Introduction: Adjuvants and immunotherapies designed to activate adaptive immunity to eliminate infectious disease and tumors have become an area of interest aimed at providing a safe and effective strategy to prevent or eliminate disease. Existing approaches would benefit from the development of immunization regimens capable of inducing efficacious cell-mediated immunity directed toward CD8+ T cell-specific antigens. This goal is critically dependent upon appropriate activation of antigen-presenting cells (APCs) most notably dendritic cells (DCs). In this regard, polyanhydride particles have been shown to be effectively internalized by APCs and induce activation.

Methods: Here, a prophylactic vaccine regimen designed as a single-dose polyanhydride nanovaccine encapsulating antigen is evaluated for the induction of CD8+ T cell memory in a model system where antigen-specific protection is restricted to CD8+ T cells. Bone marrow-derived dendritic cells (BMDCs) are used as an in vitro model system to evaluate the magnitude and phenotype of APC activation. Primary DCs, particularly those with described ability to activate CD8+ T cells, are also evaluated for their in vitro responses to polyanhydride nanoparticles.

Results: Herein, polyanhydride nanoparticles are shown to induce potent in vitro upregulation of costimulatory molecules on the cell surface of BMDCs. In contrast to the classically used TLR agonists, nanoparticles did not induce large amounts of pro-inflammatory cytokines, did not induce characteristic metabolic response of DCs, nor produce innate antimicrobial effector molecules, such as nitric oxide (NO). The polyanhydride nanovaccine results in protective CD8+ T cell responses as measured by inhibition of tumor progression and survival.

Discussion: Together, these results suggest that the use of a polyanhydride-based nanovaccine can be an effective approach to inducing antigen-specific CD8+ T cell memory by providing antigen delivery and DC activation while avoiding overt inflammatory responses typically associated with traditional adjuvants.

Keywords: nanovaccine, metabolism, nitric oxide, T cell memory, inflammation

Introduction
Cytotoxic CD8+ T cells are critical mediators of immunological protection against tumors and intracellular pathogens.1 Although naturally occurring infections are often effective at inducing long-lived CD8+ T cell memory, commonly used adjuvants such as alum, oil-in-water emulsions, or innate immune stimulating Toll-like receptor (TLR) ligands have not proven as successful for the induction of cell-mediated immunity.
(CMI). Many efficacious immunization strategies that induce rapid and robust/durable memory CD8+ T cell responses have either employed a multiple-dose regimen (ie, prime-boost) or treated animals with adoptively transferred DCs pulsed in vitro with antigen. Single-dose DC vaccines that rapidly induce a large number of memory CD8+ T cells possess the relatively unique property of providing both antigen presentation and co-stimulation without the induction of overt inflammatory responses that result when using more standard antigen-adjuvant combinations or infections. Many adjuvants are incorporated into vaccine formulations to induce inflammation and innate immune activation with a focus on the induction of long-lived antibody titers as opposed to CMI. While beneficial to antibody tiers, adjuvant-associated proinflammatory cytokines and associated inflammation have been demonstrated to divert an intrinsic CD8+ T cell pathway towards induction of effector memory T cells. It has also been shown that overt inflammatory responses impair effector CD8+ T cell trafficking and function. These blunted T cell responses result in less effective generation of memory or effector T cells. Another common class of adjuvants, TLR agonists, not only induce the production of proinflammatory cytokines and overt inflammation but also induce innate immune effector molecules such as nitric oxide (NO). Nitric oxide in particular has been described to cause deleterious effects on DC activation via altered metabolism, decreased survival, and impaired co-stimulatory molecule upregulation.

Although effective at generating rapid and elevated numbers of memory CD8+ T cells, the use of DC vaccines also comes with increased costs and the challenges associated with the personalized nature of generating ex vivo DC populations to be used therapeutically. Consequently, identification and development of novel, less inflammatory vaccine adjuvants and antigen delivery systems would benefit the induction of favorable outcomes using a more manageable immunization regimen.

