Abstract

A rectifier network is a directed acyclic graph with distinguished sources and sinks; it is said to compute a Boolean matrix $M$ that has a 1 in the entry $(i,j)$ iff there is a path from the $j$th source to the $i$th sink. The smallest number of edges in a rectifier network that computes $M$ is a classic complexity measure on matrices, which has been studied for more than half a century.

We explore two well-known techniques that have hitherto found little to no applications in this theory. Both of them build upon a basic fact that depth-2 rectifier networks are essentially weighted coverings of Boolean matrices with rectangles. We obtain new results by using fractional and greedy coverings (defined in the standard way).

First, we show that all fractional coverings of the so-called full triangular matrix have cost at least $n \log n$. This provides (a fortiori) a new proof of the tight lower bound on its depth-2 complexity (the exact value has been known since 1965, but previous proofs are based on different arguments). Second, we show that the greedy heuristic is instrumental in tightening the upper bound on the depth-2 complexity of the Kneser-Sierpiński (disjointness) matrix. The previous upper bound is $O(n^{1.28})$, and we improve it to $O(n^{1.17})$, while the best known lower bound is $\Omega(n^{1.16})$. Third, using fractional coverings, we obtain a form of direct product theorem that gives a lower bound on unbounded-depth complexity of Kronecker (tensor) products of matrices. In this case, the greedy heuristic shows (by an argument due to Lovász) that our result is only a logarithmic factor away from the “full” direct product theorem. Our second and third results constitute progress on open problem 7.3 and resolve, up to a logarithmic factor, open problem 7.5 from a recent book by Jukna and Sergeev (in Foundations and Trends in Theoretical Computer Science (2013)).

1 Introduction

Introduced in the 1950s, rectifier networks are one of the oldest and most basic models in the theory of computing. They are directed acyclic graphs with distinguished input and output nodes; a rectifier network is said to compute (or express) the Boolean matrix $M$ that has a 1 in the entry $(i,j)$ iff there is a path from the $j$th input to the $i$th output. Equivalently, rectifier networks can be viewed as Boolean circuits that consist entirely of OR gates of arbitrary fan-in. This simple model of computation has attracted a lot of attention [16], because it captures the “topological” core of other models: complexity bounds for rectifier networks extend in one way or another to Boolean circuits (i.e., circuits with Boolean gates) and to switching circuits [31, 27].

Given a matrix $M$, what is the smallest number of edges in a rectifier network that computes $M$? Denote this number by OR($M$)—this is a complexity measure on Boolean
matrices. This measure is fairly well understood: we know, from Nechiporuk [30], that the maximum of \( \text{OR}(M) \) grows as \( n^2/2 \log n \) as \( n \to \infty \) if \( M \) is \( n \times n \); we also know that random \( n \times n \)-matrices have complexity very close to \( n^2/2 \log n \). The “shape” of these two facts is reminiscent of the standard circuit complexity of Boolean functions over AND, OR, and NOT gates—but for them, the maximum is \( 2^n/n \) instead of \( n^2/2 \log n \).

However, much more is known about the measure \( \text{OR}(\cdot) \): there are explicit sequences of matrices that have complexity \( n^{2-o(1)} \), close to the maximum (in contrast, for circuits over AND, OR, and NOT gates, exhibiting a single sequence of functions that require a superlinear number of gates would be a tremendous breakthrough). In fact, nowadays a range of methods are available for obtaining upper and lower bounds on \( \text{OR}(M) \) for specific matrices \( M \); we refer the interested reader to the recent book by Jukna and Sergeev [16].

Many natural questions, however, remain open. Jukna and Sergeev list 19 open problems about \( \text{OR}(\cdot) \) and related complexity measures. Several of them refer to very restricted submodels, such as rectifier networks of depth 2: that is, networks where all paths contain (at most) 2 edges. A depth-2 rectifier network expressing a matrix \( M \) is essentially a covering of \( M \)—a collection of (rectangular) all-1 submatrices of \( M \) whose disjunction is \( M \). In our work, we look into the corresponding complexity measure \( \text{OR}_2(\cdot) \) as well as \( \text{OR}(\cdot) \). We build upon the connection between rectifier networks and (weighted) set coverings and explore two well-known ideas that have previously found few applications in the study of rectifier networks: they are associated with fractional and greedy coverings respectively.

**Fractional coverings** are a generalization of usual set coverings. In the usual set cover problem, each set \( S \) can be either included or not included in the solution (i.e., in the covering); in the fractional version each set can be partially included: a solution assigns to each set \( S \) a real number \( x_S \in [0;1] \), and for every element \( s \) of the universe the sum \( \sum_{S \in \mathcal{S}} x_S \) should be equal to or exceed 1. In other words, fractional coverings arise from linear relaxation of the integer program that expresses the set cover problem. **Greedy coverings** are, in contrast, usual coverings; they are the outcome of applying the standard greedy heuristic to an instance of the set cover problem: at each step, the algorithm picks a set \( S \) that covers the largest number of yet uncovered elements \( s \). In our work, we use fractional and greedy coverings to obtain estimates on the values of \( \text{OR}_2(M) \) and \( \text{OR}(M) \).

**Our results**

First, we demonstrate that \( \text{OR}_2(T_n) = n(\lceil \log_2 n \rceil + 2) - 2\lceil \log_2 n \rceil + 1 \), where \( T_n \) is the so-called full triangular matrix: an upper-triangular matrix that has 1s everywhere above the main diagonal and 0s on the diagonal and below. In this problem, the upper bound is easy and the challenge is to prove the lower bound. This was previously done by Krichevskii [20], and our paper provides a different proof of independent interest. In fact, we prove a stronger statement: all fractional coverings of \( T_n \) have large associated cost (Theorem 4). To this end, we take the linear program that expresses the fractional set cover problem and find a good feasible solution to the dual program. The value of this solution then gives a lower bound on the cost of all feasible solutions to the primal—that is, on the cost of fractional coverings. Since integral coverings are just a special case of fractional coverings, the result follows.

Second, we improve the upper bound on the value of \( \text{OR}_2(D_n) \), where \( D_n \) is the disjointness matrix, also known as the Kneser-Sierpiński matrix. This constitutes progress on open problem 7.3 in Jukna and Sergeev’s book [16], where the previously known bounds are obtained. The previous upper bound is \( O(n^{1.28}) \), and our Theorem 5 improves it to \( O(n^{1.17}) \), while the best known lower bound is \( \Omega(n^{1.16}) \). To achieve this improvement, we subdivide the instance of the weighted set cover problem (in which the optimal value is \( \text{OR}_2(D_n) \)) into
polylog(n) natural subproblems and reduce them, by imposing an additional restriction, to instances of unweighted set cover problems. We then solve these instances with the greedy heuristic; the upper bound in the analysis invokes the so-called greedy covering lemma by Saporozhenko [33], also known as the Lovász–Stein theorem [23, 38]. This gives us the desired upper bound on OR₂(Dₙ); in fact, the greedy strategy turns out to be optimal, and the optimal exponent in OR₂(Dₙ) comes from a numerical optimization problem. As an intermediate result we determine, up to a polylogarithmic factor, the value of OR₂(Dₖⁿ) where Dₖⁿ is the adjacency matrix of the Kneser graph on 2ₖ vertices.

Finally, we obtain (Theorem 13) a form of direct product theorem for the OR(·) measure: OR(K ⊗ M) ≥ rk*(K) · OR(M). Here K ⊗ M denotes the Kronecker product of matrices K and M, and rk*(K) is a fractional analogue of the Boolean rank of K. This resolves, up to a logarithmic factor, open problem 7.5 in the list of Jukna and Sergeev [16]; our technique applies to this model as well, giving an analogous inequality for the measure SUM(·), see Corollary [15]. Suppose K is an m × n matrix; then, by the argument due to Lovász [24], the greedy heuristic shows that rk*(K) ≥ rk*(K)/(1 + log mn), so our lower bound is indeed at most a logarithmic factor away from the “full” direct product theorem. To prove our lower bound, we take the linear programming formulation of the fractional set cover problem for the matrix K and use components of the optimal solution to the dual program to guide our argument. It is interesting to see how reasoning about coverings, or, equivalently, about depth-2 rectifier networks, enables us to obtain meaningful lower bounds on the size of rectifier networks that have unbounded depth.

