ABSTRACT

We present a statistical analysis of voids in the 2dF galaxy redshift survey (2dFGRS). In order to detect the voids, we have developed two robust algorithms. We define voids as non-overlapping maximal spheres empty of halos or galaxies with mass or luminosity above a given one. We search for voids in cosmological N-Body simulations to test the performance of our void finders. We obtain and analyze the void statistics for several volume-limited samples for the North Galactic Strip (NGP) and the South Galactic Strip (SGP) constructed from the 2dFGRS full data release. We find that the results obtained from the NGP and the SGP are statistically compatible. From the results of several statistical tests we conclude that voids are essentially uncorrelated, with at most a mild anticorrelation and that at the 99.5% confidence level there is a dependence of the void number density on redshift. We develop a technique to correct the distortion caused by the fact that we use the redshift as the radial coordinate. We calibrate this technique with mock catalogues and find that the correction might be of some relevance to carry out accurate inferences from void statistics. We study the statistics of the galaxies inside nine nearby voids. We find that galaxies in voids are not randomly distributed: they form structures like filaments. We also obtain the galaxy number density profile in voids. This profile follow a similar but steeper trend to that follow by halos in voids.

Key words: large-scale structure of Universe; cosmology: observations; methods: statistical

1 INTRODUCTION

There are many tests to constrain the models of structure formation, which range from the large-scale statistics such as correlation functions (Peebles 1980; Davis & Peebles 1983; Zehavi et al. 2002; Norberg et al. 2002) or the power spectrum (Peebles 1980; Tegmark et al. 2004; Cole et al. 2005), to detailed studies of the physical properties of individual galaxy clusters and voids. Although dense environments (i.e., galaxy clusters and groups) have been extensively studied, the underdense regions like giant voids attract less attention. Yet, they are not less important and can provide important information on galaxy formation (Hoyle et al. 2002; Goldberg et al. 2002; Rojas et al. 2002; Croton et al. 2003) and can give independent constraints on cosmological models (Peebles 1980; Plionis & Basilakos 2002; Solevi et al. 2005; Conroy et al. 2005). Large voids have woken up more and more interest since their first detections 25 years ago (Kirshner et al. 1981, Rood 1981). At present, thanks to the advent of larger redshift surveys like the 2dFGRS (Colless et al. 2001) and the SDSS (York et al. 2000), higher resolution of cosmological simulations and better analytical frameworks, we can extract accurate statistical information about voids. This information can be used in different ways but one of the most important is to test the models of structure formation.

Voids can be studied in different ways. One of the classical methods is the Void Probability Function (VPF White 1974; Fry 1986), which gives the probability that a randomly located sphere of a given radius contains no galaxies (see e.g. Einasto et al 1991, Croton et al. 2004, Solevi et al. 2005). The number density of voids with radius greater than $R$ is an-
other useful statistic. This number density and also the void significance can be estimated analytically (see Patiri et al. 2004). So far, it has been done only using numerical simulations or mock catalogs (Colberg et al. 2003).

Voids in the 2dFGRS were previously studied by Hoyle & Vogeley (2004) and Croton et al. (2004). Croton et al. (2004) have measured the VPF for volume-limited galaxy samples covering the absolute magnitude range $M_B - 5 \log_{10} h = -18$ to $-22$. Their work mainly focused on the study of the dependence of the VPF on the moments of galaxy clustering as a test to discriminate among different clustering models. They found that the VPF measured from the 2dFGRS is in excellent agreement with the paradigm of hierarchical scaling of the galaxy clustering. In addition, they showed that the negative binomial model gives a good approximation of the 2dF data over a wide range of scales. On the other hand, Hoyle & Vogeley (2004) have also calculated the VPF in the 2dFGRS obtaining similar results. They have obtained the VPF for the dark matter halos in ΛCDM simulations and galaxy mock catalogs from semi-analytic models of galaxy formation to compare with the data. They have found that the results from the semi-analytic models that include feedback effects provide a VPF that agree with the VPF measured for the 2dFGRS and differ from that measured from the dark matter distribution.

In spite of the fact that the notion of voids is not new, there is no standard definition of what is a void. “Voids” sometimes mean quite different objects. It all depends on used data and goals of the analysis. For example, to explain the patterns of the galaxy distribution in the Universe Van de Weygaert & Van Kampen (1993) and Sheth & Van de Weygaert (2004) define voids as irregular low-density regions in the density field. Colberg et al. (2004) use a similar definition to study void properties in a ΛCDM universe. However, as these definitions are not based on point distributions, it may be difficult to deal with the galaxy samples provided by large scale redshift surveys. El Ad & Piran (1997), Hoyle & Vogeley (2002) and Hoyle & Vogeley (2004) define voids as irregular regions of low number-density of galaxies, which may contain bright galaxies. Thus, by construction, voids are not empty even of very luminous and likely massive galaxies. By contrast, Gottlöber et al. (2003) define voids as spherical regions which do not have massive objects (halos in this case). Voids also can be defined in a statistical point of view as maximal spheres (Otto et al. 1986; Einasto, Einasto & Gramann, 1986; Gottlöber et al. 2003; Patiri, Betancort-Rijo & Prada, 2004).

In this paper we define voids as the maximal non-overlapping spheres empty of objects with mass (or luminosity) above a given value. For example, we could define voids as maximal spheres empty of Milky Way-size galaxies. While voids are empty of these galaxies, they could have fainter galaxies inside. See Figure 1 for a graphical representation of our definition.

The first step to follow using voids as a test for large scale structure and galaxy formation models is to develop a robust algorithm to detect them, to calibrate it, and to obtain the statistical properties of voids for different catalogs both real and simulated ones. With this information and with the predictions made through the analytical formalism we may be able to contrast different structure formation models. To achieve this goal we develop two algorithms. They are conceptually different but are based on the same definition of void model. We develop them as complementary tools. One algorithm is intended to search for all the voids in galaxy or dark matter halo samples and the other is developed to search for the rarest voids.

Once we have the tools to detect the voids, we study statistical properties that will be used to test the structure formation models. These properties go from the void correlations to the redshift dependence of voids. In the present work, we apply the tools we mentioned above in order to study the statistic of voids in the 2dF Galaxy redshift Survey. One important point that could provide clues on the galaxy formation processes is the galaxy contents of voids.

In this work, we present the first results on the distribution of faint galaxies in nearby voids.

In section 2 we briefly describe how to detect voids. In section 3 we present the statistics of voids found in cosmological numerical simulations and compare the performance of our algorithms. In section 4 we present the voids that we have found in the 2dFGRS together with their statistical properties. In section 5 we develop a method to get from the redshift space coordinates, the real space ones. In section 6 we present the statistics of the galaxies inside nearby rare voids. finally, in section 7 conclusions and discussions are presented. In Appendix A we give details of our void finders presented in section 2. Here we also provide tests in order to check the performance of them.