To improve vaccines’ ability to induce optimal cytotoxic CD8+ T cell memory, design of vaccine delivery systems that mimic the beneficial effects of DC vaccination (ie, MHC I presentation of antigen) could be used. Polyanhydride particle-based vaccines in particular represent a unique alternative to existing vaccines that employ more traditional adjuvants. Nanoparticles (NPs) consisting of combinations of sebacic acid (SA), 1,6-bis(p-carboxyphenoxy)hexane (CPH), and 1,8-bis(p-carboxyphenoxy)-3,6-dioxaocante (CPTEG) are readily phagocytosed by DCs and activate them as measured by cytokine and costimulatory molecule upregulation. Following administration in vivo, these nanovaccines are also known to persist in the local tissues, thus, facilitating the prolonged release of their encapsulated payload. When delivered subcutaneously, polyanhydride NPs induce a mild inflammatory response with no evidence of adverse histopathological reactions. Previous studies have also illustrated the ability of polyanhydride NPs to prophylactically enhance CD8+ T cell memory responses and elicit protection in a tumor challenge model. However, the addition of a TLR ligand such as CpG oligodeoxynucleotides (ODN) to the polyanhydride platform decreased relative efficacy indicating that the induction of inflammation adversely affected the generation of effector CD8+ T cell responses. Considering the unique innate immune stimulatory properties of polyanhydride NPs, the ability of this platform to activate DCs and induce an effective memory CD8+ T cells was tested and compared to the inflammatory TLR agonist CpG ODN. This was evaluated via an ovalbumin (Ova)-expressing tumor model where Ova is expressed cytosolically and antigen-specific protection is restricted to MHC I:CD8+ T cell-mediated immune responses.

**Materials and Methods**

**Materials Synthesis**

Chemicals used for the polymer and nanoparticle synthesis, 4-p-hydroxybenzoic acid, tri-ethylene-glycol, and 1,6-dibromohexane were obtained from Sigma Aldrich (St. Louis, MO); dimethylformamide, acetic acid, acetonitrile, acetic anhydride, toluene, methylene chloride, pentane were purchased from Fisher Scientific (Fairlawn, NJ) and 4-p-flourobenzonitrile was purchased from Apollo Scientific (Cheshire, UK).

**Polyanhydride Synthesis**

Monomers of CPTEG and CPH were synthesized and used in a 20:80 molar ratio to synthesize a 20:80 CPTEG:CPH copolymer via melt polycondensation reaction as previously described. The purity and molecular weight of the copolymer was characterized using 1H nuclear magnetic resonance spectroscopy in deuterated chloroform. The molecular weight of the copolymer was about 5.3 kDa, consistent with previous work.

**Nanoparticle Synthesis**

20:80 CPTEG:CPH nanoparticles encapsulating 5 wt.% Ova were synthesized using flash nanoprecipitation as
previously described. Briefly, a solution of 20:80 CPTEG:CPH and ovalbumin in methylene chloride at a concentration of 20 mg/mL was poured into pentane at a solvent to anti-solvent ratio of 1:250. The nanoparticles were then collected using vacuum filtration. The particle morphology and size were examined using scanning electron microscopy. The average particle size of nanoparticles used for these studies was about 200 nm.

Animals
Female BALB/c mice, aged six to eight weeks, were obtained from Charles River Laboratories (Wilmington, MA) for in vitro studies. Female C57BL/6 mice, aged six to eight weeks, were obtained from Charles River and Envigo (Somerset, NJ). Studies involving the use of mice were conducted in accordance with Iowa State University guidelines for the care and use of animals and upon approval of the Institutional Animal Care and Use Committee.

Cell Culture
The E.G7-OVA (ATCC, Manassas, VA) cell line was cultured and maintained in RPMI 1640 (Cat #10-040-CM, Corning) medium containing 2 mM L-glutamine 1.5 g/L sodium bicarbonate, 4.5 g/L glucose, 10 mM HEPES, 1 mM sodium pyruvate, 0.05 mM 2-mercaptoethanol, 0.4 mg/mL G418 (Cat #30-234-CI, Cellgro), 100 U/mL penicillin, 100 µg/mL streptomycin, and 10% fetal bovine serum. The EL4 (ATCC) cell line was culture and maintained in DMEM (Cat #15-013-CV, Corning) supplemented with 2 mM L-glutamine, 100 U/mL penicillin, 100 µg/mL streptomycin, and 10% horse serum.

Bone Marrow DC Generation
Naïve female BALB/c mice were used to generate BMDC cultures. Bone marrow was collected from femurs and tibias. Cells were washed and plated in RPMI 1640 medium supplemented with 100 U/mL penicillin and 100 µg/mL streptomycin, 2 mM glutamine, and 10% FBS in 100 mm petri plates, at a density of 4 x 10^6 bone marrow cells per plate with 10 mL of medium supplemented with GM-CSF (Peprotech, Rocky Hill, NJ) at 10 ng/mL. On day three of culture, 10 mL of GM-CSF containing medium was added. On days six and eight of culture, 10 mL of culture medium was exchanged for fresh GM-CSF containing medium. DCs were harvested on day 10 of culture by gently rinsing and collecting non-adherent cells.

Splenic DC Isolation
Naïve female BALB/c mice were euthanized to collect spleens. Spleens from eight to ten mice were harvested, pooled, and used to generate a population of single cells. Using these splenocytes, highly enriched populations of DCs were recovered using a pan-DC isolation kit (13–100-875) (Miltenyi Biotec, Auburn, CA) on an autoMACS Pro separator (Miltenyi Biotec) according to manufacturer’s protocol.