2 Discussion and related work

We use the matrix language in this paper, but all results can be restated in terms of biclique coverings of bipartite graphs.

The OR₂-complexity of full triangular matrices, Tₙ, is tightly related to results on biclique coverings of complete undirected (non-bipartite) graphs from the early days of the theory of computing. The n log n lower bound, in one form or another, was known to Hansel [10], Krichevskii [20], Katona and Szemerédi [19], and Tarján [39]. Apart from purely combinatorial considerations, the interest in this problem is motivated by its applications in formula and switching-circuit complexity of the Boolean threshold-2 function (which takes on the value 1 if and only if at least two of its inputs are set to 1). For more context, see treatments by Radhakrishnan [33] and Lozhkin [26]. Our lower bound is obtained in a slightly more restrictive setting, because of explicit asymmetry: for OR₂(Tₙ), one needs to cover entries (i,j) with i < j in the matrix; in biclique coverings of undirected graphs, it suffices to cover either of (i,j) and (j,i). Nevertheless, to the best of our knowledge, ours is the only proof that goes via linear programming (LP) duality and provides a tight lower bound on the size of fractional coverings. This result is new; we are not aware of other lower bounds for rectifier networks that come from feasible solutions to the LP dual (in approximation algorithms, a related technique is known under the name of “dual fitting” [44, Section 9.4]).

As for the greedy heuristics, we are not the first to use them in the context of depth-2 rectifier networks. Andreev [11] obtained a tight worst-case upper bound for a class of matrices potentially containing “wildcard” entries (*). This upper bound is in terms of the number of

1 Not all of these arguments compute the exact value of OR₂(Tₙ).
Fractional coverings, greedy coverings, and rectifier networks

occurrences of 0s and 1s, provided that these numbers satisfy certain conditions as the matrix size tends to infinity. Our Theorem \[8\] however, does not follow from Andreev’s worst-case bound. The disjointness matrix, \( D_n \), which we apply this technique to, is a well-studied object in communication complexity \[21\]; it is a discrete version of the Sierpiński triangle. Boyar and Find \[2\] and Selseneva \[35\] proved that \( \text{OR}(D_n) = \Theta(n \log n) \) and \( \text{SUM}(D_n) = \frac{1}{2} n \log n \). In depth 2, the previous bounds are due to Jukna and Sergeev \[10\]; it is unknown if greedy heuristics are also of use for SUM-circuits, as their upper bound for \( D_n \) does not extend to this model (our coverings are not partitions).

Direct sum and direct product theorems in the theory of computing are statements of the following form: when faced with several instances of the same problem on different independent inputs, there is no better strategy than solving each instance independently. For rectifier networks, these questions are associated with the complexity of Kronecker (tensor) products of matrices. Indeed, denote the words have length two, within a factor of 3. In some contexts, the terms “direct sum theorem” and “direct product theorem” have slightly different meanings \[36\], but in the current context we do not distinguish between them.
Appendix for details. At the same time, the circuit computes a linear operator over the monoid viewed as a circuit: its Boolean inputs are located at the vertices in a collection instead of their total cost. The smallest size of a covering of every rectangle, where the graph $G_N = (V, E)$ is acyclic, and in: $\{1, \ldots, n\} \to V$ and out: $\{1, \ldots, m\} \to V$ are injective functions whose images contain only sources (and, respectively, only sinks) of $G_N$. The network $N$ is said to have size $|E|$.

A rectifier network $N$ expresses a Boolean $m \times n$ matrix $M = M(N)$ such that $M_{ij} = 1$ if $G_N$ contains a directed path from in$(j)$ to out$(i)$ and $M_{ij} = 0$ otherwise. A rectifier network $N$ is said to have depth $d$ if all maximal paths in $G_N$ have exactly $d$ edges. Given a Boolean matrix $A \in \{0, 1\}^{m \times n}$, let OR$_2(A)$ denote the smallest size of a depth-$2$ rectifier network that expresses $A$ and let OR$(A)$ denote the smallest size of any rectifier network that expresses $A$.

This notation is justified by the following observation. A rectifier network $N$ may be viewed as a circuit: its Boolean inputs are located at the vertices in$(\{1, \ldots, n\})$, and gates at all other vertices compute the disjunction (Boolean OR) of their inputs. From this point of view, the circuit computes a linear operator over the monoid $(\{0, 1\}, \text{OR})$, and the matrix of this linear operator is exactly the Boolean matrix expressed by the rectifier network $N$.

\begin{itemize}
  \item **Example 1.** A depth-$3$ rectifier network is shown in Figure 1a. It expresses the matrix $B$ in Figure 1b, showing that OR$_3(B) \leq 19$. In fact, this network is optimal and OR$_3(B) = 19$; see Appendix for details. At the same time, OR$_2(B) = 20$: the upper bound is achieved by the network in Figure 1c and the lower bound is due to Jukna and Sergeev [10, Theorem 3.18].
\end{itemize}

### Coverings of Boolean matrices

Let us describe an alternative way of defining the function OR$_2(\cdot)$. Given a Boolean matrix $A$, a rectangle (or a 1-rectangle) is a pair $(R, C)$, where $R \subseteq \{1, \ldots, m\}$ and $C \subseteq \{1, \ldots, n\}$, such that for all $(i, j) \in R \times C$ we have $A_{ij} = 1$. A rectangle $(R, C)$ is said to cover all pairs $(i, j) \in R \times C$. The cost of a rectangle $(R, C)$ is defined as $|R| + |C|$.

Suppose a matrix $A$ is fixed; then a collection of rectangles is called a covering of $A$ if for every $(i, j) \in \{1, \ldots, m\} \times \{1, \ldots, n\}$ there exists a rectangle in the collection that covers $(i, j)$. The cost of a collection is the sum of costs of all its rectangles.

Given a Boolean matrix $A \in \{0, 1\}^{m \times n}$, the cost of $A$ is defined as the smallest cost of a covering of $A$. It is not difficult to show that the cost of $A$ equals OR$_2(A)$ as defined above.

Similarly, we can think of minimizing the size of a covering, i.e., the number of rectangles in a collection instead of their total cost. The smallest size of a covering of $A$ is called the OR-rank (or the Boolean rank) of $A$, denoted $rk_\vee A$. 

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{rectifier_networks}
\caption{Illustrations for Example 1.}
\end{figure}
The set cover problem can easily be recast as an integer program: see Figure 2a. For each $x$ variable, the value in the program is the smallest weight of a covering. The following lemma summarizes the properties of these programs needed for the sequel.

**Lemma 2.** If $(y_u)_{u \in U}$ is a feasible solution to the dual, then $\sum_{u \in U} y_u \leq \tau^* \leq \tau$. There exists a feasible solution to the dual, $(y^*_u)_{u \in U}$, such that $\sum_{u \in U} y^*_u = \tau^*$.

The proof can be found in, e.g., [17]. We use the first part of Lemma 2 in Section 5 to obtain a lower bound on $\tau$, and the second part in Section 7 to associate “weights” with 1-elements in the matrix.
Greedy coverings

The greedy heuristic for the unweighted set cover problem works as follows. It maintains the set of uncovered elements, initially \( U \), and iteratively adds to \( F' \) (which is initially empty) a set \( S \in F \) which covers the largest number of yet-uncovered elements. Any covering obtained by this (nondeterministic) procedure is called a greedy covering. (There is a natural extension to the weighted version as well.)