Throughout this work we adopt a ΛCDM cosmology model with parameters $\Omega_m = 0.3$ and $\Omega_\Lambda = 0.7$.

2 VOID DETECTION ALGORITHMS

Once we have defined what is a void (as the maximal non-overlapping spheres empty of galaxies brighter than a given magnitude), the next step is to develop an algorithm to be able to find them in galaxy or dark matter halo samples. The computation structure of the algorithm naturally will depend mainly on the void definition. Following the definition we have stated in the previous section, the algorithm should try to find the maximal sphere that the void can accommodate.

There are many algorithms in the literature inspired by the different void definitions (see e.g. Einasto et al 1989, Kauffmann & Fairall 1991, El Ad & Piran 1997, Aikio & Mahoe 1998, Gottlöber et al. 2003, Colberg et al 2004). Aikio & Mahoe 1998 and Colberg et al 2004 have developed similar algorithms. Following their definitions of voids, they generate a field smoothing the point distribution on a cubic grid and find the local minima; then, they put spheres around those minima filling the entire underdense region. The radius of these voids are the effective ones taken from the sphere that contain the same volume as the void. Gottlöber et al. 2003 have developed an algorithm based on the minimal spanning tree for halos selected by intrinsic properties, in this case with mass above a given value. Although they have searched for voids as local maximal spheres, they did not do voids statistics in their work.

Another algorithm in literature is the so-called void finder developed by El Ad & Piran (1997) and its modifica-
galaxies more luminous than a given luminosity \(L\), which are empty of objects classified by some intrinsic property. For example, in galaxy samples our voids will be defined by galaxies more luminous than a given luminosity \(L\) (filled circles). Open circles denote galaxies with luminosity fainter than \(L\). Note that for simplicity we do not show the open circles located outside the maximal sphere.

Figure 1. A graphic representation of our void definition. Voids are maximal non-overlapping spheres, in the observational domain, which are empty of objects classified by some intrinsic property. For example, in galaxy samples our voids will be defined by galaxies more luminous than a given luminosity \(L\) (filled circles). Open circles denote galaxies with luminosity fainter than \(L\). Note that for simplicity we do not show the open circles located outside the maximal sphere.

\[

\text{(h^{-1}Mpc)} & \text{(h^{-1}M_{\odot})} & & \\
80 & 3.18 \times 10^8 & 512^3 & 0.90 \\
120 & 1.07 \times 10^9 & 512^3 & 0.90 \\
500 & 7.80 \times 10^{10} & 512^3 & 0.90 \\
\end{array}
\]

Table 1. Parameters of simulations

tions done by Hoyle & Vogeley (2002). This algorithm search for arbitrarily shaped regions delimited by the so-called wall galaxies in order to get the maximum volume of the void. They classify the galaxy sample in wall galaxies and field or voids galaxies by mean of a criteria that depends on the galaxy distribution itself, i.e. they define a length parameter \(l_n\) such that any galaxy that does not have \(n\) neighbours within a sphere of radius \(l_n\) is classify as field galaxy. Note that field galaxies could be, for example, bright galaxies. These field galaxies are removed before searching for voids. Once the classification is done, the algorithm search for the maximal spheres defined by the wall galaxies based on a cubic mesh. Once all the spheres are obtained, they define an overlapping parameter to discriminate if two spheres belong to the same void. Similarly to Aikio & Mahoenen (1998) and Colberg el al (2004), they finally fill the voids with spheres to get the maximum volume. Again, they define the effective radius of a void by means of a sphere that contain the same volume as the void.

Note that, although this may be interesting for some studies (e.g. the shapes of voids), these kind of statistics degrade in some amount the information available in the actual galaxy distribution, so they might not be particularly powerful to conduct accurate statistical inferences. This is similar to what happens with the binned data: the best statistical test using binned data is never better and usually worst than the best test using the raw data.

To identify voids, we designed two algorithms that are conceptually different but both are based in our definition of voids. The algorithms are complementary. They help us to investigate the variety of aspects present in the statistics of voids.

One of the algorithms, which we call \textit{CELLS void finder}, was designed to search for all the voids in a galaxy or halo sample based on a computational grid. This grid define the working resolution. To determine the void centers, the code computes the distances between each of the empty grid cells and all the galaxies or halos in the whole observational domain, keeping the minimum distance. Once we have the list with the minimum distances, we search for the local maxima which corresponds to the void centers. Obviously, the voids radius are those maximum distances.

The other algorithm, which we denominate \textit{HB Void Finder} is conceptually simple. This code searches for the maximal non-overlapping spheres with radius \textit{larger} than a given value. First of all, we generate over the sample a large sample of random spheres of a given radius. After this, we check and keep the spheres that are empty of galaxies. We inflate these spheres until they reach the maximum radius. Finally, we eliminate the overlapping spheres keeping the maximal ones. This code is very accurate and computationally efficient to search the biggest voids in a galaxy sample. Detailed descriptions of the two algorithms are given in the Appendix.

3 VOID STATISTICS IN SIMULATIONS

3.1 Numerical simulations

We perform a series of numerical simulations with the Adaptive Refinement Tree code (ART, Kravtsov et al. 1997) and the Tree-SPH code GADGET (Springel, Yoshida & White, 2001). Dark matter halos are identified in the simulation by the Bound Density Maxima algorithm (BDM, Klypin & Holtzman 1997; Klypin et al. 1999).

In this work we detect and study voids in simulation boxes of \(80h^{-1}\)Mpc, \(120h^{-1}\)Mpc and \(500h^{-1}\)Mpc size. The parameters of all the simulations are summarized in Table 1. With these boxes we have enough volume to study accurately the void statistics and compare the results obtained with our two void finders.

3.2 The statistics

In Figure 4 we show the number density of voids as a function of their radius obtained with our void finders (squares for \textit{CELLS void finder} and circles for the \textit{HB void finder}). These results were obtained for voids defined by two halo masses (\(1 \times 10^{12}M_{\odot}\) (open symbols) and \(5 \times 10^{12}M_{\odot}\) (filled symbols)).

In order to search for voids with the \textit{HB Void Finder}, we have generated \(1 \times 10^7, 2 \times 10^7, 5 \times 10^7\) trial spheres for the
2dFRGS is taken from the APM galaxy catalogue (Mad-dox et al. 1990). The spectroscopic targets are galaxies with extinction corrected magnitudes brighter than $b_j = 19.45$. The median depth of the survey is $z \sim 0.11$. The final data releases contains a total of 221,144 high quality redshifts. There are two large contiguous survey regions, one in the south Galactic pole (SGP) and another one towards the north Galactic pole (NGP). There are also a number of random fields which we have eliminated from our void search. Full details of the 2dFGRS can be found in Colless et al.(2001, 2003).