BMDC and sDC Stimulation
DCs were plated at 5 x 10^5 cells/well in a 96-well round bottom tissue culture plate in 200 µL of RPMI 1640 medium supplemented with 100 U/mL penicillin and 100 µg/mL streptomycin, 2 mM glutamine, and 10% FBS. The in vitro treatments consisted of 100 µg/well of 20:80 CPTEG:CPH NPs encapsulating 5 µg of Ova, 5 µg/mL of CpG ODN 1668 (Cat #16E17-MM InvivoGen) with 5 µg Ova, or medium alone (ie, control wells). After the addition of the stimulants, the BMDCs were incubated for 48 h after which supernatants and cells were harvested for cytokine analysis and cell surface marker expression by flow cytometry, respectively.

Nitric Oxide Quantification
Supernatants from stimulated DCs were analyzed for NO indirectly via nitrite concentration by Griess assay. A standard curve was created using two-fold dilutions of sodium nitrite ranging from 100 µM to 0 µM. One hundred microliters of supernatant was incubated with 100 µL of Griess reagents (Cat. No. 03553, Sigma-Aldrich) in a 96-well microtiter plate. Samples were incubated for 15 min at room temperature and read at 540 nm on a SpectraMAX 190 (Molecular Devices, Sunnyvale, CA).

Extracellular Flux Analysis
BMDCs from BALB/c mice were stimulated in RPMI 1640 medium supplemented with 100 U/mL penicillin and 100 µg/mL streptomycin, 2 mM glutamine, and 10% FBS for 18 h with 100 µg of 20:80 CPTEG:CPH encapsulating 5 µg of Ova, 5 µg/mL of CpG ODN with 5 µg Ova, or no stimulation control in 5 mL polypropylene tubes. Treated BMDCs were washed with Seahorse assay media consisting of Agilent Seahorse XF Base medium (Cat #102,353, Agilent, Santa Clara, CA) supplemented with 1 mM sodium pyruvate, 2 mM L-glutamine, and 10 mM glucose with a pH adjusted to
7.4, were seeded into 24-well seahorse plates coated with Cell-Tak (Corning, Corning NY) at a density of 2.5 x 10^5 cells per well. Metabolic phenotyping was conducted on a Seahorse XFe24 (Agilent). Mitochondrial function was analyzed via mitochondrial stress test according to manufacturer specifications. Final concentrations of 1 µM oligomycin, 2 µM FCCP, and 0.5 µM rotenone and antimycin were used (Agilent) and prepared in Seahorse assay medium.

**Vaccination**

Two antigen doses were evaluated in the in vivo studies. In the high antigen dose (2.0 mg Ova) studies, female C57BL/6 mice were vaccinated with formulations consisting of 250 µg Ova encapsulated in 5 mg of 20:80 CPTEG:CPH (5% loaded) plus 1.75 mg Ova soluble (NP), 2 mg soluble Ova (sOva), or unvaccinated control. In the prime-boost experiment, the mice were vaccinated with formulations consisting of 1.75 mg sOva along with 5 mg of 20:80 CPTEG:CPH polyanhydride nanoparticles encapsulating 250 µg Ova with and without a boost (NPx1, NPx2), 2 mg soluble Ova with 5 mg of blank 20:80 CPTEG:CPH polyanhydride nanoparticles (Blank NP x2), or PBS control. Mice that received a booster (indicated by x2) were given the same formulations at half the original dose of antigen and particle mass. In the low antigen dose (100 µg Ova) studies, mice were vaccinated with formulations consisting of 75 µg soluble Ova plus 500 µg of 20:80 CPTEG:CPH polyanhydride nanoparticles encapsulating 25 µg Ova (NP), 100 µg soluble Ova (sOva), or PBS control. In the multi-adjuvant experiment, mice received formulations consisting of 75 µg soluble Ova plus 500 µg of 20:80 CPTEG:CPH polyanhydride nanoparticles encapsulating 25 µg Ova (NP), 100 µg soluble Ova adjuvanted with 20 µg CpG ODN 1668 (CpG), a combination of 75 µg soluble Ova plus 500 µg of 20:80 CPTEG:CPH polyanhydride nanoparticles encapsulating 25 µg Ova adjuvanted with 20 µg CpG ODN (NP+CpG), or PBS control. All formulations were delivered subcutaneously at the nape of the neck.

**Tumor Challenge**

C57BL/6 mice were challenged subcutaneously on the flank with 2–5 x 10^6 E.G7 Ova-expressing lymphoma cells or 2.5 x 10^6 EL4 lymphoma cells that had been washed and suspended in PBS prior to implantation. Tumor growth was monitored three times a week and volumes were calculated by using the equation to determine the volume of an ellipsoid (see below). Mice were removed from study when tumor volume surpassed 1000 mm³. As mice did not succumb to the tumor and were removed based on the criteria of tumor volume, time on study is presented for survival analysis.