A standard analysis of the greedy heuristic is performed in the framework of approximation algorithms: the size of a greedy covering is at most \( O(\log |U|) \) times larger than that of the optimal covering [4, 24]. But for our purposes a different upper bound will be more convenient: an “absolute” upper bound in terms of the “density” of the instance. Such a bound is given by the following result, which is substantially less well-known:

▶ Lemma 3 (greedy covering lemma). Suppose every element \( s \in U \) is contained in at least \( \gamma |F| \) sets from \( F \), where \( 0 < \gamma \leq 1 \). Then the size of any greedy covering does not exceed

\[
\left\lceil \frac{1}{\gamma} \ln^+(\gamma |U|) \right\rceil + \frac{1}{\gamma},
\]

where \( \ln^+(x) = \max(0, \ln x) \) and \( \ln x \) is the natural logarithm.

Several versions of the lemma can be found in the literature. It was proved for the first time in 1972 by Sapozhenko [34] and appears in later textbooks [40, Lemma 9 in Section 3, pp. 136–137], [41, pp. 134–135]. A slightly different form, attributed to Stein [38] and Lovász [23], was independently obtained later and is sometimes known as the Lovász–Stein theorem; yet another proof is due to Karpinski and Zelikovsky [18]. Recent treatments with applications and more detailed discussion can be found in Deng et al. [5] and in Jukna’s textbook [14, pp. 34–37].

Since the upper bound of Lemma 3 is hardly a standard tool in theoretical computer science as of now, a remark on the proof is in order. A standalone proof goes via the following fact: on each step of the greedy algorithm the number of yet-uncovered elements shrinks by a constant factor, determined by the density parameter \( \gamma \) and the size of the instance. Alternatively, one can use the result due to Lovász [23] that the size of any greedy covering is within a factor of \( 1 + \log |U| \) from the optimal fractional covering. Since assigning the value \((\min_{S \in U} |\{S \in F : s \in S\}|)^{-1} = 1/\gamma |U|\) to all \( x_S, S \in F \), in the linear program in Figure 2b leads to a feasible solution, an upper bound of \((1/\gamma) \cdot (1 + \log |U|)\) follows.

We use Lemma 3 in Section 6 to obtain an upper bound on the OR2-complexity of Kneser-Sierpiński matrices. We remark that instead of greedy coverings one can use random coverings to essentially the same effect (cf. Deng et al. [5]).

5 Lower bound for the full triangular matrices

Define the \( n \times n \) full triangular matrix \( T_n = (t_{ij})_{0 \leq i, j < n} \) by \( t_{ij} = 1 \) if \( i < j \) and \( t_{ij} = 0 \) otherwise. This matrix \( T_n \) is the adjacency matrix of the Hasse diagram of the strict linear order \( 0 < 1 < \cdots < n - 1 \); it has 1s everywhere above the main diagonal and 0s on the diagonal and below. In this section, we study the smallest size of depth-2 rectifier networks that express \( T_n \).

Define \( s(n) = n([\log_2 n] + 2) - 2^{[\log_2 n]+1} \) for \( n \geq 1 \). Note that \( s(n) \) is the so-called binary entropy function, sequence A003314 in Sloane’s Encyclopedia of Integer Sequences [37]. Its properties were studied previously by Morris [29] because of its connection with mergesort.
Fractional coverings, greedy coverings, and rectifier networks

- **Theorem 4.** All fractional coverings of $T_n$ have cost of at least $s(n)$.
- **Corollary 5.** $\text{OR}_2(T_n) = s(n)$.

Note that the equality of Corollary 5 gives the exact value of $\text{OR}_2(T_n)$. The upper bound is an easy divide-and-conquer argument (reproduced in Appendix for completeness), and the main challenge is to obtain the lower bound.

Consider the weighted set covering formulation for $T_n$, where the optimal value is $\text{OR}_2(T_n)$ as discussed in Section 4. By Lemma 2, it suffices to find a feasible solution to the dual linear program with the value $s(n)$. Our feasible solution is given by a certain infinite diagonal matrix $M$, with rows and columns indexed by the natural numbers, defined as follows:

\[ M_{i,j} = \begin{cases} 2, & \text{if } j - i = 1; \\ 1, & \text{if } j - i = 2^q \text{ for some } q \geq 1; \\ 0, & \text{otherwise}. \end{cases} \]

The first 17 rows and columns of $M$ are displayed in Figure 3a. Notice that each row is a shift, by 1, of the preceding row.

- **Lemma 6.** The sum of the elements of $M^{(n)}$, the $n \times n$ upper left submatrix of $M$, is equal to $s(n)$.
- **Lemma 7.** $y_{i,j} = M_{i,j}$ for $0 \leq i < j < n$ is a feasible solution to the dual program.

**Proof of Lemma 6.** $M^{(n+1)}$ is obtained from $M^{(n)}$ by concatenating a row of 0’s on the bottom, and a column that contains a single 2 and 1’s corresponding to the powers of 2 that are $\leq n$. In other words, $s(n+1) = s(n) + \lceil \log_2 n \rceil + 2$. The result now follows by an easy induction.

**Proof of Lemma 7.** To prove feasibility, we need to see that for each pair of nonempty sets $R, C \subseteq \{0, 1, \ldots, n-1\}$ with $\max R < \min C$—only such pairs $(R, C)$ are rectangles of $T_n$—we have

\[ \sum_{i \in R, j \in C} M_{i,j} \leq |R| + |C|. \]  

(1)

Here $R$ corresponds to a choice of rows of $M$ and $C$ to a choice of columns.
Suppose there exists a counterexample to (1). Among all counterexamples to (1), consider one with the smallest possible value of $|R| + |C|$. If $|R| = 1$ then since at most one entry in each row is 2 and all others are either 0 or 1, we clearly have $\sum_{i\in R} M_{i,j} \leq |R| + |C| = |C| + 1$. Hence $|R| \geq 2$. The same argument applies if $|C| = 1$. Thus the minimal counterexample to (1) has at least two rows and columns.

We now observe that the row sum of each row in our counterexample is at least 2. For if it is 0 or 1 we could omit that row, and (1) would still be violated. The same argument applies to the column sums. We now prove

Claim. Suppose there are at least two nonzero elements in the submatrix of $M$ formed by rows 0, 1, …, b and column e of $M$. Then e ≤ 2b.

Proof. The nonzero elements in column e occur precisely in the rows numbered $e - 1, e - 2, \ldots, e - 2^i$ where i is the largest integer with $e - 2^i \geq 0$. So if there are nonzero elements in rows 0, 1, …, b, these would be given by $e - 2^i$ and $e - 2^{i-1}$. So $e - 2^{i-1} \leq b$. It now follows that $e - b + 2^{i-1} = b + \frac{1}{2} \cdot 2^i \leq b + \frac{1}{2} e$ (since $e \geq 2^i$), and so $e \leq 2b$. This concludes the proof of the claim.

Now let us assume that our minimal counterexample has $c = \max R$. Let $e = \max C$. Since column e has 2 nonzero elements, by the Claim above we know $e \leq 2c$. Now let b be the largest element ≤ e in R for which there is a nonzero element in column e; this must exist since column e has at least two nonzero elements. Let a be any row < b in R with a nonzero element in column e. Again, this must exist since column e has at least two nonzero elements. Finally, let d be any column < e in C with a nonzero element in row a. This must exist because every row in R has at least two nonzero elements. We claim $d \leq e$.

To see this, note that $b = e - 2^j \leq e$ for some $j \geq 0$. (In fact, $j = \lceil \log_2(e - e) \rceil$.) Then we must have $a = e - 2^k \geq 0$ where $k \geq j + 1$. Then $d = a = 2^\ell$ for some $\ell$. So $d - a = d - (e - 2^k) = 2^\ell$ and hence $d = e + 2^\ell - 2^k$. Since $d < e$ we have $\ell < k$. So $d \leq e + 2^{k-1} - 2^k = e - 2^k \leq e - 2^j = b \leq e$. This is illustrated in Figure 3b.