In order to search for the voids we have selected from 2dFGRS two rectangular regions; the region in the SGP defined by $-34^h40^m < \delta < -25^h12^m$ and $21^h49^m < \alpha < 3h26^m$ and the region in the NGP defined by $-4^h35^m < \delta < 2^h17^m$ and $9^h33^m < \alpha < 14^h54^m$; that is, $\sim 690$ and $\sim 550$ sq. degrees respectively.

The 2dFGRS is magnitude-limited, i.e. the survey has been constructed by taking spectra of galaxies brighter than a fixed apparent magnitude of $b_j = 19.45$. However the survey is not uniform in space, since intrinsically faint galaxies have been observed only if they are relatively nearby, while at large distances only bright galaxies will be targeted. This non uniformity of the magnitude-limited survey must be taken into account in order to make our void analysis. There are mainly two ways to deal with this; one is to use the selection functions provided by the 2dFGRS and another more simple way which we have followed here is to build volume-limited samples.

We construct four volume-limited samples, two for each survey region (SGP and NGP), one with depth $D_{max} = 406.15h^{-1}$Mpc which corresponds to $z = 0.14$. For this $D_{max}$ we have a limiting absolute magnitude $M_{lim}^{max} = -19.32 + 5 \log h$ and the other with depth $D_{max} = 571.71h^{-1}$Mpc corresponding to $z = 0.2$ and a limiting absolute magnitude $M_{lim}^{max} = -20.18 + 5 \log h$. All distances are comoving ones. In Table 2 we give the properties of the volume-limited samples. Now, we have guaranteed that any galaxy brighter than $M_{lim}^{max}$ is observed in our volume. We have computed the absolute magnitudes from the apparent magnitudes assuming a $\Lambda$CDM cosmology and applying the needed corrections to model the change in the galaxy magnitudes due to the redshifted $b_j$ filter bandpass ($k$-correction) and to account for the galaxy evolution ($e$-correction). These corrections for each galaxy are given in Norberg et al.(2002).

To test the spatial homogeneity of our SGP,1,2 and NGP,1,2 volume-limited samples we have computed the average of the cube of the radial distances, i.e. a modified version of the $V_{max}$ test (Rowan-Robinson 1968), which for a homogeneous sample must satisfy:

$$\left< \left( \frac{r}{r_{max}} \right)^3 \right> = \frac{1}{2} \pm \frac{1}{\sqrt{12} N'}$$

$$N' = \frac{N}{1 + N < \xi(r) >}$$

where $r$ is the comoving distance to each galaxy, $r_{max}$ is the same as $D_{max}$, the maximum distance of the sample, $N$ is the number of galaxies (given in table 2) and $< \xi(r) >$
is the average value of the correlation function over all pair of galaxy positions within the sample, defined as:

\[ < \xi > = \frac{1}{V} \int \int \xi(|r_1 - r_2|) \, dr_1 \, dr_2 \quad (2) \]

where \( V \) is the volume of the sample. Assuming for \( \xi(r) \) (Peebles 1980):

\[ \xi(r) = \left( \frac{r}{5.4 h^{-1} \text{Mpc}} \right)^{-1.77} \quad (3) \]

we found \( < \xi(r) > = 6.7910 \times 10^{-3} \). It must be noted that we have used eq. (3) for any value of \( r \), while in fact, it is known that for \( r \gg 10 h^{-1} \text{Mpc} \) \( \xi(r) \) must be close to the fourier transformed of the linear power spectra. This would lead to smaller values of \( < \xi(r) > \). However, this would not affect our analysis too much. With this value we find that for a homogeneous sample:

\[ \eta \equiv \left( \frac{r}{r_{\max}} \right)^3 = \frac{1}{2} \pm 0.024. \quad (4) \]

The actual \( \eta \) values for the SGP1 and NGP1 are \( \eta(\text{SGP1}) = 0.524 \) and \( \eta(\text{NGP1}) = 0.51 \). For the SGP2 and NGP2 to be homogeneous (assuming that \( < \xi(r) > \) takes the same values as in the previous sample):

\[ \eta \equiv \left( \frac{r}{r_{\max}} \right)^3 = \frac{1}{2} \pm 0.0253, \quad (5) \]

and the actual values are \( \eta(\text{SGP2}) = 0.511 \) and \( \eta(\text{NGP2}) = 0.475 \). Therefore, we can conclude that we do not detect inhomogeneities.

### 4.2 The void statistics

As described in section 3.2, once we have constructed our samples, we have to define which objects will define the voids. In the SG1 and NGP1 volume limited samples we present in table 2 we search for voids defined by two types of galaxies. In the one hand, we search voids defined by galaxies brighter than \( M_{bJ} = -19.32 + 5 \log h \). Using these samples we also find voids defined by galaxies brighter than \( M_{bJ} = -20.5 + 5 \log h \). The number of galaxies brighter than \( M_{bJ} = -20.5 + 5 \log h \) is 2427 for the SGP1 sample and 2074 for the NGP1. In the SGP2 and NGP2 samples, we have searched for voids defined by galaxies brighter than \( M_{bJ} = -20.18 + 5 \log h \). In Figure 3 we show a plot with the voids we have detected in the NGP1 sample. In table 3 we summarize the results for the NGP1 and SGP1 samples. Note that, as we saw in the simulations, voids defined by bright galaxies are larger than the ones defined by fainter ones. In table 4 we present the statistics for the NGP2 and SGP2 samples. We have obtained these voids applying the HB algorithm. In the radius ranges that we present here both codes have a similar performance. We generate \( 8 \times 10^7 \) trial spheres to search for voids larger than \( 7.5 h^{-1} \text{Mpc} \) which are our main interest.

We have also calculated the VPF which is the probability that a randomly located sphere of fixed radius contains

### Table 2. Parameters of our Volume Limited Samples.

| Name   | \( M_{1m} \) \( M_{bJ} - 5 \log h \) | \( z_{\text{max}} \) | \( D_{\text{max}} \) \( h^{-1} \text{Mpc} \) | Volume \( 10^6 h^{-3} \text{Mpc}^3 \) | \( N_{\text{vox}} \) |
|--------|----------------------------------|----------------|----------------------------------|----------------------------------|----------------|
| SGP1   | -19.32                           | 0.14           | 406.15                           | 4.693                            | 22037          |
| SGP2   | -20.181                          | 0.20           | 571.71                           | 13.088                           | 14475          |

\]

no galaxies. Figure 4 presents our VPF, which we find for the SGP1,2 and NGP1,2 samples. We calculate the \textit{rms} of the VPF in the following way. Assuming that voids are independent, we get from the central limit theorem that

\[ \text{rms}^2(P_0(r)) = \frac{N(r)}{V^2} (< \Delta v^2 > - < \Delta v >^2) \]  

(6)

where \( \Delta v \) is the volume where the center of an empty sphere of radius \( r \) may be moved so that it remains empty. \( V \) is the volume of the sample and \( N(r) \) is the number of voids found with radius larger than \( r \) in that volume. The parenthesis in the right hand side of eq. 6 divided by \( V^2 \) is the contribution of each individual void to the variance of the VPF.