Tumor volume (V) = (4/3)π r₁r₂r₃.

**Cytokine and Chemokine Analysis**

Cytokine quantification was performed using supernatants from the previously described DC stimulations. A Millipore Milliplex cytokine/chemokine panel (MCYTOMAG-70K-32, Burlington, MA) was used to detect cytokines and analyzed on a Bio-Plex 200 System (Bio-Rad, Hercules, CA) according to manufacturer’s specifications.

**Flow Cytometry**

Splenic DCs and BMDCs were analyzed for costimulatory marker expression using flow cytometry. 5 x 10^5 DCs were aspirated from a 96-well plate and transferred to FACS tubes. Prior to labeling with specific monoclonal antibodies, Fc receptors on DCs were blocked to prevent nonspecific antibody binding by incubating the cells with 100 µg/mL of rat IgG (Sigma Aldrich) and 10 µg/mL of anti-CD16/32 (eBioscience, San Diego, CA). Subsequently, DCs were stained with fluorescently conjugated antibodies specific for CD80 (Biolegend, San Diego, CA, PerCP-Cy5.5, clone 16–10A1), CD86 (eBioscience, FITC, clone M5/114.15.2), and CD8 (Biolegend, APC-Cy7, clone 53–67) diluted in PBS containing 0.1% bovine serum albumin (BSA) and 0.1% sodium azide. Cells were fixed using BD stabilizing fixative (BD Bioscience, Franklin Lakes, NJ). Mitochondrial superoxide production was evaluated using live cells stained with MitoSOX Red (Cat # M36008, Invitrogen, Carlsbad, CA) according to manufacturer’s specifications. All data were collected on a FACS Canto II (BD Bioscience, Franklin Lakes, NJ). Data were analyzed using FlowJo (FlowJo LLC, Ashland, OR).

**Antibody Responses**

Where applicable, immunized mice were bled via saphenous vein 5 weeks post-immunization. Anti-Ova serum IgG titers were measured via indirect ELISA. Costar
3590 96-well EIA/RIA high binding plates (Corning) were coated with 100 µL of Ova (5 µg/mL PBS) or PA (0.5 µg/mL PBS) and incubated overnight at 4°C. Plates were blocked using 2.5% (w/v) powdered skim milk PBS containing 0.05% Tween-20 (PBS-T), that has been heat inactivated at 56°C for hours to inactivate any phosphatase activity, for two hours at room temperature. After three washes using PBS-T, serum samples were titrated across the plate using two-fold serial dilutions, starting at 1:100, in PBS-T and 1% (v/v) normal goat serum. Samples were incubated overnight at 4°C. After three washes in PBS-T, an alkaline phosphatase-conjugated goat anti-mouse IgG (H+L) secondary detection antibody (Cat# 115-005-003, Jackson ImmunoResearch, West Grove, PA) was diluted 1:1000 in PBS-T and added to the wells and allowed to incubate at room temperature for two hours. Plates were washed three times with PBS-T and alkaline phosphatase substrate was added at 1 mg/mL in buffer containing 50 mM sodium carbonate, 2 mM magnesium chloride, and sodium bicarbonate was titrated into the solution in order to achieve a pH of 9.3. Plates were allowed to develop for 30 min and analyzed using the SpectraMAX 190 at a wavelength of 405 nm.

Statistical Analysis
Data generated during flow cytometry assays, metabolic assays, and Griess assays were analyzed via one-way ANOVA with a Tukey, Dunnet, or Sidak post-test for multiple comparisons. Survival data were analyzed using a Log rank (Mantel-Cox) test with a Bonferroni correction for multiple comparisons. All analyses were performed using GraphPad Prism 8.0 (GraphPad Software, La Jolla, CA).

Results
High Antigen Dose Polyhnydride Nanoparticle vaccination Reduced Tumor Burden and Increased Time on Study
Previous studies from our laboratories have shown that immunization with a high dose (ie, 2 mg) of Ova in a polyhnydride particle-based vaccine regimen induced OTI CD8+ T cell memory and the ability of these CD8+ T cells to expand upon reencounter with antigen.27 Herein, the ability of polyhnydride nanoparticles to induce efficacious endogenous antigen-specific CD8+ T cell memory and subsequent effector expansion upon challenge was evaluated using a tumor challenge model, where antigen-specific protection is restricted to CD8+ T cell:MHCI recognition. C57BL/6 mice were vaccinated prophylactically with high antigen dose (2.0 mg Ova) formulations consisting of polyhnydride nanoparticles (NP) (characterization data of the NPs are shown in Supplemental Figure 1), sOva alone, or a PBS control. Six weeks later, mice were challenged subcutaneously by implanting Ova-expressing E. G7 tumor cells or EL4 tumor cells (ie, do not express Ova), and tumor progression was tracked. Vaccination with the NP formulation reduced tumor progression in comparison to naive mice and mice immunized with the sOva alone (Figure 1A). NP vaccination also significantly improved time on study (ie, % of mice with tumors <1000 mm3) compared to control animals (Figure 1C). No significant improvements in survival were observed for mice receiving sOva alone compared to controls.