Now max $R < \min C$, but $d \leq e$ while $d \in C$ and $e \in R$, a contradiction. Hence there are no minimal counterexamples and no counterexamples at all. Thus (1) holds. It follows that $M$ represents a feasible solution. This concludes the proof of Lemma 7.

Let us complete the proof of Theorem 1. Apply the first part of Lemma 2 to the weighted set covering formulation of the problem and take the solution $y_{i,j} = M_{i,j}$, $0 \leq i < j < n$, as described above. This solution has value $s(n)$ by Lemma 6 and is feasible by Lemma 7. Hence, all fractional coverings have cost at least $s(n)$.

6 Upper bound for Kneser-Sierpiński matrices

Suppose $n = 2^k$. A Kneser-Sierpiński matrix (or a disjointness matrix) of size $2^k \times 2^k$ is the matrix $D_n$ defined as follows. Rows and columns of the matrix are indexed from 0 to $2^k - 1$. The matrix has a 1 at all positions $(i,j)$ such that $i$ and $j$ have no common 1 in their binary expansion; all other elements of the matrix are 0.

Note that if we identify each number from $0, \ldots, n - 1$ with a subset of $\{1, \ldots, k\}$ in the natural way, then $D_n$ is naturally associated with a Boolean function that maps a pair of subsets of $\{1, \ldots, k\}$ to 1 if they are disjoint, and to 0 if they have an element in common. An alternative way to define $D_n$ is by a recurrence $D_{2n} = (D_n D_n) / D_0$ for $n \geq 1$; $D_1 = (1)$;
here subsets of \( \{1, \ldots, k\} \) are ordered lexicographically. Using the antilexicographic order for rows and the lexicographic order for columns would lead to a lower triangular matrix.

What is the size of smallest depth-2 rectifier networks that express Kneser-Sierpiński matrices? Jukna and Sergeev \cite{JS10} Lemma 4.2 prove that

\[
n^{1/2 \log 5} / \text{polylog}(n) \leq \text{OR}_2(D_n) \leq n^{\log(1+\sqrt{2})} \cdot \text{polylog}(n),
\]

and in this section, we prove the following result:

\begin{itemize}
  \item \textbf{Theorem 8.} \( \text{OR}_2(D_n) \leq n^{\log(9/4)} \cdot \text{polylog}(n). \)
\end{itemize}

Note that \( \frac{1}{2} \log 5 \approx 1.16966 \), \( \log(9/4) \approx 1.16993 \), and \( \log(1 + \sqrt{2}) \approx 1.27 \).

Suppose \( n = 2^k \) as above, and let \( D^{x,y}_{[k]} \) be the submatrix of \( D_n \) whose rows and columns correspond to \( x \)-sized and \( y \)-sized subsets of \( \{1, \ldots, k\} \), respectively. This matrix \( D^{x,y}_{[k]} \) has size \( \binom{k}{x} \times \binom{k}{y} \). If \( x = y \), then \( D^{x,x}_{[k]} \) is the adjacency matrix of the Kneser graph \cite{Jukna01}.

For \( 0 \leq y \leq x \leq k \), write \( z = (k - x - y)/2 \) and \( f(x,y) = \binom{k}{x,y} / \binom{k}{x,z} \). Jukna and Sergeev \cite{JS10} Lemma 4.2 show that all coverings of \( D^{x,y}_{[k]} \) have cost at least \( f(x,y) \cdot \text{poly}(k) \), and this gives the lower bound in equation (2): taking \( x = 0.4k \) brings \( f(x,y) \) to its maximum of \( n^{1/2 \log 5} \), if we disregard factors \( \text{polylogarithmic} \) in \( n = 2^k \). Our Theorem 8 follows from Lemmas 9 and 11 below.

\begin{itemize}
  \item \textbf{Lemma 9.} There exists a covering of \( D^{x,y}_{[k]} \) with cost at most \( f(x,y) \cdot \text{poly}(k) \).
\end{itemize}

\begin{proof}
  Consider \( \mathcal{F} \), the family of all ordered bipartitions of \( \{1, \ldots, k\} \) into sets of size \( x + z \) and \( y + z \), where \( z = (k - x - y)/2 \). Technically, an ordered bipartition is simply a subset of \( \{1, \ldots, k\} \), but it is more instructive to view it as an ordered pair: this subset and its complement. Every such bipartition, \( (S, \overline{S}) \), corresponds to a (maximal) rectangle in \( D^{x,y}_{[k]} \); elements of \( D^{x,y}_{[k]} \) covered by the rectangle are pairs \((X,Y)\) of disjoint sets that respect the bipartition: \( X \subseteq S \) and \( Y \subseteq \overline{S} \).

  Use the greedy covering lemma (Lemma 3) for the unweighted set covering formulation with \( \mathcal{F} \). There are \( \binom{k}{x+z} \) bipartitions in this family, and every pair of disjoint sets \((X,Y)\) of size \( x \) and \( y \) respects \( \binom{k}{x+z} \) of them, so \( \gamma = \binom{k}{x+z}/\binom{k}{x} \) and any greedy covering will contain at most \( N \) sets, where

\[
N = \frac{\binom{k}{x+z}}{\binom{k}{x}} \cdot (1 + \ln(4^k)) + 1 = \frac{\binom{k}{x+z}}{\binom{k}{x}} \cdot \text{poly}(k).
\]

For every bipartition in the covering, the corresponding 1-rectangle in \( D^{x,y}_{[k]} \) will include \( \binom{x+z}{x} \) rows and \( \binom{y+z}{y} \) columns; its cost will be at most \( 2 \binom{x+z}{x} \) as \( y \leq x \). So the total cost of the covering will not exceed

\[
\binom{x+z}{x} \cdot 2N = 2 \binom{k}{x} \binom{x+z}{z} \cdot \text{poly}(k) = \binom{\binom{k}{x+z}}{z} \cdot \text{poly}(k) = f(x,y) \cdot \text{poly}(k).
\]
\end{proof}

\begin{itemize}
  \item \textbf{Corollary 10.} Suppose \( 0 \leq m \leq k/2 \) and let \( D^m_k = D^{m,m}_{[k]} \) be the adjacency matrix of the (bipartite) Kneser graph: vertices in each part are size-\( m \) subsets of \( \{1, \ldots, k\} \), and two vertices from different parts are adjacent if and only if the subsets are disjoint. Then \( d(m,k)/\text{poly}(k) \leq \text{OR}_2(D^m_k) \leq d(m,k) \cdot \text{poly}(k) \), where \( d(m,k) = \binom{m,k/2-m,k/2}{k/2-m} / \binom{k}{k/2-m} \).
\end{itemize}

\footnote{We use the standard notation for multinomial coefficients: \( \binom{k}{a,b,c} = \frac{k!}{a!b!c!} \) provided that \( a + b + c = k \).}
Lemma 11. If $0 \leq y \leq x \leq k$, then $f(x, y) \leq 2^{k \log(9/4) \cdot \text{poly}(k)}$, and there exists a pair $(x^*, y^*)$ such that $f(x^*, y^*) \geq 2^{k \log(9/4) / \text{poly}(k)}$.

Proof. As above, let $2z = k - (x + y)$. Denote $\alpha = z/k$ and recall that the values of the binomial coefficients may be estimated with the help of the binary entropy function (not to be confused with $s(n)$ from Section 2) as $z \to \infty$, where $H(\lambda) = -\lambda \log \lambda - (1 - \lambda) \log (1 - \lambda)$. This formula follows from Stirling’s approximation for the factorial [7, Chapter 9 and Solution to Exercise 9.42]. Now

$$f(x, y) = \left(\frac{k}{z}\right)^{2z} \leq \left(\frac{k}{(k-z)/2}\right)^{(k-z)/2} = 2^{kH(\alpha)2(1-\alpha)kH(1/2)/2} \cdot \text{poly}(k) = 2^{(H(\alpha)+1-3\alpha)k} \cdot \text{poly}(k)$$

as $H(1/2) = 1$. Simple calculations show that for $0 < \alpha < 1/2$ the inequality $H(\alpha) + 1 - 3\alpha \leq H(1/9) + 1 - 3 \cdot 1/9 = \log(9/4)$ holds. This corresponds to $x = 4/9 \cdot k$ and $y = 3/9 \cdot k$.