On the other hand we have from Betancort-Rijo \cite{1992} that

\[ \frac{N(r)}{V} = \frac{P_0(r)}{< \Delta v >} \]  

(7)

Now we square this expression and substitute it in expression 6 to obtain:

\[ \text{rms}^2(P_0(r)) = \frac{P_0(r)}{< \Delta v >} (g(r) - 1) \]  

(8)

\[ g(r) \equiv \frac{< \Delta v^2 >}{< \Delta v >^2} \]  

(9)

So that, taking into account the correlations in the sample, the \textit{rms} of the VPF is given by:

\[ \text{rms}(P_0(r)) \simeq g(r)^{1/2} \frac{P_0(r)}{N(r)^{1/2}} (1 - w\bar{n}_v(R))^{1/2} \]  

(10)

where \( w\bar{n}_v(R) \) is as defined in Eq. 24. In the rare voids limit, i.e. when \( P_0 << 1 \) it is shown that Betancort-Rijo \cite{1992}:

\[ g(r) \simeq 9.20 \]  

(11)

For voids with radius larger than 12h^{-1}\text{Mpc in the SGP1 and NGP1 samples and larger than 17h^{-1}\text{Mpc in the SGP2 and NGP2 samples, the asymptotic value } g(r)^{1/2} = 2.86 \text{ is a good approximation. For smaller values of } r, g(r)^{1/2} \text{ is somewhat smaller (no less than } \sim 2). \text{ So in figure 4, where the asymptotic value of } g(r) \text{ have been used, the error may be slightly overestimated for small values of } r. \text{ It must be noted, however, that the probability distribution of the fluctuations of the VPF around the mean is strongly non-Gaussian for small values of } N(r); \text{ most fluctuating being quite smaller than the } \text{rms} \text{ and a few of them being very large. So, to decide the compatibility between couples of measurements, this fact has to be taken into account. In the present case, however, this problem do not arise because all results are within the error bars.}

Our results are in good agreement with the previous calculations of the VPF \cite{1994}. In Croton et al.\cite{2004} the VPF was obtained for the whole 2dFGRS while Hoyle & Vogeley \cite{2004} have studied the VPF for both strips (NGP and SGP). In this last result, they found that the VPF for both strips are not compatible for large spheres (see figure 7 in Hoyle & Vogeley 2004). This is due to the fact that they underestimated the error bars. We have shown above that using a more accurate expression for the \textit{rms} of the VPF we obtain that both strips are compatible.

### 4.3 Voids spatial distribution

If we neglect the redshift dependence of the power spectra, the spatial distribution of the voids found in a statistically homogeneous sample must be statistically homogeneous itself, but conditioned to the fact that the maximal sphere must lay within the sample. This fact implies that the center of the maximal spheres can not occupy all the volume of the sample. The available volume, \( V(R) \), for the maximal spheres of radius \( R \) is:

\[ V(R) = \int_{\delta_0-B(R,\delta)}^{\delta_0+B(R,\delta)} \int_{\delta_0+B(R,\delta)}^0 r^2 \cos \delta \alpha \, d\delta \, d\alpha \]  

(11)

\[ B(r, R, \delta) = \sin^{-1} \left( \frac{\sin^{-1}(\frac{\Delta \delta}{\cos \delta})}{\cos \delta} \right) \]  

(12)

Eq. 11 may be considerably simplified by carrying out the integrals over \( \alpha \) and \( \delta \) keeping \( B \) fixed (using its value at \( \delta_0 + \Delta \delta/2 \)). This is a very good approximation since \( \Delta \delta << 1 \). So, we could write:

\[ V(R) \simeq \int_{\delta_0-B(R,\delta)}^{\delta_0+B(R,\delta)} P(r, R) r^2 \, dr \]  

(13)
\[ P(r, R) = \left[ \sin(\delta_0 + \Delta \delta - \sin^{-1}(\frac{R}{r})) - \sin(\delta_0) \right] \times \]
\[ \times \left[ \Delta \alpha - 2 \sin^{-1}\left(\frac{\sin^{-1}(\frac{R}{r})}{\cos(\delta + \frac{\Delta \delta}{2})}\right) \right] \]  
\( \Delta \delta, \Delta \alpha \) are, respectively, the widths of the strips in declination and right ascension, while \( \delta_0 \) is its southernmost declination. Although expression (13) for \( V(R) \) is not exact, its percentual error is completely negligible (less than \( 10^{-8} \)).

Using \( P(r) \) we may obtain the mean of the cube of the distance (from the observer), \( r \), to the center of the maximal sphere with radius larger than \( R' \):

\[ \eta(R') \equiv \left( \frac{r}{r_{\text{max}}} \right)^3 \Bigg|_{R < R' < R} = \frac{1}{V(R)} \int_{r_{\text{max}} - R}^{r_{\text{max}}} P(r, \bar{R}) \left( \frac{r}{r_{\text{max}}} \right)^3 r^2 dr \]  

where \( \bar{R} \) is the mean radius of all maximal spheres larger than \( R' \).

In a similar manner we may obtain the variance for the estimate of \( \eta(R'/h^{-1}\text{Mpc}) \) from the void list we have obtained in the 2dFGRS. The values found in the SGP1,2 and NGP1,2 for voids defined by galaxies brighter than \( -19.32 + 5 \log h \) are listed in Table 5.

| Radius \((h^{-1}\text{Mpc})\) | \(\eta\) NGP1 | \(\eta\) SGP1 |
|-----------------------------|-------------|-------------|
| 7.5                        | 0.512 (0.563 ± 0.02) | 0.503 (0.53 ± 0.02) |
| 10.0                       | 0.579 (0.579 ± 0.038) | 0.508 (0.54 ± 0.03) |
| 13.0                       | 0.660 (0.615 ± 0.116) | 0.433 (0.558 ± 0.08) |
| 18.0                       | 0.475 (0.611 ± 0.085) | 0.588 (0.556 ± 0.06) |

**Table 5.** The values of \( \eta(R') \) found in the SGP1,2 and NGP1,2 samples. The values within the parenthesis are 1σ predictions assuming that the center of the maximal spheres are uniformly distributed conditioned to lay entirely within the sample (see text).

