–29]. Improvements in MRI techniques, and particularly in functional imaging, have enabled radiologists to play an important role in the risk stratification and management of patients [30–32].

$^{18}$F-FDG PET/CT is primarily useful in the diagnosis and staging of prostate cancer because it combines the metabolic information of PET with the anatomic information of CT. Moreover, whole-body scanning facilitates the detection of primary tumours in multiple organs. Additionally, $^{18}$F-FDG PET/CT can accurately diagnose cancer
recurrence. In this study, prostate cancer was confirmed via histopathological examinations in 9 of 14 patients, whereas the remaining 5 patients had benign lesions (including 2 misdiagnoses of prostate cancer). The diagnostic accuracy of $^{18}$F-FDG PET/CT for prostate cancer was 81.8% (9/11). Of the 14 patients, we detected multiple primary tumours that were confirmed pathologically as prostate cancer in 4 patients (28.6%). One of the 9 patients exhibited a tumour recurrence and metastatic bone lesion on $^{18}$F-FDG PET/CT, which was eventually confirmed as prostate cancer.

Despite the enthusiasm surrounding the use of PET and MRI for diagnosing prostate cancer, prostate biopsy remains the gold-standard diagnostic option. Prostate biopsies have been used to diagnose prostate cancer since the beginning of the last century [5–6]. Ideally, prostate biopsy should be minimally invasive with few side effects, and should identify a large proportion of men who would benefit from treatment while minimising the identification of men with clinically insignificant cancer to prevent over-treatment. Although the optimal method of prostate biopsy remains controversial, TRUS-guided biopsy is the most widely accepted method for the diagnosis of prostate cancer. Greyscale TRUS has a low sensitivity and specificity for prostate cancer detection, and some studies reported low detection rates for saturation prostate biopsy via the trans-rectal or trans-perineal route (21.7–45% [33–36] and 22.7–42.2%, respectively [37–39]). Despite the advantages of TRUS-guided prostate biopsy, its invasive nature and rectal approach could potentially cause complications. Infectious complications ranging from asymptomatic bacteriuria to septic shock may occur during TRUS-guided prostate biopsy via the manipulation of infected prostate tissue, which also increases the risk
of introducing the rectal flora into the prostate tissue, urine, and blood.

Here, we introduce a novel approach to prostate biopsy, namely $^{18}$F-FDG PET/CT-guided percutaneous trans-pararectal space prostate biopsy. PET/CT is a widely accepted modality for detecting prostatic lesions and identifying cancer recurrence and metastasis, particularly when conventional imaging findings are equivocal or conflicting. PET/CT also increases the choice of biopsy location, which can increase the associated accuracy and safety.

Besides the primary lesion, PET/CT also enables the biopsy of other metabolically active lesions, such as metastatic bone lesions that cannot be detected using conventional imaging methods. In such cases, PET/CT-guided biopsy allows the sampling of multiple hypermetabolic lesions, thereby reducing false-negative or false-positive biopsy rates. In our study, PET/CT-guided biopsies were performed in 14 patients with indications of prostate cancer based on PET/CT images. The 4th patient in our study underwent prostate, lung, and iliac bone biopsy under PET/CT guidance, despite the lack of apparent bone morphological changes on a CT scan. The histopathological analysis revealed that both the prostatic and pulmonary lesions had originated from the primary prostate tumour, whereas the bone lesions had metastasised from the lung lesion rather than the prostate tumour.

Before performing PET/CT-guided percutaneous $^{18}$F-FDG-avid target biopsy, we selected the optimal puncture site based on the target location to ensure a favourable biopsy success rate and the optimal needle path to minimise trauma.

When selecting the target location, the site with the highest metabolic $^{18}$F-FDG accumulation among all focal hypermetabolic prostate lesions was selected first, as such lesions would more likely represent the true cancer grade and would thus
affect the clinical classification, staging, and prognosis. Other visible but controversial lesions were targeted thereafter.

The optimal needle path is extremely important when aiming to avoid puncturing the nearby blood vessels, spinal nerve trunk, and other vital organs. In our study, we chose the anatomically safer trans-pararectal space, rather than the trans-rectal or trans-perineal approach. This option can avoid the damage to the rectum or perineum associated with a conventional biopsy path, and may minimise the occurrence of complications. Altogether, we considered these factors to ensure a safe, feasible, and effective prostate biopsy procedure. $^{18}$F-FDG PET/CT-guided percutaneous trans-pararectal space prostate biopsy is the third prostate biopsy technique worldwide that can accommodate all these factors simultaneously. This novel method can reduce the false-negative or false-positive rate and is a relatively safer and more effective way to obtain a pathological diagnosis.

In our study, a correct biopsy-assisted diagnosis was made on all cases. The diagnostic success of $^{18}$F-FDG PET/CT-guided percutaneous trans-pararectal space prostate biopsy was 100.0% (14/14). Simultaneous PET/CT-guided targeted biopsies of the prostate and other organs were performed in 57.1% (8/14) of the patients. Finally, histopathological examination confirmed the presence of primary prostate lesions in 4 patients. In summary, $^{18}$F-FDG PET/CT-guided percutaneous trans-pararectal space prostate biopsy mitigates the issue of trans-visceral puncture trauma by accurate biopsy, and enables a pathological diagnosis from a smaller tissue volume. Moreover, the ability to biopsy other organs simultaneously provides additional diagnostic possibilities, thus avoiding an unnecessary diagnosis or overtreatment.
Our study had several limitations. First, the small sample size might have limited the statistical significance of the results. Second, $^{18}$F-FDG PET/CT is associated with some disadvantages. For example, small tumours might remain undetected because of partial-volume effects, which would cause falsely low measurements of the true $^{18}$F-FDG activity level. Moreover, $^{18}$F-FDG frequently accumulates in areas of inflammation. However, physiological variants and benign pathological causes of $^{18}$F-FDG uptake can be recognised specifically and categorised properly using other approaches. Accordingly, we will evaluate the efficacy of $^{68}$Ga-PSMA PET/CT-guided prostate biopsy in a future study.