Remark 12. Although Theorem 8 leaves a gap between the bounds on $\text{OR}_2(D_n)$, the greedy strategy is, in fact, optimal: For each $D^y_{k|x}$, it suffices to use bipartitions into sets of size $\ell$ and $k - \ell$, for some $\ell = \ell(k; x, y)$. (See Appendix for more details.) Our choice of $\ell$ in Lemma 9 is $\ell = x + (k - x - y)/2$, and the optimal choice, $\ell = \ell^*(k; x, y)$, will deliver a tight upper bound on $\text{OR}_2(D_n)$. Numerical experiments seem to indicate that the actual value of $\text{OR}_2(D_n)$ is within a polylog($n$) factor from $n^\frac{3}{2} \log^5$, but no formal proof is known to us.

7 Lower bound for Kronecker products

Given two matrices $K \in \{0, 1\}^{m_1 \times n_1}$ and $M \in \{0, 1\}^{m_2 \times n_2}$, their Kronecker (or tensor) product is the Boolean matrix $K \otimes M$ of size $(m_1 \cdot m_2) \times (n_1 \cdot n_2)$ defined as follows. Its rows are indexed by pairs $(i_1, i_2)$ and its columns by pairs $(j_1, j_2)$ where $1 \leq i_s \leq m_s$ and $1 \leq j_s \leq n_s$ for $s = 1, 2$. The entry of $K \otimes M$ at position $((i_1, i_2), (j_1, j_2))$ is defined as $K_{i_1,j_1} \cdot M_{j_1,j_2}$.

In this section we prove a lower bound on the $\text{OR}()$-measure of Kronecker products. Recall that the Boolean rank $rk_\oplus(K)$ is the optimal value of the unweighted set covering formulation (as in Figure 2a) where the set of 1-entries in the matrix $K$ is covered by all-1 rectangles. In the linear relaxation of this problem (as in Figure 2b), the goal is to assign weights $w(R) \in [0, 1]$ to each 1-rectangle $R$ such that $\sum_{(i,j) \in R} w(R) \geq 1$ for each 1-entry $(i, j)$ of $K$, minimizing $\sum w(R)$. Let the fractional rank $rk_\oplus^*(K)$ be the optimal value of this linear relaxation. The integrality gap result for the set cover problem [24] and the duality theorem imply that $rk_\oplus(K)/\left(1 + \log m_1n_1\right) \leq rk_\oplus^*(K) \leq rk_\oplus(K)$. In the graph-theoretic language, the number $rk_\oplus^*(K)$ is the fractional biclique cover number, denoted by $bc^*(G)$ where $K$ is the adjacency matrix of the (bipartite) graph $G$. Fractional rank is known to be bounded from below by the fooling set number, see Watts [22, Theorem 2.2].

Theorem 13. For any pair $K, M$ of Boolean matrices, $\text{OR}(K \otimes M) \geq rk_\oplus^*(K) \cdot \text{OR}(M)$.

Proof. First consider the unweighted set covering formulation for $K$, where the optimal value is $rk_\oplus(K)$ as discussed in Section 4 and take its linear relaxation, with the optimal
value $\text{rk}^*_\gamma(K)$. By Lemma 2 there is an assignment of weights to 1-elements of this matrix, $w(i, j) \in [0, 1]$ for all $(i, j)$ with $K_{i,j} = 1$, such that the following two conditions are satisfied (see Figure 2c). First, for each 1-rectangle $R \times C$ of $K$, the sum $\sum_{(i,j) \in R \times C} w(i, j)$ is at most 1. Second, $\sum_{(i,j) \in K_{i,j}} w(i, j) = \text{rk}^*_\gamma(K)$.

Now let $\mathcal{N} = (V, E, \text{in, out})$ be a rectifier network of size $\text{OR}(K \otimes M)$ that expresses $Q = K \otimes M$, where $K$ and $M$ have size as above. For an edge $e \in E$, let $\text{To}(e) \subseteq \{1, \ldots, m_1\} \times \{1, \ldots, m_2\}$ be the set of row indices $(i_1, i_2)$ of $Q$ such that the node $\text{out}(i_1, i_2)$ is reachable from the target of $e$. Similarly, let $\text{From}(e) \subseteq \{1, \ldots, n_1\} \times \{1, \ldots, n_2\}$ be the set of column indices $(j_1, j_2)$ of $Q$ such that the source of $e$ is reachable from $\text{in}((j_1, j_2))$. Then $R(e) = (\text{To}(e), \text{From}(e))$ is a rectangle of $Q$. Moreover, define $\pi_s((i_1, i_2), (j_1, j_2)) = (i_s, j_s)$ for $s = 1, 2$ and $\pi_s(R) = \{\pi_s(r, c) : (r, c) \in R\}$. Then $\pi_1(R(e))$ and $\pi_2(R(e))$ are rectangles in $K$ and $M$ respectively.

We assign real weights based on $w$ to each edge $e$ of $\mathcal{N}$ by the following rule:

$$w'(e) = \sum_{(i,j) \in \pi_1(R(e))} w(i, j).$$

Since $\pi_1(R(e))$ is a rectangle of $K$, one of the constraints on $w$ ensures that $w'(e) \leq 1$ for each edge $e$ of $\mathcal{N}$. Consequently, $\sum_{e \in E} w'(e) \leq |E| = \text{OR}(K \otimes M)$; furthermore, the following chain of inequalities holds:

$$\text{OR}(K \otimes M) \geq \sum_{e \in E} w'(e) = \sum_{e \in E} \left( \sum_{(i_1, j_1) \in \pi_1(R(e))} w(i_1, j_1) \right) = \sum_{(i_1, j_1) : K_{i_1,j_1} = 1} \sum_{(i_1, j_1) \in \pi_1(R(e))} w(i_1, j_1) = \sum_{(i_1, j_1) : K_{i_1,j_1} = 1} \sum_{(i_1, j_1) \in \pi_1(R(e))} w(i_1, j_1) \cdot \{|e \in E : (i_1, j_1) \in \pi_1(R(e))\}|$$

$$= \sum_{(i_1, j_1) : K_{i_1,j_1} = 1} \sum_{(i_1, j_1) \in \pi_1(R(e))} w(i_1, j_1) \cdot \{|e \in E : i_1 \in \pi_1(\text{To}(e)), j_1 \in \pi_1(\text{From}(e))\}|. \quad (3)$$

Fix an arbitrary entry $(i_1, j_1)$ of $K$ with $K_{i_1,j_1} = 1$. Consider the subgraph $\mathcal{N}_{j_1 \rightarrow i_1}$ of $\mathcal{N}$ induced by the nodes that are reachable from some source of the form $\text{in}((j_1, j_2))$ and from which a node of the form $\text{out}(i_1, i_2)$ is reachable—in other words, take all nodes and edges on all paths from $\text{in}((j_1, j_2))$ to $\text{out}(i_1, i_2)$ for some $i_2, j_2$. Then, since $K_{i_1,j_1} = 1$, the node $\text{out}(i_1, i_2)$ is reachable from $\text{in}((j_1, j_2))$ in $\mathcal{N}_{j_1 \rightarrow i_1}$ if and only if $M_{i_2,j_2} = 1$. So the network $\mathcal{N}_{j_1 \rightarrow i_1}$ expresses $M$ (with the mappings $\text{in}((j_2)) = \text{in}((j_1, j_2))$ and $\text{out}((i_2)) = \text{out}((i_1, i_2))$). Hence, the number of edges in $\mathcal{N}_{j_1 \rightarrow i_1}$ is at least $\text{OR}(M)$. But by our definitions, the relations $i_1 \in \pi_1(\text{To}(e))$ and $j_1 \in \pi_1(\text{From}(e))$ hold together exactly for the edges $e$ of $\mathcal{N}$ present in $\mathcal{N}_{j_1 \rightarrow i_1}$. Thus $\{|e \in E : i_1 \in \pi_1(\text{To}(e)), j_1 \in \pi_1(\text{From}(e))\}| \geq \text{OR}(M)$ and we conclude from equation 3 that

$$\text{OR}(K \otimes M) \geq \sum_{(i_1, j_1) : K_{i_1,j_1} = 1} \sum_{(i_1, j_1) \in \pi_1(R(e))} w(i_1, j_1) \cdot \text{OR}(M) = \text{rk}^*_\gamma(K) \cdot \text{OR}(M). \tag*{\blacktriangleleft}$$