The maximal spheres are chosen so that they do not overlap, in order that they very rarely corresponds to the same connected underensity. So, by construction, for the maximal spheres with radius larger than \( R \) the two point correlation function of their centers is \(-1\) at least to a distance of \( 2R \). The main question is how is the correlation at larger distances. Note that if more than one maximal sphere were associated with the same underlying connected underdensity the correlation would be positive for distances somewhat larger than \( 2R \). However, as there is typically only one maximal sphere per underdense region and in the standard scenario of structure formation these regions are essentially uncorrelated (for the relevant \( R \) values) (Colberg et al. 2004), we do not expect to find correlations between the maximal spheres.

To test whether voids are correlated we compare the actual nearest neighbour statistics with the theoretical predictions corresponding to centers which are uncorrelated for distances larger than \( 2R \) and completely anticorrelated for smaller distances. For maximal spheres with radius \( R \) the theoretical predictions for the mean and quadratic mean distance to the nearest neighbour \( < D_{oo} > \) and \( < D_{oo}^2 > \) respectively) is given by:

\[ < D_{oo} > = \left( \frac{4\pi \bar{n}_v(R)}{3} \right)^{-1/3} \int_{w_0}^{\infty} e^{-(w-w_0)} w^{1/3} dw \]  

\( w_0 \equiv \frac{4\pi}{3} (2\bar{R})^3 \bar{n}_v(R) \)  

where \( \bar{n}_v(R) \) is the mean number density of the maximal spheres larger than \( R \) and \( \bar{R} \) is the mean radius. The sampling error of \( < D_{oo} > \) when estimated using \( N \) centers is:

\[ \text{rms}(< D_{oo} >) = \sqrt{\frac{\bar{N}(< D_{oo}^2 > - < D_{oo} >^2)^{1/2}}{(3N - 2)^{1/2}}} \]  

with these expressions we may compute the mean and the variance of \( q \):

\[ q \left( \frac{R}{h^{-1}\text{Mpc}} \right) \equiv \left( \bar{n}_v(R) \right)^{1/3} E(< D_{oo} >) \]  

where \( E(< D_{oo} >) \) is the estimate of \( < D_{oo} > \) using the void sample. For typical voids we find for \( q \):

\[ \text{rms}(q) = \sqrt{\frac{\bar{N}(q^2 - (q))^2}{(3N - 2)^{1/2}}} \]
where $R = 7.5 h^{-1}$ Mpc ($\bar{R} = 9.58 h^{-1}$ Mpc) correspond to SGP1, NGP1 and $R = 13.0 h^{-1}$ Mpc ($\bar{R} = 15.08 h^{-1}$ Mpc) to SGP2, NGP2. The values in the parenthesis correspond to 1σ predictions obtained using Eqsns. (14) and (15).

It is apparent that the estimated values are slightly shifted upwards. The bias is large in terms of the rms’s but we can not conclude from this that the centers are anticorrelated since the predictions do not account for border effect, which in this cases is small for the SGP samples but larger than the rms.

On the other hand, for rare voids, i.e. $R = 13.0 h^{-1}$ Mpc for the SGP1, NGP1 samples ($\bar{R}_{SGP1} = 14.1 h^{-1}$ Mpc, $\bar{R}_{NGP1} = 13.42 h^{-1}$ Mpc) and $R = 18.0 h^{-1}$ Mpc for the SGP2, NGP2 samples ($\bar{R}_{SGP2} = 19.5 h^{-1}$ Mpc, $\bar{R}_{NGP2} = 18.45 h^{-1}$ Mpc) we find:

\begin{align*}
q_{SGP1}(7.5) & = 0.978 (0.958 \pm 0.006) \\
q_{NGP1}(7.5) & = 1.029 (0.958 \pm 0.008) \\
q_{SGP2}(13.0) & = 0.966 (0.879 \pm 0.01) \\
q_{NGP2}(13.0) & = 1.1 (0.879 \pm 0.013)
\end{align*}

The upward bias with respect to the values for the uncorrelated centers (without accounting for border effects) is now large even in the SGP. To assess the border effect we have simulated a random set of spheres with $R = 19.5 h^{-1}$ Mpc, which lay entirely within the catalogue and do not overlap, with the results of Colberg et al. 2004. The reason is that the maximal spheres show some anticorrelation. We prefer, however, to conclude simply that those centers are basically uncorrelated, which is the necessary result for the subsequent statistical inferences, and leave open the question of the possible existence of a weak anticorrelation, which shall be treated in more detail in a future work. Incidentally, it must be noted that a slight anticorrelation of the centers arise naturally in the standard scenario, being compatible with the results of Colberg et al. 2004. The reason is that the connected underdense regions are somewhat larger than the maximal spheres they contain.

4.4 Compatibility between SGP and NGP samples

Here we compare the void statistics found in our samples in order to assess their compatibility. To this end we must estimate the mean number density of voids, $\bar{n}_v(R)$, in each sample and obtain their sampling error. To estimate $\bar{n}_v(R)$ we simply divide the number of voids, $N(R)$, with radius larger than $R$, by the mean available volume $V(R)$. To estimate the sampling error we must take into account that, although the center of the maximal spheres are basically uncorrelated for $r > 2\bar{R}$, they are totally anticorrelated for $r < 2\bar{R}$ (we use a model in which all spheres have radius $\bar{R}$). In this case the number of spheres in a given volume do not follow a Poissonian distribution, but a negative binomial one (Betancort-Rijo 1999). For this distribution the sampling error of the estimate of $\bar{n}_v(R)$ could be obtained by means of the following expression:

$$w = \frac{32\pi}{3} \bar{R}^3 \left[ 1 + 2.73 \bar{n}_v(R) \frac{32\pi}{3} \bar{R}^3 \times \left( 1 - \frac{3}{4} \left( \frac{\bar{n}_v(R)^{-1/3}}{2\bar{R}} \right) + \frac{1}{8} \left( \frac{\bar{n}_v(R)^{-1/3}}{2\bar{R}} \right)^2 \right) \right]^{-1}$$

For SGP1 we find:

\begin{align*}
\bar{n}_v(7.5) & = 9.364 \pm 0.164 \times 10^{-5} \\
\bar{n}_v(10.0) & = 3.98 \pm 0.11 \times 10^{-5} \\
\bar{n}_v(13.0) & = 7.26 \pm 1.70 \times 10^{-6}
\end{align*}

For NGP1 we find:

\begin{align*}
\bar{n}_v(7.5) & = 9.597 \pm 0.214 \times 10^{-5} \\
\bar{n}_v(10.0) & = 4.27 \pm 0.15 \times 10^{-5} \\
\bar{n}_v(13.0) & = 6.56 \pm 2.10 \times 10^{-6}
\end{align*}

The corresponding $\bar{R}$’s are: $\bar{R}(7.5) = 9.58$ and $\bar{R}(10.0) = 11.35$ (the mean over NGP and SGP), $\bar{R}(13.0) = 14.14$ in the SGP1 and $\bar{R}(13.0) = 13.41$ in the NGP1.