Conclusion

Conventional prostate biopsy methods remain associated with several risks and side effects. In this study, we present a new molecular imaging-guided approach to the targeted biopsy of prostate lesions. PET/CT-fusion-guided percutaneous trans-pararectal space prostate biopsy may provide an effective approach to the diagnosis of prostate cancer, and can be performed safely without any complications associated with trans-rectal puncture.

Tables

Table 1. Characteristics of prostate lesions in 14 patients

| Pt | Age range (y) | PSA (ng/mL) | PET/CT Diagnosis | Nodule size (cm²) | Site (lobe) | SUV_max | Gleason score | Synchronized multiple organ biopsy |
|----|---------------|-------------|------------------|------------------|-------------|---------|--------------|----------------------------------|
| 1  | 52–78         | 13.28       | Pca              | 1.1*1.1          | Left        | 5.18    | 3+4          | N/A                              |
| 2  | 61.52         | 1.5*1.5     | Right            | 6.70             | Benign      | N/A     |
| 3  | 100.0         | 2.0*2.0     | Left             | 9.30             | 4+5         | N/A     |
| 4  | 26.15         | 2.6*2.6     | Right            | 5.72             | 4+3         | Lung biopsy (lung cancer) |
| 5  | 6.45          | 3.7*2.8     | Left             | 11.30            | Benign      | N/A     |
| 6  | 3.61          | 1.8*2.2     | Right            | 3.25             | Benign      | Lung biopsy (inflammation) |
| 7  | 2.51          | 1.6*1.6     | Right            | 8.10             | Benign      | Lung biopsy (CC) |
| 8  | 22.6          | 1.0*1.0     | Left             | 2.50             | Benign      | LN biopsy (EC Metastasis) |
| 9  | 87.3          | 3.2*2.5     | Left             | 3.10             | 4+5         | Renal biopsy (Renal cancer) |
| 10 | 100.0         | 1.3*1.2     | Right            | 2.33             | 4+5         | N/A     |
| 11 | 100.0         | 1.6*1.4     | Left             | 2.50             | 4+4         | Bone biopsy (Metastasis) |
| 12 | 100.0         | 2.9*2.2     | Left             | 8.33             | 4+5         | Bone biopsy (Metastasis) |
| 13 | 100.0         | 2.7*3.0     | Left             | 4.70             | 4+4         | Bone biopsy (Metastasis) |
| 14 | 100.0         | 3.2*4.4     | Left             | 3.75             | 4+4         | N/A     |

Pca, Prostate cancer; LN, Lymph Node; EC, Oesophageal Carcinoma; CC, Cholangiocarcinoma; PET/CT, Positron emission tomography/computed tomography; PSA, Prostate-specific antigen; N/A, Not applicable; SUV_max, Maximum standard uptake value
Table 2. Diagnostic accuracy of $^{18}$F-fluorodeoxyglucose PET/CT for malignant and benign lesions of the prostate (n=14)

| Diagnosis of $^{18}$F-FDG PET/CT | Biopsy pathology and follow-up (gold standard) |
|----------------------------------|-----------------------------------------------|
|                                  | Malignant | Benign | Total |
| Positive                         | 9         | 2      | 11    |
| Negative                         | 0         | 3      | 3     |
| Total                            | 9         | 5      | 14    |

Prostate cancer diagnostic accuracy rate: 81.8% (9/11)

$^{18}$F-FDG PET/CT, $^{18}$F-fluorodeoxyglucose positron emission tomography/computed tomography

Table 3. Diagnostic accuracy of PET/CT-guided biopsy for detecting malignant and benign lesions of the prostate (n=14)

| PET/CT targeted biopsy | Biopsy pathology and follow-up (gold standard) |
|------------------------|-----------------------------------------------|
|                        | Malignant | Benign | Total |
| Positive               | 9         | 5      | 14    |
| Negative               | 0         | 0      | 0     |
| Total                  | 9         | 5      | 14    |

Biopsy diagnostic success rate: 100.0% (14/14)

PET/CT, positron emission tomography/computed tomography

Table 4. Complications associated with PET/CT-guided trans-pararectal space prostate biopsy

| Complication                           | % of biopsies |
|----------------------------------------|---------------|
| Slight pain                            | 14            |
| Little bleeding of needle tract         | 13            |
| Fever                                  | 0             |
| Rectal bleeding                        | 0             |
| Haematospermia                         | 0             |
| Urine retention                        | 0             |
| Other complications requiring hospitalisation | 0    |
Figure 1

Workflow of the PET/CT-fusion-guided percutaneous trans-pararectal space prosta
The patient was hospitalised with fever, a 2-month history of subcutaneous nodules, and an elevated serum alanine aminotransferase (ALT) level. Pathological analysis revealed that hematopoietic activation of the bone marrow was drug-induced.

The patient presented with a 1-month history of back pain and weakness of both lower extremities. Pathological analysis of the puncture specimen revealed prostate adenocarcinoma (Gleason score 4+5=9).