**Remark 14.** Let $\text{SUM}(K)$ be the smallest size of an unambiguous rectifier network that expresses $K$. A rectifier network is unambiguous if for all $i, j$ it has at most one path from $\text{in}(j)$ to $\text{out}(i)$. Such networks are also known under the names of SUM-circuits [16] and cancellation-free circuits [19]. The same construction as above also proves the inequality $\text{SUM}(K \otimes M) \geq \text{rk}^*_\gamma(K) \cdot \text{SUM}(M)$.

**Corollary 15.** For any pair of matrices $K \in \{0,1\}^{m_1 \times n_1}$ and $M \in \{0,1\}^{m_2 \times n_2}$, and $L \in \{\text{OR, SUM}\}$ it holds that $L(K \otimes M) \geq \text{rk}^*_\gamma(K) \cdot L(M)/(1 + \log m_1n_1)$.

A Depth-3 lower bound in Example 1

Consider the matrix \( M_n = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} \odot J_n \) for some \( n \geq 1 \) where \( J_n \) is the \( n \times n \) all-one matrix.

Known bounds give \( \text{OR}(M_n) \geq 4n + 1 \) and this bound is indeed attainable. For \( \text{OR}_3(M_n) \), i.e., realization by some rectifier network of exact depth 3 we show \( \text{OR}_3(M_n) = 4n + 3 \) using the following lemma:

\[ \text{Lemma 16.} \ Suppose M is a Boolean matrix and \( N = (V,E,\text{in},\text{out}) \) is a rectifier network realizing \( M \) of some depth \( d \). Then there exists a rectifier network \( N' = (V,E',\text{in},\text{out}) \) with \( |N'| \leq |N| \) having depth at most \( d \) satisfying the following conditions:

i) whenever the \( i_1 \)th and the \( i_2 \)th row are the same in \( M \), then the sets \( \{ v \in V : (v,\text{out}(i_1)) \in E \} \) and \( \{ v \in V : (v,\text{out}(i_2)) \in E' \} \) coincide;

ii) dually, whenever the \( j_1 \)th and the \( j_2 \)th column of \( M \) are the same, then \( \{ v \in V : (\text{in}(j_1),v) \in E \} = \{ v \in V : (\text{in}(j_2),v) \in E' \} \).

\[ \text{Proof.} \] Let \( v = \text{in}(j) \) be a source node and let \( X_j \) stand for the set \( \{ w \in V : (v,w) \in E \} \) of its neighbours. Since \( N \) realizes \( M \), the set of target nodes \( \text{out}(i) \) which are reachable in \( N \) is exactly the image under \( \text{out} \) of those indices \( i \) for which \( M_{i,j} = 1 \). Now for each column index \( j \) let \( j' \) be the index for which the \( j \)th and the \( j' \)th column of \( M \) is the same, \( |X_{j'}| \) is the smallest possible among these sets and \( j' \) is the smallest among these indices. Note that \( j' \) is always well-defined and whenever the \( j_1 \)th and the \( j_2 \)th column of \( M \) coincide, then \( j'_1 = j'_2 \).

Then, define \( N_0 \) as \((V,E_0,\text{in},\text{out})\) with \( E_0 = E - \{ (\text{in}(j),v) \} \cup \{ (\text{in}(j),v) : v \in X_{j'} \} \). (That is, we reattach the edges coming out from sources to the neighbours of the representative source of their equivalence class.)

Then by the choice of the values \( j' \) (in particular, with \( |X_{j'}| \) having been minimized) we have that i) is satisfied, \( N_0 \) also realizes \( M \), the depth is not increased (if \( N \) is strictly levelled) and \( |N'| \leq |N| \). Applying the analogous transformation to the targets we get a network \( N' \) satisfying ii) as well.

Thus we get that there exists a depth-3 network of minimal size realizing \( M_n \) such that

- each source \( \text{in}(i) \) for \( i = 1, \ldots, n \) have the same set \( X_1 \) of neighbours;

- each source \( \text{out}(i) \) for \( i = n + 1, \ldots, 2n \) have the same set \( X_2 \) of neighbours;

- each target \( \text{out}(j) \) for \( j = 1, \ldots, n \) have the same set \( Y_1 \) of neighbours and

- each target \( \text{out}(j) \) for \( j = n + 1, \ldots, 2n \) have the same set \( Y_2 \) of neighbours since the corresponding rows and columns coincide. In this network there are \( n(|X_1| + |X_2| + |Y_1| + |Y_2|) \) edges in total between the outermost layers (and some additional edges between the two middle layers. Clearly none of these sets can be empty (since all the rows and columns are nonzero), and if any of them is a non-singleton set, the size of the network is at least \( 5n > 4n + 3 \). So in order to go below \( 5n \), \( X_1 = \{ x_1 \} \), \( X_2 = \{ x_2 \} \) etc. have to be singleton sets. Now since not all rows (columns, resp.) are equal, \( x_1 \neq x_2 \) and \( y_1 \neq y_2 \) has to hold, and there is only one choice (because the sets are singletons) to wire the two middle layers together, namely adding the edges \((x_1, y_1), (x_1, y_2)\) and \((x_2, y_2)\), giving \( 4n + 3 \) edges in total as optimal value for depth \( d = 3 \).

Note that if the network is not required to be strictly levelled, we can merge \( x_1 \) with \( y_1 \) and \( x_2 \) with \( y_1 \) and add only the edge \((x_1, x_2)\) reaching the optimal bound \( 4n + 1 \).
B Upper bound in Corollary 5

Recall that a SUM-circuit for a matrix $M$ is the same as an unambiguous rectifier network: it is a rectifier network that has at most one path between any input—output pair. The smallest size of an unambiguous rectifier network that expresses $M$ is denoted by $\text{SUM}(M)$; similarly, $\text{SUM}_2(M)$ is the smallest size of an unambiguous rectifier network of depth 2 that expresses $M$. In the same way as rectifier networks of depth 2 correspond to rectangle coverings, unambiguous rectifier networks of depth 2 correspond to rectangle partitions (that is, coverings with no overlap between rectangles). If one views the matrices as adjacency matrices of bipartite graphs, then the measures $\text{OR}_2(\cdot)$ and $\text{SUM}_2(\cdot)$ correspond to minimal biclique coverings and minimal biclique partitions, respectively. Clearly, $\text{OR}(M) \leq \text{SUM}(M)$ and $\text{OR}_d(M) \leq \text{SUM}_d(M)$ for each depth $d$. Also, if $M = \left( \begin{smallmatrix} M_1 & M_2 \\ M_3 & M_4 \end{smallmatrix} \right)$, then $\text{SUM}(M) \leq \sum_{i=1}^4 \text{SUM}(M_i)$.

We show below that $\text{SUM}_2(T_n) \leq s(n) = n(\log_2 n) + 2 - 2^{\log_2 n} + 1$. Theorem 4 will then imply that $\text{OR}_2(T_n) = \text{SUM}_2(T_n) = s(n)$.