It is apparent that the three pair of values are compatible. It is true that for the SGP1 the galaxy density is roughly a 10% smaller than for the NGP1 and that the theoretical expression [Patiri, Betancort-Rijo & Prada 2004] predict about a 20% enhancement of the density of voids with $R \geq 13 h^{-1}$ Mpc in the SGP1 over that in the NGP1, and smaller differences for more common voids, but this differences do not show up above the sampling errors.

Similar results were found for the SGP2:

\begin{align*}
\bar{n}_v(13.0) & = 1.685 \times 10^{-5} \\
\bar{n}_v(15.0) & = 9.49 \times 10^{-6} \\
\bar{n}_v(18.0) & = 2.978 \pm 0.58 \times 10^{-6}
\end{align*}

and NGP2:

\begin{align*}
\bar{n}_v(13.0) & = 2 \times 10^{-5} \\
\bar{n}_v(15.0) & = 1.202 \times 10^{-5} \\
\bar{n}_v(18.0) & = 2.22 \pm 0.69 \times 10^{-6}
\end{align*}

Although the implications of this results for the large scale structure formation models is left to for a future work, it is interesting to note that they are generally in good agreement with the predictions of the standard model.
4.5 Redshift dependence of void number densities

We have checked that the galaxies in our samples are, within the sampling errors, homogeneously distributed over the sample volumes. In this situation, the only possible explanation of an statistically significant departure of the void distribution from the homogeneity must be the redshift dependence of the properties of the large scale structure.

Using a theoretical framework (Patiri, Betancort-Rijo & Prada 2004) to compute the number density of voids in the distribution of dark matter halos, we found that the predicted number density of voids larger than $13.0h^{-1}$Mpc for $M_{b_{0}}^{lim} = -19.32 + 5\log h$ decreases by 28% from $z=0$ to $z=0.1$ and a further 28% when going to $z=0.2$. For $M_{b_{0}}^{lim} = -20.181 + 5\log h$ and $R \geq 18h^{-1}$Mpc the void density decreases by 26% from $z=0$ to $z=0.1$ and another 28% from $z=0.1$ to $z=0.2$. Where, in order to link light with dark matter halos, we assumed that there is one galaxy in each dark halo. These numbers suggest the possibility of a measurable effect. To this end we conduct first a test where we divide every sample into two bins (a 'near' region and a 'far' region) both with the same volume available for the voids considered. Then we compare the total number of voids larger than the chosen radius in the near regions with the total number in the far regions. If the first number is significantly larger than the latter this should be interpreted as evidence for a redshift dependence.

The problem now is that the effect we are trying to measure is strong only for the rare voids which have poorer dependence of the properties of the large scale structure. We reach a compromise between both trends. We measure is strong only for the rare voids which have poorer dependence.

5 REDSHIFT SPACE DISTORTIONS

Redshift galaxy maps like the 2dFGRS or SDSS are distorted by the peculiar velocities of galaxies along the line of sight. This effect, which produce deformations such as the “finger of God”, is due to the fact that the distance to the survey galaxies is obtained by means of the Hubble distance which is obtained with the total velocity (the Hubble flow plus the peculiar velocity).

We present in this section a method to correct this effect for the galaxies around voids. We first suppose that if in the distorted space we have a void of radius $R$, we will have the same void of radius $R$ in the real space. This is a good approximation because the distortion around a void cause an elongation along the line of sight of the maximal sphere without changing the “transversal” radius, i.e., although the distortion is not volume conservative, the maximal radius will be approximately the same in both spaces.

With this assumption, we have in the position of the void in the distorted space a mean under-density, $\delta_0$, within the maximal sphere with radius $R$ (Patiri, Betancort-Rijo & Prada 2004):

$$\delta_0 = \int_{-1}^{\infty} \delta_0 P(\delta_0/R) d\delta_0$$

where $P(\delta_0/R)$ is the probability distribution for $\delta_0$ within a maximal sphere of radius $R$.

We associate with this void a matter distribution given by the mean profile, $\delta(r/\delta_0, R)$. In Patiri, Betancort-Rijo & Prada (2004) we derive this profiles. So, it has a peculiar velocity profile $V(\delta(r), r)$ given by the spherical collapse model (Betancort-Rijo et al. 2005):

$$V(\delta(r), r) = -0.5 \frac{r}{1 + \delta} \delta_0(\delta) \left( \frac{db_0(\delta)}{d\delta} \right)^{-1}$$
where $H$ is the Hubble constant, $\delta(\delta)$ is given in Sheth & Tormen (2002) and $\delta$ is the mean profile (note that for simplicity we do not show the dependence on $r$, $\delta_0$ and $R$).

We have derived an analytical approximation for $\delta(r/\delta_0, R)$ which gives good results for $r \lesssim 1.5 R$:

$$\delta(r/\delta_0, R) \approx \delta_0 + (0.1645 + 0.085 \delta_0)(r/1.4 R)^7$$

So that, we correct the galaxy “measured” distance $r(z)$:

$$r_{\text{real}} \approx r(z) - \frac{\delta_r - \delta_c}{\delta_r - \delta_c} V(\delta(r/\delta_0, R), r)$$

where $\delta_r$ is the vector to the galaxy and $\delta_c$ is the vector to the center of the void. We apply this correction to galaxies with distance to the center of the void $\lesssim 1.5 R$. Once we have the corrected catalogue, we search for voids over this new catalogue.

In order to test our technique, we have applied it to a simulated catalogue, the Millennium Run galaxy catalogue (Springel et al. 2005). The public available catalogue contains a total of about 9 million galaxies in the simulation box of 500$h^{-1}$Mpc. For each galaxy, it is available the position and velocity, the total and bulge galaxy magnitudes in 5 bands (ugriz SDSS bands), the total and bulge stellar mass, cold, hot and ejected gas mass, the black hole mass and the star formation rate. The dark matter halos in the simulation were populated using semi-analytic models of galaxy formation (see Croton et al. 2005 for full details).

We have constructed from the full simulated box a smaller one of 250$h^{-1}$Mpc. With this box we have enough volume to study large (and rare) voids. Also, as we have available in the original catalogue the coordinates in real space, we have constructed another box of 250$h^{-1}$Mpc with the same galaxies but with the coordinates in redshift space.

We have applied our HB void finder to search for voids larger than 13$h^{-1}$Mpc in both distorted and real catalogues. With the list of voids in the distorted catalogue, we have applied the correction to those galaxies that lie within 1.4 radius of the voids. After we have obtained the corrected galaxy catalogue, we run the void finder over this catalogue. In table (6) we show the statistics of voids in the 3 different catalogues: the distorted, the real and the corrected.