To determine whether antigen-specific immune activation was responsible for the observed anti-tumor responses, another set of mice was challenged with the EL4 parent tumor that does not express Ova (Figure 1B and D). Neither the NP formulation nor sOva significantly improved time on study after subsequent tumor challenge (Figure 1B and D). Together, these data demonstrate that the NP formulation is able to induce efficacious antigen-specific, memory CD8+ T cells capable of responding to re-exposure to antigen (ie, tumor implantation).

Encapsulation of Antigen in Polyhnydride NPs is Critical for Inducing Optimal CD8+ T Cell Memory
Even though the high antigen dose (2.0 mg Ova) vaccine formulation contained a large amount of unencapsulated soluble antigen (1.75 mg), we hypothesized that the portion of antigen encapsulated within the polyhnydride NPs would be more important to the induction of CD8+ T cell memory than the soluble bolus. This hypothesis was tested by vaccinating C57BL/6 mice with a single-dose NP formulation, a prime-boost of the same NP formulation, a prime-boost of blank NPs with no encapsulated antigen (ie, soluble Ova only), or injecting PBS alone (ie, control). Six weeks after their last immunization, all mice were challenged subcutaneously with the Ova-expressing E.G7 tumor, and the tumor progression and time on study for each treatment compared (Figure 2A and B). The only treatments that significantly inhibited tumor progression compared to PBS injections were the single-dose NP (NP x1) and the prime-boost NP (NP x2) regimens. Mice immunized twice with blank NPs (x2) plus sOva tended to have an
improved median survival time compared to naïve control mice; however, this difference was not significant.

Polyanhydride NPs Upregulated Co-Stimulatory Molecule Expression on DCs but Resulted in Low Levels of Inflammatory Cytokine and Chemokine Production

Previous work on polyanhydride particle formulations illustrated that bone marrow-derived dendritic cells (BMDCs) readily take up and respond to these particles by upregulating co-stimulatory molecules and cytokine secretion similar to other pathogen-mimicking moieties. The low inflammatory response induced by polyanhydride NP vaccines is similar to that induced by DC-based vaccines that support the induction of CD8+ T cell memory.

Herein, the ability of the 20:80 CPTEG:CPH polyanhydride NP formulation to activate BMDC was compared to the effects of CpG ODN. After 48 h of in vitro stimulation with NPs or CpG ODN, BMDCs significantly (P < 0.05) upregulated the co-stimulatory molecules CD86 and CD40 as compared to non-stimulated BMDCs (Figure 3A).

Superantigens from stimulated BMDCs were also evaluated for induction of inflammatory cytokine and chemokine production. Other than MIP2, CXCL1 (KC), and IL-6, the NP formulation induced secretion of markedly less inflammatory cytokines when compared to that induced by CpG ODN (Supplemental Figure 2).

Dendritic cell populations isolated from the spleens of naïve mice were also evaluated for their response to stimulation. Splenic DCs (sDC) were stimulated with either the NP
formulation or CpG ODN for 48 h. The CD11c+ population of the sDC was evaluated for upregulation of the costimulatory molecules CD86 and CD40 (a gating diagram is shown in Supplemental Figure 3). The NP formulation upregulated CD86 and CD40 expression while CpG ODN only upregulated CD40 as compared to non-stimulated sDC (Figure 3B). The CD8α+ subpopulation of sDC has been previously reported to cross-prime CD8+ T cells.4,30–32 To determine