First, let $J_n$ be the $n \times n$ all-1 matrix and $J_{m,k}$ the $m \times k$ all-1 matrix. Clearly, $\text{SUM}_2(J_{m,k})$ is $m + k$. Second, observe that $T_{2n} = \left( \begin{smallmatrix} T_n & J_{n,n} \\ J_{n,n} & T_n \end{smallmatrix} \right)$ and $T_{2n+1} = \left( \begin{smallmatrix} T_n & J_{n,n+1} \\ J_{n,n+1} & T_{n+1} \end{smallmatrix} \right)$. It follows that $\text{SUM}_2(T_{2n}) \leq 2\text{SUM}_2(T_n) + 2n$ and $\text{SUM}_2(T_{2n+1}) \leq \text{SUM}_2(T_n) + \text{SUM}_2(T_{n+1}) + 2n + 1$. This shows, by induction, that $\text{SUM}_2(T_n) \leq s(n)$, since the induction basis is easily checked.

C Optimality of the greedy strategy for Kneser-Sierpiński matrices

Although Theorem 8 leaves a gap between the bounds of $\Omega(n^{1.16})$ and $O(n^{1.17})$ on $\text{OR}_2(D_n)$, the greedy strategy is, in fact, optimal. We first give a brief sketch of the argument, and then fill in all the details below.

Consider the linear relaxation of the set covering formulation for each $D_{[k]}^{x,y}$. Note that only maximal rectangles (i.e., those associated with bipartitions) can participate in optimal fractional coverings. In fact, for any $\ell \in [x,k-y]$ there exists a fractional covering $\eta(\ell)$ of $D_{[k]}^{x,y}$ which uses only bipartitions into sets of size $\ell$ and $k-\ell$ and for which all “covering” constraints in the LP are tight; it suffices to pick a single $\ell$ since this fractional covering $\eta(\ell)$ uses all such bipartitions with multiplicity $1/(\binom{k}{\ell} - \binom{k}{\ell-x-y})$. Hence, the problem reduces to an unweighted set covering formulation, where the greedy heuristic achieves a value within a factor of $1 + \log(\binom{k}{\ell}) \leq 1 + 2k = \text{polylog}(n)$ of the optimum.

In more detail, first consider an arbitrary weighted set cover problem: let $S_1, \ldots, S_k \subseteq U$ be the sets, with $w_i > 0$ being the cost of $S_i$. Let $\mu = \min\{\frac{w_i}{|S_i|} : i = 1, \ldots, k\}$ be the best cost/utility ratio offered by the sets. Then, in the dual formulation of its LP relaxation, if one assigns uniformly $\mu$ to each element $u \in U$ of the universe, then each set $S_i$ gets $\mu \cdot |S_i| \leq w_i$ total charge, hence this uniform distribution is a solution to the dual, hence $\mu \cdot |U|$ is a lower bound for the optimum of the primal problem by the weak duality theorem.

For the case of the weighted covering by rectangles, a rectangle of size $k \times m$ has cost $k + m$ and covers $km$ elements, hence its offered ratio is $\frac{k + m}{km} = \frac{1}{k} + \frac{1}{m}$, i.e., it decreases strictly by increasing either $k$ or $m$, thus the best ratios are always offered by maximal rectangles.

Now considering a rectangle $R$ in a matrix $D_{[k]}^{x,y}$, formed by the rows $X_1, X_2, \ldots, X_k$ and columns $Y_1, \ldots, Y_m$, we have by definition that each $X_i$ is disjoint from each $Y_j$, thus choosing $S = \bigcup_{i=1}^k X_i$ we have that $R$ is a subrectangle of the rectangle corresponding to the bipartition $(S, \overline{S})$, yielding that only rectangles corresponding to bipartitions can be maximal.
Fractional coverings, greedy coverings, and rectifier networks

On the other hand, any such rectangle is clearly maximal. Denoting \(|S|\) by \(\ell\) we get that the ratio offered by these rectangles is \(\mu(k, x, y, \ell) = \frac{1}{(\ell - x)} + \frac{1}{(\ell - y)}\). Then setting \(\ell^* = \ell^*(k, x, y) = \arg\min\{\mu(k, x, y, \ell) : x \leq \ell, y \leq k - \ell\}\) is the parameter of those rectangles offering the best possible ratio \(\mu^* = \mu(k, x, y, \ell^*)\) for \(D^r_{[k]}\). Thus, \(\mu^* \cdot \|D^r_{[k]}\| = \left(\frac{\ell^*}{\ell^*}\right) + \left(\frac{k - \ell^*}{k - \ell^*}\right)\langle\frac{k}{y}\rangle\) is a lower bound for the cost of the optimal solution.

Observe that this bound is indeed attainable by the greedy strategy, since each set \((X, Y)\) with \(|X| = x\) and \(|Y| = y\), \(X \cap Y = \emptyset\) is covered exactly by \((k - x - y)^r\) such rectangles (i.e. respects this number of such bipartitions), thus considering the fractional covering \(\eta(\ell^*)\) which uses all such bipartitions with multiplicity \(1/(k - x - y)\) we get a covering of \(D^r_{[k]}\), with total cost \(1/\left(\frac{k - x}{\ell^* - x}\right) + \left(\frac{k - \ell^*}{k - \ell^*}\right)\langle\frac{k}{y}\rangle\). The last expression is the same as \(\left(\frac{\ell^*}{\ell^*}\right) + \left(\frac{k - \ell^*}{k - \ell^*}\right)\langle\frac{k}{y}\rangle\), since \(\left(\frac{k}{y}\right)(k - x - y)/k - x - y) = \left(\frac{k}{\ell^*}\right)\langle\frac{k}{y}\rangle\). Both of these products calculate the number of possibilities to choose an \(\ell^*\)-element subset \(L\) of a \(k\)-element set \(K\), and an \(x\)-element subset \(X\) of \(L\), as well as a \(y\)-element subset of \(K - L\). The first formula achieves this by choosing \(X\) from \(K\) first, then \(Y\) from \(K - X\), finally \(L - X\) from \(K - X - Y\), the second one by choosing \(L\) from \(K\) first, then \(X\) from \(L\) and finally \(Y\) from \(K - L\). Thus, choosing all these bipartitions with this multiplicity provides an optimal solution.

Note that for any fixed \(\ell\), the weighted set covering problem using only the bipartitions \((S, \emptyset)\) with \(|S| = \ell\) is a uniform-cost, i.e., an unweighted set covering problem. On such a problem the greedy heuristic achieves a value within a factor of \(1 + \log(\ell^*)\langle\frac{k}{y}\rangle \leq 1 + 2k = \text{polylog}(n)\) of the optimum in the linear relaxation. Therefore, it suffices to pick some \(\ell\) and construct a greedy covering using bipartitions into sets of size \(\ell\) and \(k - \ell\). Our choice of \(\ell\) in Lemma 9 is \(\ell = x + (k - x - y)/2\), and the argument above shows that the optimal choice, \(\ell = \ell^*(k; x, y)\) will deliver an upper bound on \(\text{OPT}_{\ell^*}(D_{[k]})\) that is tight up to a polylogarithmic factor, thus reducing the problem to a parametric optimization task.

### D Application: size of regular expressions

A regular expression over \(\Sigma\) is a well-formed expression \(r\) consisting of the symbols

\[e, \emptyset, (,), *, *\], \(\cdot\) \(a \in \Sigma\),

with the usual semantics (e.g., as in [11]).

The size of a regular expression \(r\) can be specified in a number of different ways, but for our purposes, the easiest is the so-called alphabetic length, which is the number of symbols in \(r\) belonging to \(\Sigma\) [24]. For example, the alphabetic length of

\[r = a_0 a_1 + a_2 a_3 + (a_0 + a_1)(a_2 + a_3)\]

is 8.

