Abstract: Odontoma is the most common type of benign odontogenic tumor, and often causes disturbances in the eruption of its associated tooth. Odontomas usually occur in the permanent dentition, and rarely occur solely in the primary dentition. This case report documents a six-year-old-child with a compound odontoma located in the mandible, which caused the impaction of the primary second molar.

Keywords: Odontoma, primary tooth, eruption disturbance.

INTRODUCTION

An odontoma is a mixed tissue benign tumor of odontogenic origin, which exhibits complete dental tissue differentiation. Odontomas constitute about 22% of all odontogenic tumors of the jaws. The World Health Organization has subdivided odontomas into a compound and complex type based on histologic criteria. Compound odontomas consist of multiple miniature or rudimentary teeth, whereas complex odontomas appear as an amorphous and disorderly pattern of calcified dental tissues. Although odontomas are classified as odontogenic tumors according to the WHO classification, they lack proliferative potentiation. Odontomas are probably a hamartomatous malformation of functional ameloblasts and odontoblasts rather than true neoplasms. The etiology is not clear, although local trauma, infection and genetic factors have been suggested as possible causes [1]. Odontomas are usually detected in school-age children, and the mean age at the time of diagnosis is 14 years [2-4]. The majority of odontomas are asymptomatic and seldom causes swelling, pain, suppuration, bony expansion, and displacement of teeth [2, 5]. These lesions are commonly small, seldom larger than a tooth. Odontomas are generally discovered through routine radiographic examination in dental treatment. An odontoma is essentially a benign lesion, but, often causes disturbances in the eruption of its associated tooth. [6-8]. Odontomas mainly occur in the permanent dentition and are rarely associated with the primary teeth [5, 9, 10]. We have found only six reports of odontomas associated with primary molars in the English literatures [11-16].

In this paper, a rare case of an unerupted lower primary second molar due to the presence of compound odontoma in a young patient is reported and the few similar reports that appear in the bibliography are discussed.

CLINICAL REPORT

A six-year-old-girl was referred to Okayama University Hospital due to the failure of the right lower primary second molar to erupt. Past family and medical histories were unknown. Her general medical history was noncontributory. She was taking no medications. There was no history of trauma to the face or mouth. The lesion was asymptomatic, and there was thus no spontaneous or oppressive pain.

Intraoral examination revealed a mixed dentition period, and all primary teeth except for the right lower primary second molar were present in the mouth. Extraoral examination revealed no abnormal signs in gingiva, buccal tissue and alveolar bone of the right mandible. Periapical and panoramic radiographs revealed that a small single radio-opaque structure was present above the crown of the unerupted lower primary second molar. The mass was surrounded by a narrow radiolucent zone. The root formation of the impacted primary tooth was complete at that time. The successor tooth germ was identified, except for the right lower permanent second premolar. The right lower permanent second premolar appeared to be congenitally missing. Therefore, on the basis of the radiographic evaluations, we diagnosed a compound odontoma interfering with the eruption of the primary tooth (Fig. 1). Surgical removal of the tumor was performed in 2007 with the patient under local anesthesia. After the thin overlying bone was removed, 2 small toothlike structures (sizes: 1 mm and 5 mm) covered with a thick fibrous capsule were revealed. The odontoma was completely removed without disturbing the underlying primary second molar. After surgical removal, the patient was followed up regularly and the impacted primary teeth kept under observation. The diagnosis was confirmed histologically. Histologically, the well-defined tumor mass was composed of 2 toothlike structures exhibiting an irregular arrangement of enamel matrix, dentin cementum, and pulpal tissue. The surface of these structures was partially covered with connective tissue containing an odontogenic epithelium. The histologic diagnosis...
was a compound odontoma as diagnosed by clinical and radiographic examination. The postoperative period was uneventful.