Figure 2 Encapsulated antigen is crucial to induce antigen-specific CD8+ T cell memory. C57BL/6 female mice were immunized subcutaneously at the base of the neck with formulations consisting of 1.75 mg soluble Ova with 5 mg of 20:80 CPTEG:CPH polyanhydride nanoparticles encapsulating 250 μg Ova with (NP x2) and without a boost (NP x1) (n=16); 2 mg soluble Ova with 5 mg of blank 20:80 CPTEG:CPH polyanhydride nanoparticles (Blank NP x2) (n=8); or PBS control (n=16). Mice that received a booster (NP x2) were given the same formulations at half the original dose subcutaneously at the base of the neck 28 days after the primary immunization. Mice were challenged subcutaneously in the flank with E.G7 Ova-expressing tumor cells 42 days after the primary or boost immunization, respectively. (A) Tumor volume of individual mice was tracked. (B) Survival was evaluated 31 days post-challenge. Statistical significance was determined using a Log rank (Mantel-Cox) test with a Bonferroni correction for multiple (6) comparisons. Significance from naïve control group is indicated in the treatment group legend as *p ≤ 0.0083. Median survival of each group is also reported parenthetically. (C) Diagram of vaccination schedule. 1° = primary vaccination, 2° = primary vaccination, following which all mice received an injection of E.G7 tumor cells as described in Materials and Methods.
whether NP stimulation activated CD8α+ sDC, we measured co-stimulatory marker expression on CD8α+ sDC. CpG ODN induced only a moderate upregulation of co-stimulatory molecules on CD8α+ sDC; however, NP stimulation induced a marked increase in the expression of CD86, CD80, and CD40 (Figure 3C). These findings suggest that NPs are capable of activating a critically important DC sub-type involved in the presentation of antigen to and activation of CD8+ T cells. Supernatants from the total population of stimulated sDC were also evaluated for cytokine production via a multiplex assay. As observed for the BMDCs, a lower magnitude of inflammatory cytokine and chemokine responses were observed for NP stimulated sDC compared to those induced by CpG ODN (Supplemental Figure 4).

Polyanhydride Nanoparticles Activate BMDCs Without Inducing Innate Effector Molecules or Altering Cellular Metabolism

Upon natural infection or after stimulation with TLR ligands such as CpG ODN, activated APCs produce innate effector molecules such as NO or reactive oxygen species (ROS). Although these molecules provide critical microbicidal activity during acute infections, NO and ROS can also have inhibitory effects on innate and adaptive immune responses. After 48 h of in vitro stimulation, NO production by BMDC was measured indirectly by assessing nitrite content in culture supernatants. Unlike CpG ODN, which induced high concentrations of NO, stimulation of BMDCs with polyanhydride NPs did not induce significant amounts of NO (Figure 4A). Lower concentrations of mitochondrial superoxide (mROS) were also observed following NP stimulation compared to CpG ODN treatment (Supplemental Figure 5).

After encountering TLR ligands, murine BMDCs exhibit a profound metabolic shift away from mitochondrial oxidative phosphorylation and towards sustained aerobic glycolysis. This extended commitment to aerobic glycolysis is a consequence of the concentration of the innate effector molecule NO. In this context, it must be noted that NO plays an important antimicrobial role during acute infections and in response to TLR-stimulation. Because polyanhydride nanoparticles were observed to activate BMDCs without inducing NO, it was hypothesized that NP stimulation would result in a BMDC activation phenotype that maintained functional mitochondria. After an 18-hour stimulation with NP or CpG, a mitochondrial stress test (MST) was performed on BMDCs and revealed marked differences in metabolic states. CpG ODN stimulation resulted in the expected inhibition of ATP production, loss of spare respiratory capacity, and increased proton leak (Figure 4B and C). In contrast, NP stimulation of BMDCs resulted in an overall maintenance of mitochondrial functionality resembling that of non-stimulated BMDCs (Figures 4B and C). During the MST, the extracellular acidification rate (ECAR) was also measured as an indicator of glycolysis. As expected, the CpG ODN stimulated BMDCs exhibited an elevated glycolytic rate while NP stimulated cells did not (Supplemental Figure 6). Together, these results demonstrate that polyanhydride nanoparticles, while inducing effective DC activation, induced a distinctly less overt activation phenotype that avoid excessive production of innate effector molecules (eg, NO).
Low Antigen Dose Polyanhydride Nanovaccine Reduced Tumor Burden and Increased Time on Study

Although high doses of antigen and polyanhydride nanoparticles were effective at inducing CD8+ T cell memory upon vaccination, experiments were designed to determine whether lower doses of both Ova and polymer particles could also induce an efficacious immune response. A lower dose of Ova (100 µg) and nanoparticles (500 µg) were administered to mice and the induction of antigen-specific CD8+ T memory was evaluated. C57BL/6 mice were vaccinated prophylactically with formulations consisting of the polyanhydride nanoparticles (NP-Ova), sOva alone, or a PBS control. Six weeks later, mice were challenged subcutaneously with Ova-expressing E.G7 tumor cells and the progression of tumor volume monitored (Figure 5A). The number of mice remaining on the study was evaluated at 30 days post-challenge and only mice immunized with the NP formulation experienced a significant increase in survival compared to the non-vaccinated controls and mice receiving sOva alone (Figure 5B). Together, these results demonstrate that a lower dose NP vaccine regimen had comparable effectiveness as the high dose regimen with respect to the induction of an efficacious immune response.