Given a regular language \(L\) specified in some way (for example, as the language accepted by a finite automaton), it is, in general, quite difficult to determine the size of the shortest regular expression specifying \(L\). In fact, this problem is PSPACE-hard [25] [13] and not even approximable within a factor of \(o(n)\) [8] (unless \(P = \text{PSPACE}\)).
Extended example

In this subsection we examine a specific family of finite languages, namely

\[ L_n = \sum_{0 \leq i < j < n} a_i a_j, \]

over the alphabet \( \Sigma_n = \{a_0, a_1, \ldots, a_{n-1}\} \) of size \( n \), and we provide matching upper and lower bounds on for the size of the shortest regular expression for it. For example, for \( n = 4 \) this is the language

\[ L_4 = \{a_0a_1, a_0a_2, a_0a_3, a_1a_2, a_1a_3, a_2a_3\}. \]

Evidently one can produce a regular expression for \( L_n \) of length \( n(n-1) \) by listing the elements of \( L_n \), but it is possible to do much better. For example, the regular expression given in [4] specifies \( L_4 \) with alphabetic length 8, as opposed to length 12 using the brute-force approach.

Our upper and lower bounds follow Corollary 3 in the main text. For the lower bound, we relate the alphabetic length of regular expressions to the cost of coverings of Boolean matrices; for the upper bound, we provide a direct proof to make the connection between regular expressions and coverings more transparent.

We first show how to construct a small regular expression for \( L_n \) through a simple divide-and-conquer strategy. We generalize \( L_n \) to \( L_{A,B} = \bigcup_{A \leq i < j \leq B} a_i a_j \) so that \( L_n = L_{0,n-1} \). Then our divide-and-conquer solution is given by

\[ L_{A,B} = L_{A,C} \cup L_{C+1,B} \cup \{a_A + a_{A+1} + \cdots + a_C\} \cdot \{a_{C+1} + \cdots + a_B\}, \]

where \( C = \lfloor (A + B)/2 \rfloor \). The alphabetic length \( t(n) \) of the regular expression so constructed satisfies the recurrence \( t(1) = 0 \) and \( t(2n) = 2t(n)+2n \) and \( t(2n+1) = t(n+1)+t(n)+2n+1 \). Now an easy induction proves that in fact \( t(n) = s(n) \), with \( s(n) = n \lfloor \log_2 n \rfloor + 2^{\lfloor \log_2 n \rfloor + 1} \).

We now turn to the lower bound. Let \( r_n \) be a regular expression of shortest length for \( L_n \) for \( n \geq 2 \). Clearly we can assume that \( r_n \) contains no occurrence of the empty set symbol \( \emptyset \). Since \( L_n \) is finite, we can also assume \( r_n \) contains no occurrence of \( \ast \). So all the operators in \( r_n \) are either union or concatenation. Consider any instance of concatenation, say \( L_1L_2 \). Then if either \( L_1 \) or \( L_2 \) contains strings of two different lengths, the resulting concatenation would also, which is impossible since \( L_n \) contains only strings of length 2. So all strings on one side of any concatenation are of the same length. On the other hand, no strings can be of length 3 or more, and if one side contains only strings of length 0 (the empty string) we could simply omit the concatenation. So in fact we may assume, without loss of generality that any concatenation in \( r_n \) looks like \( R \cdot C \), where both languages consist of subsets of \( \Sigma_n \).

Finally, every letter in \( C \) must be numbered higher than all those of \( R \); otherwise we would obtain a word not in \( L_n \). This means that we can write \( r_n \) as

\[ R_1 \cdot C_1 + R_2 \cdot C_2 + \cdots + R_t \cdot C_t \]

where we have inserted dots to make the concatenation explicit. The alphabetic length of this expression is \( \sum_{1 \leq i \leq t} (|R_i| + |C_i|) \).

We now create an integer program to minimize this length. Define \( I_n = \{0, 1, \ldots, n-1\} \) and let \( x_{R,C} \) for nonempty sets \( R, C \subseteq I_n \) be an indicator variable for the presence of the term \( R \cdot C \) in the expression [5]: 1 if it is present and 0 otherwise. Our integer program is
minimize $\sum_{R,C \text{ nonempty}} \max_{R \subseteq \mathcal{I}_n} \text{max} \min_{C}$ \ni x_{R,C}$
subject to the constraints

$x_{R,C} \in \{0, 1\}$ for nonempty $R, C \subseteq \mathcal{I}_n$ and $\text{max} \min_{C} n$ 

$\sum_{j < C} x_{R,C} \geq 1$ for nonempty $R, C \subseteq \mathcal{I}_n$ and $\text{max} \min_{C}$.

The last constraint means that every string $a_i a_j$ with $i < j$ is covered by at least one concatenation of sets. Note that we write “$\geq 1$” in the last group of inequalities instead of “$= 1$”, because we are not insisting that our regular expression be unambiguous.

For example, if $n = 3$ then the integer program is

minimize $2x_{0,1} + 2x_{0,2} + 2x_{1,2} + 3x_{01,2} + 3x_{0,12}$
subject to the constraints

$x_{0,1}, x_{0,2}, x_{1,2}, x_{01,2}, x_{00,12} \in \{0, 1\}$

$x_{0,1} + x_{0,12} \geq 1$

$x_{0,2} + x_{01,2} + x_{0,12} \geq 1$

$x_{1,2} + x_{01,2} \geq 1$.

It is not difficult to see that our integer program, in fact, is the weighted set covering formulation, from Section 4, where the optimal value is $\Omega_R(T_n)$ with $T_n$ the $n \times n$ full triangular matrix, as in Section 5. So we can conclude from Corollary 5 that the smallest alphabetic length of a regular expression for the language $L_n$ is $s(n) = n(\lceil \log_2 n \rceil + 2) - 2^{\lceil \log_2 n \rceil + 1}$.

In what follows, we illustrate the approach taken in the main text by formulating the linear relaxation of the integer program above and taking its dual. This follows Figure 2 in Section 4.

The integer program above is an instantiation of the one in Figure 2a. We now relax the constraints on the $x_{R,C}$ to be $0 \leq x_{R,C} \leq 1$. The dual linear program then has variables $y_{i,j}$ corresponding to the string $a_i a_j$, for $0 \leq i < j < n$; compare to Figure 2b. The corresponding dual, as in Figure 2c, is

maximize $\sum_{0 \leq i < j < n} y_{i,j}$
subject to the constraints

$y_{i,j} \geq 0$ for $0 \leq i < j < n$

$\sum_{j < C} y_{i,j} \leq |R| + |C|$ for nonempty $R, C \subseteq \mathcal{I}_n$ and $\text{max} R < \text{min} C$.

For example, for $n = 3$ the corresponding dual is

maximize $y_{0,1} + y_{0,2} + y_{1,2}$
subject to the constraints

$y_{0,1} \geq 0$

$y_{0,2} \geq 0$

$y_{1,2} \geq 0$

$y_{0,1} \leq 2$

$y_{0,2} \leq 2$

$y_{1,2} \leq 2$

$y_{0,1} + y_{0,2} \leq 3$

$y_{0,2} + y_{1,2} \leq 3$.
General connection

Whenever $L \subseteq \Sigma \Delta$ for the alphabets $\Sigma = \{1, \ldots, m\}$ and $\Delta = \{1, \ldots, n\}$, and $M_L$ is its characteristic $m \times n$ matrix $M_{i,j} = 1$ iff $ij \in L$, then the following statements hold:

1. The value $\text{OR}_2(M_L)$ coincides with the smallest possible alphabetic length of a regular expression for $L$.
2. The value $\text{OR}_2(M_L)$ also coincides with the size of the smallest $\varepsilon$-free nondeterministic finite automaton (NFA) recognizing $L$.
3. The value $\text{OR}(M_L) + m + n$ is an upper bound on the size of the smallest nondeterministic finite automaton with possible $\varepsilon$-transitions ($\varepsilon$-NFA) recognizing $L$.

The proof of the first statement follows the example above, and the last two statements can be found in [12].