In this case, there was little chance of spontaneous eruption of the right lower primary second molar because of the complete root formation at the time of diagnosis. The case needs to be referred for orthodontic consultation. An overall evaluation of the occlusion as well as the local problems of impacted second primary molar and congenital missing second premolar should take place.

DISCUSSION

In clinical setting, dentists often encounter the problem of tooth impaction, which has been defined as a situation where a tooth fails to erupt into a normal functional position by the expected times [11]. Tooth impaction is seen more commonly in permanent dentition and rarely in primary dentition [17, 18]. For tooth impaction, numerous local etiologic factors have been described. These include odontomas [11, 19, 20], odontogenic tumors [21-23], ankylosis [24], trauma [25], and dentigerous cysts [26]. Among these factors, odontoma is the most common aetiological factor.

In this case report, we presented a rare case of a compound odontoma localized in the mandible, which is associated with the underlying primary second molar. The reason for the impaction of the primary molar was the presence of a compound odontoma. Odontoma is a comparatively common odontogenic tumor, but often causes disturbances in the eruption of teeth [6-8]. In general, odontoma occurs more often in permanent dentition, and rarely associated with primary teeth [9, 10]. There are very few reports in the literature of odontomas associated with unerupted primary teeth [5, 11, 19, 20, 27-29], especially with primary molars [11-16]. Various locations of the odontomas associated with primary molars were observed in these reports. One was located between the roots of a right lower second primary molar (Fig. 2a), one was in a periapical location in association with a left lower second primary (Fig. 2b), one was located

Radio-opaque mass odontoma was present above the tooth crown of the lower right primary second molar. The tooth germ of the right lower second premolar is absent. (a) Panoramic radiograph. (b) Periapical radiograph before operation.

**Fig. (2).** Location of odontomas (grey painting) associated with primary molars. (a) Compound odontoma located between the roots of the right lower second primary molar (30y, ref.13) (b) Mature complex odontoma seen in a periapical location and in association with the left lower second primary (25y, ref.14) (c) Odontoma located between the crowns of the upper first and second primary molars (2.6y, ref.15) (d) Unerupted upper second primary molar impacted by an odontoma and a dentigerous cyst (3y, ref.11) (e) Complex odontoma above the tooth crown of the lower right primary second molar (3.7 y, ref.16).
between the crowns of the upper first and second primary molars (Fig. 2c), one was above the unerupted upper second primary molar (Fig. 2d), and one was above the tooth crown of the lower right primary second molar (Fig. 2e).

The treatment for odontomas in both primary and permanent dentition is their surgical removal. If odontomas are extirpated early without disturbing the underlying teeth, the eruption of the impacted teeth can then be expected spontaneously or after orthodontic traction [2, 3, 10, 11, 19, 28]. However, underlying impacted teeth are sometimes extracted in association with the removal of odontomas [30]. In this case, the overlying odontoma was surgically removed and the impacted primary tooth kept under observation to monitor its eruption. Periapical and panoramic radiographs revealed that the lower permanent second premolar appeared to be congenitally missing. A full complement of permanent successor tooth germs with the exception of the right lower second premolar was identified. Every effort should be made to preserve lower impacted primary molars. In general, if the root of the impacted tooth is still developing, the tooth may erupt normally; but, once the root apex has closed, the tooth has lost its potential to erupt [31]. Unfortunately, root formation of the impacted molar was complete when we saw the patient. Therefore, it was anticipated that the chance of re-eruption of the impacted right primary molar in this case was low. Interestingly, orthodontic therapy is not usually necessary and is not applied to improve the malocclusion caused by compound odontoma after extirpation of the tumor [9, 32]. The reason is that most odontomas are very small, and the influence of the tumor on occlusion of the tumor is not usually necessary and is not applied to improve the malocclusion caused by compound odontoma after extirpation of the tumor [9, 32].

In conclusion, the much earlier detection and removal of a compound odontoma associated with an impacted tooth might have contributed to the favorable results for establishing acceptable occlusion.