From the study of the simulated catalogues we learn that, although the correction may be larger than $3h^{-1}$Mpc (for $R \gtrsim 16h^{-1}$Mpc) for galaxies close to the line of sight to the center of the voids, the correction for the radius of the maximal sphere is, as expected, much smaller. Even so, the difference is not negligible for sufficiently rare voids. We find that the 20 largest voids in the simulated catalogues are on average slightly smaller ($\sim 5\%$) in the corrected catalogue.

From the void statistics found in the corrected SGP1 and NGP1 samples we find that for the corrected SGP1 the ten largest voids are on average 0.83$h^{-1}$Mpc smaller than for the uncorrected one and that the number of voids larger than 12$h^{-1}$Mpc in both samples is 25 for the uncorrected case and 14 for the corrected one. So, since the strongest constraint on the models comes from relatively rare voids, it seems likely that the corrected catalogues must be used in order to be able to make accurate inferences.

### 6 GALAXIES IN NEARBY VOIDS

In this section we study the galaxy content of the nearby rarest voids in our 2dFGRS samples. To this end, we have selected the voids from our SGP1 volume-limited sample described in Section 5.1 (see Table 3). The voids are defined by galaxies brighter than $-19.32 + 5 \log h$. We have searched for faint galaxies down to $M_{b,\text{lim}} = -18.3 + 5 \log h$ inside nine voids with radius larger than $13h^{-1}$Mpc in a volume limited sample up to $z=0.095$. These voids are uncommon (with mean radius of $14.0h^{-1}$Mpc) due to the fact that a randomly placed sphere with radius equal to the mean size of these voids should contain about 50 galaxies brighter than $-19.32 + 5 \log h$. In total we find 130 faint galaxies inside these 9 rare voids, i.e. on average 14 galaxies per void. We have estimated the number density contrast of the galaxies located inside these voids by

$$\delta_{\text{gal}} = \frac{\bar{n}_{\text{void}} - \bar{n}}{\bar{n}}.$$
a 8$h^{-1}$Mpc thick slice of a 18.25$h^{-1}$Mpc void in this sample. The galaxies inside this void almost fully fill the void (open circles). This is not surprising due to the fact that the density contrast of these voids is not too big.

7 DISCUSSION & CONCLUSIONS

We have developed two robust and accurate algorithms to detect non-overlapping maximal spheres in halo or galaxy samples. We have applied them to several numerical simulations boxes in order to study the performance of the algorithms. The results found were very satisfactory.

We have then studied the void statistics in the 2dFGRS. We have detected $\sim$ 350 voids with radius larger than 7.5$h^{-1}$Mpc defined by galaxies with $M_{b_j} < -19.32 + 5\log h$ and $\sim$ 70 voids with radius larger than 13.0$h^{-1}$Mpc defined by galaxies with $M_{b_j} < -20.5 + 5\log h$ in the volume limited samples up to $z_{\text{max}} = 0.14$. We have also obtained the void statistics for the volume limited samples up to $z_{\text{max}} = 0.2$. For this case, we have detected $\sim$ 170 voids with radius larger than 13$h^{-1}$Mpc defined by galaxies brighter than $M_{b_j} < -20.181 + 5\log h$.

The number density of voids larger than $R$ found in the SGP and NGP samples are in good agreement with each other for all values of $R$. We have obtained the VPF for both strips finding results in good agreement with previous ones (Croton et al. 2004; Howle & Voges 2004). We have shown, using an appropriate expression for the VPF sampling errors, that the results found in both strips are statistically compatible.

From the results of several statistical tests we conclude that except for the anticorrelation implicit in the fact that the maximal sphere are chosen so that they do not overlap, they are essentially uncorrelated. There is, however, some evidence for a weak additional anticorrelation, which may be easily explained within the standard scenario of structure formation. We conclude at least at 99.5% confidence level that there is a dependence of the void number density on redshift. We do this by means of a modified version of the $V_{\text{max}}$ test which reveals a small trend towards small $z$ values.

We have also obtain preliminary results on the galaxy contents of nearby voids found in volume-limited galaxy samples in the 2dFGRS. For the nine nearby voids up to $z < 0.095$ in our sample, we have found inside them on average only 15 galaxies fainter than $-19.32 + 5\log h$ (the magnitude of the galaxies which define the voids). These voids are rather empty compare to those defined by brighter galaxies. The galaxies within the voids are not randomly distributed: they are clustered forming well define filamentary structures as that observed in the large-scale structure of the galaxy distribution of the Universe. Moreover, this is the same pattern that show the dark matter halo distribution found inside voids in high resolution N-body simulations. The halos inside voids are distributed in a way that resemble a miniature of the Universe (see Figure 2 in Gottlöber et al. 2003). We have also obtained the number density profile for the galaxies inside the voids. The number density of faint galaxies fall almost a factor 7 from the border of the voids to the inner half. Moreover, the number density of galaxies close of the borders of the voids are still too low compared with the field (almost a factor 5). Gottlöber et al. (2003) and Patiri, Betancort-Rijo & Prada (2004) have obtained the number density profile for halos in voids. From the comparison of these results we can see that even though the number density of galaxies and halos follow

![Figure 6. Averaged enclosed number density profile of faint galaxies ($-19.32 + 5\log h < M_{b_j} < -18.3 + 5\log h$) in nearby voids as a function of the distance from the center of the void (in void radius units). The mean number density of galaxies in the field for these magnitude band is $7.0 \times 10^{-3}(h^{-1}\text{Mpc})^{-3}$.](image6.png)

![Figure 7. Galaxies inside a common void. We show a central 8$h^{-1}$Mpc thick slice of a 18.25$h^{-1}$Mpc void defined by galaxies brighter than $-20.5 + 5\log h$ (filled circles). The galaxies inside the void are fainter down to $M_{b_j} = -18.3 + 5\log h$ (open circles).](image7.png)
similar trends, the galaxy profile is steeper than halos (they fall just a factor 2).

In a future work, we will use the framework developed in Patiri, Betancort-Rijo & Prada (2004) along with the results given here for the number density of voids and their redshift dependence in order to constrain the value of $\sigma_8$. Furthermore, using a halo occupation model (e.g. Berlind et al. 2003) along the lines described in Patiri, Betancort-Rijo & Prada (2004) we shall establish constraints in the relationship between halos and galaxies from void statistics and the statistics of the galaxies inside the voids. In particular, we hope to be able to determine whether or not the conditional luminosity function depends on environment.