Polyanhydride NPs Provided a More Efficacious Induction of CD8+ T Cell Memory Upon Vaccination Compared to CpG ODN

As previous work described overt CpG-induced inflammatory activation of APCs that diverted CD8+ T cell fate towards effector versus memory phenotypes, the observed low magnitude pro-inflammatory responses induced by polyanhydride NPs on DCs may lead to improved recall responses to challenge.5,7 This led to the hypothesis that the magnitude and/or consequences of inflammation induced by different adjuvants would alter the efficacy of the ensuing immune response. This hypothesis was tested by subcutaneously immunizing C57BL/6 mice with vaccine formulations containing a low dose of Ova (100 µg) as described above: NP, CpG ODN, NP + CpG ODN, or a naïve PBS only control. After implantation of the EG.7 cells, tumor volumes were tracked (Figure 6A) and time on study was compared (Figure 6B). Anti-Ova antibody titers were also evaluated to ensure that mice were effectively vaccinated (Supplemental Figure 7). At 30 days post-tumor challenge, time on study was significantly improved for mice immunized with either the NP + Ova formulation or the combination NP + CpG ODN + Ova formulation compared to unvaccinated control (Figure 6B). Vaccination with CpG ODN + Ova lead to no improvement in survival time compared to unvaccinated controls. These results suggest that polyanhydride nanovaccines containing encapsulated antigen are able to initiate effective T cell memory on their own as well as when co-administered with the pro-inflammatory TLR agonist CpG ODN.

Discussion

In this work, the ability of a polyanhydride nanovaccine to induce CD8+ T cell memory was investigated. Polyanhydride nanoparticles, encapsulating Ova, enhanced the development of antigen-specific CD8+ T cell memory upon vaccination. The induction of this antigen-specific response occurred without inducing the overt inflammatory responses commonly associated with the use of microbial-associated molecular patterns (MAMPs) that stimulate immune cells via pattern recognition receptors such as...
as TLRs. Direct in vivo comparison between the TLR agonist CpG ODN and the polyanhydride nanoparticle formulation illustrates the relative benefits of a low inflammatory vaccine adjuvant formulation on the resulting CD8+ T cell immune response.

Previously, inclusion of a TLR agonist in the nanoparticle vaccine formulation negatively affected the ability of 20:80 CPTEG:CPH polyanhydride NPs to induce an immune response that inhibited tumor progression. Inflammatory adjuvants, while effective at enhancing antibody production and expansion of terminally differentiated effector CD8+ T cells, often fail to induce optimal T cell memory populations among other less than optimal outcomes. Vaccination strategies that rapidly induce high numbers of CD8+ T cell memory, such as DC vaccination or antigen-coated particle formulations, share an important quality. The common feature of these strategies is that they induce CD8+ T cell memory more effectively when the antigen is delivered in the absence of overt inflammation (eg, DC-based vaccines). One component of the overt inflammatory responses induced by pathogens or TLR-based adjuvants is the production of microbicidal innate immune effector molecules such as NO. Although NO is important for the innate immune response to overcome acute pathogenic infections, it has negative autocrine or paracrine effects on APCs. When NO is produced by BMDCs, it inhibits the electron transport chain (ie, oxidative phosphorylation) leading to a dependence on aerobic glycolysis for ATP production and cellular survival. This sustained dependence on aerobic glycolysis, while not necessary for activation, has been described to provide the necessary energy demands for BMDC survival when stimulated via a TLR agonist. Previous studies have also indicated that mitochondrial functional deficiencies are associated with suboptimal antigen processing and presentation by APCs. Compressed stimulation of DCs by TLR ligands, the low inflammatory activation phenotype of DCs following polyanhydride particle stimulation likely contributed to the enhanced anti-tumor immune response demonstrated in these studies.

Figure 5 Polyanhydride nanoparticles induce CD8+ T cell memory with a low antigen dose. C57BL/6 female mice were immunized subcutaneously with formulations consisting of 75 μg soluble Ova plus 500 μg of 20:80 CPTEG:CPH polyanhydride nanoparticles encapsulating 25 μg Ova (NP) (n=12); 100 μg soluble Ova alone (sOva) (n=11); or PBS control (n=12). Mice were challenged subcutaneously in the flank with E.G7 Ova-expressing tumor cells 42 days post-immunization and (A) tumor volume of individual mice was tracked. (B) Survival was evaluated 30 days post-challenge. Significance from PBS control was determined using a Log rank (Mantel-Cox) test with a Bonferroni correction for multiple (2) comparisons. Significance from naïve control group is indicated in the treatment group legend as follows *p ≤ 0.025. Median survival of each group is also indicated parenthetically.
Previous intervention strategies targeting the inflammatory response to enhance CD8\(^+\) T cell memory have focused on interfering with chemokine actions and chemokine effects on lymphocytes.\(^{56-59}\) Other strategies have inhibited the expansion of effector cells at strategic time-points after immunization, such as dosing with the mTOR inhibitor rapamycin to interfere with the metabolic requirements of expanding effector cells in order to shift differentiation toward memory development.\(^{52,60,61}\)

Although these approaches have positively affected DC activation and memory CD8\(^+\) T cell induction, the systemic effects of using these inhibitors may have unintended consequences. Reducing the magnitude of the inflammatory response associated with vaccine adjuvants may be able to provide many of these same benefits without the necessary post-vaccination intervention with inhibitors such as rapamycin. Together, these studies along with the current observations suggest that induction of effective adaptive immune memory following vaccination can be induced using adjuvant formulations that provide optimal innate activation of APCs with a “just-right” amount of inflammation.\(^{62}\)

Polyanhydride nanoparticle adjuvants have been shown to be endocytosed by APCs, provide innate immune
activation, and induce co-stimulatory molecule upregulation. These stimulatory capabilities of polyanhydride nanoparticles have contributed to the successful generation of long-lived protective antibody responses to various encapsulated protein antigens.\textsuperscript{15,17,63–65}\textsuperscript{*} In the present work, it was shown that a 20:80 CPTEG:CPH polyanhydride nanoparticle formulation induced antigen-specific CD8\textsuperscript{+} T cell memory capable of providing protection against a tumor challenge distant from the vaccination site at both high (Figure 1) and low dosages of antigen (Figure 5). This immune-enhancing effect was associated with the ability to activate DCs, particularly the CD8\textsuperscript{α+} subpopulation of DCs associated with cross-priming CD8\textsuperscript{+} T cells (Figure 3). Such activation was accomplished in the absence of deleterious vaccination site inflammation, which can lead to dysfunctional CD8\textsuperscript{+} T cell trafficking and effector functions. Further, it was demonstrated that the delivery of empty nanoparticles with soluble antigen did not provide the same benefits as particulate formulations including encapsulated antigen. This finding suggests that there is a critical role for antigen encapsulation in the capability of polyanhydride NP formulations to induce CD8\textsuperscript{+} T cell memory (Figure 2). The benefits of antigen encapsulation with a single-dose regimen that provide comparable results of prime-boost formulations were also described (Figure 2). Direct in vivo comparison of polyanhydride nanoparticles with the TLR agonist CpG ODN, illustrates the effectiveness of the low inflammatory nature at work to provide significantly greater survival and decreased tumor burden while the CD8\textsuperscript{+} T cell memory induced by CpG ODN vaccination failed to do so (Figure 6). Related to its phlogistic potential, the addition of CpG ODN to vaccine formulations has been shown to limit the effectiveness of the polyanhydride nanovaccine administered by the parenteral route.\textsuperscript{4,7,20} This suggests that the nature of the innate inflammatory phenotype induced by a vaccine plays a key role in the outcome of CD8\textsuperscript{+} T cell response. It is also of note that, in this study, the addition of CpG ODN to the polyanhydride nanoparticle formulation did not have any inhibitory impact. This observation suggests that the encapsulation of antigen and persistence of the polyanhydride particles allows the host to overcome the apparent negative impact of the acute inflammatory response induced by CpG ODN at the time of immunization (Figure 6).

In conclusion, these results indicate that the beneficial effects of polyanhydride nanoparticles arise, in part, from their ability to activate DCs and upregulate costimulatory molecule expression without overt induction of inflammatory cytokines, chemokines, and effector molecules (eg, NO) that are often associated with a pathogenic infection or TLR ligand administration. The use of adjuvants that closely mimic the immunological activation similar to that of a natural infection has been successful in generating protective antibody mediated immunity, but many of these adjuvants induce relatively poor CD8\textsuperscript{+} T cell responses. By virtue of their low inflammatory activation properties (ie, selectively pathogen mimicking), the use of polyanhydride nanovaccines is emerging as a strategy to more effectively generate CD8\textsuperscript{+} T cell memory through the absence of adverse innate inflammatory effects.

\section*{Abbreviations}

APC, antigen-presenting cell; BMDC, bone marrow-derived dendritic cell; CMI, cell-mediated immunity; CPH, 1,6-bis (p-carboxyphenoxo) hexane; CPTEG, 1.8-bis(p-carboxyphenoxo)-3,6-dioxaoctante; DC, dendritic cell; ECAR, extracellular acidification rate; mROS, mitochondrial reactive oxygen species; MST, mitochondrial stress test; NO, nitric oxide; NP, nanoparticle; OCR, oxygen consumption rate; ODN, oligodeoxynucleotide; Ova, ovalbumin; ROS, reactive oxygen species; sOva, soluble ovalbumin; TLR, Toll-like receptor.