In the other hand, the study of the physical properties of the galaxies inside voids could imply constraints on the galaxy formation processes. So, we will analyze the physical properties like colors, metallicities, star formation rates, etc. of galaxies in rare voids that are available from the biggest galaxy surveys (2dFGRS and SDSS) in order to test, for example, the galaxy luminosity function in voids and the density-morphology correlations.

ACKNOWLEDGMENTS

We thank the referee for the comments and suggestions which improved the previous version of the paper. S.G.P. would like to thank the hospitality of the Department of Astronomy of the New Mexico State University where part of this work was done. We also thank support from grant PNAYA 2005-07789.

This work was also partially supported by the Acciones Integradas Hispano-Alemanas. A.K. acknowledges support of NSF and NASA grants to NMSU. Computer simulations have been done at CESGA (Spain), NIC Jülich, LRZ Munich and NASA.

The Millennium Run simulation used in this paper was carried out by the Virgo Supercomputing Consortium at the Computing Centre of the Max-Planck Society in Garching.

APPENDIX A: VOID FINDER ALGORITHMS

A1 Algorithm 1: Cell Void Finder

The first step is to select the sample of galaxies or dark matter halos in our redshift survey or cosmological simulation that will define the voids. We will select galaxies with luminosity greater than a given value $L$ or halos with virial mass greater than $M$.

Once the galaxy or halo sample has been selected our code generates a cubic mesh where the cell size determines the working resolution. Afterwards, the objects are assigned to cells. So we have three types of cells: those that contain galaxies or halos (filled cells), the cells that are empty but are inside the observational domain (empty cells) and those cells which are also empty but they are located outside the observational domain or in a not observed region inside the observational domain (a 'hole') (not observed empty cells). The code searches for the voids among the observed empty cells inside the observational domain. In the case of cosmological simulations the dark matter halo samples are in 3D boxes and generally all the cells are inside the observational domain. However, in the case of galaxy samples in redshift surveys which have irregular geometry, some of the cells are located outside the observational domain. We can easily determine which cell has been observed and which has not by using the survey masks.

Once the cell classification procedure have been completed the code is then ready to search for the voids, finding their centers and radii. In principle, each observed empty cell could be a potential void center, but it is easy to realize that the observed empty cells which are located close to filled cells that contain galaxies or halos will not be the center of a void. So, in order to save computational time, we mark these neighbours cells and they will not be taken into account at the time of searching for the void centers. This is an iterative process, i.e. once we have marked the observed empty cells closer to the filled cells we can go to the next level and mark the observed empty cells that are neighbours of already marked empty cells. Note that we will stop this iteration depending on the working resolution (see Figure A1).

To determine the void centers, the code computes the distances between each of the unmarked observed empty cell and all the galaxies or halos in the whole observational domain and we retain the minimum distance. Once we have the list with the minimum distances, we search for the local maxima which corresponds to the void centers. Obviously, the voids radius are those maximum distances.

Finally, the code removes the overlapping maximal spheres, keeping the biggest one, i.e. if the distance between two maximal spheres is less than the sum of their radius, then the voids overlap and we remove the smaller one.

The main advantage of the Cell Void Finder algorithm is that in only one run we get all the voids in the sample. However, its main disadvantage is that it consumes quite a lot of memory, which scale with the resolution that we require. There is a similar memory problem when we have a large number of galaxies or halos in the sample. If we are only interested in the biggest voids (rare voids) this algorithm is not the best strategy. Some studies are focused in these kind of voids, so, here we have developed a complementary algorithm which is more efficient in this respect.
A2 Algorithm 2: HB Void Finder

Here we give the details of our second algorithm whose main task is the detection of rare voids and we will use it as a complement of the CELLS algorithm. The HB Void Finder is conceptually simple. It searches for the non-overlapping maximal spheres with radius larger than a given value. As we mentioned above this code is designed for statistical studies focused on the biggest voids. In these cases the code is very accurate and computationally efficient as compared with our Cell Void Finder.

The first step in the algorithm is to generate a sample of random trial spheres with a fixed radius \( R \). These spheres are generated directly over the observational domain with the condition that the entire sphere lies inside the observational domain. We check which spheres contain no objects and keep them.

In the next step we find for each trial empty sphere the four nearest object and we expand the sphere to contain them in its surface. These new spheres are potentially maximal (see subsection A4). Note that the new expanded spheres could in principle contain objects. If this is the case, those spheres are removed. The potential maximal spheres will be actual maximal spheres if they do not overlap, which is decided by means of the same criteria as for the Cell Void Finder (i.e. if the distance between two spheres is less than the sum of their radius they overlap, so we keep the largest one) and if the four nearest objects are not located in the same hemisphere (see Figure A2). We put in both algorithms the additional constrain that the maximal spheres have to be entirely inside the observational domain. Note that, we need to do many realizations of the trial spheres in order to get the maximal spheres. Typically, four realizations are needed for each void in order to reach its maximum radius, when the maximal sphere is only slightly larger than \( R \) and an increasing number as the maximal sphere is larger with respect to \( R \).

A3 Performance test

We construct random samples of objects in order to test the code performance and check the results of both algorithms. We generate two samples, one with 1,000 points and another one with 10,000 points. Both samples are in a box of 100 Mpc. We give in Table A1 the void statistics computed from both algorithms. Note that the agreement between codes is excellent. We obtain the void statistics using \( \sim 10^7 \) trial spheres with the HB Void Finder. The resolution of the Cell Void Finder is 0.5 Mpc.

The cpu time of the codes mainly depends on the number of particles, the number and radius of trial spheres in the case of the HB algorithm and on the number of cells (i.e. resolution) and the levels of neighbours cell marking for the Cell Void Finder. For example, in the case of the sample with 1,000 random particles and for the voids with radius larger than 10 Mpc, the HB Void Finder takes \( \sim 1 \) hour for \( 10^7 \) trials, while the Cell Void Finder takes \( \sim 3 \) hours with a resolution of 0.5 Mpc. Notice that the voids with radius larger than 10 Mpc are common in this box, so the running time differences are not so big between both algorithms. However, if we search for voids with radius larger than 12 Mpc, the HB Void Finder takes only 20 minutes, while the Cell Void Finder last the same \( \sim 3 \) hours. These tests were done in a Pentium IV processor (3.06 GHz clock and 2GB RAM) and in an Itanium-2 processor (1.5 GHz clock, 2GB RAM) giving both similar performances.

A4 How to grow the trial spheres

To determine the sphere passing through the four nearest objects to an empty trial sphere we proceed as follow: We first take the two nearest objects (whose coordinates we denote as \( \vec{x}_1 \) and \( \vec{x}_2 \)) and calculate the middle point \( (\vec{x}_1 + \vec{x}_2)/2 \). From this point, we move along a vector in the plane containing the three nearest objects and perpendicular to \( \vec{x}_2 - \vec{x}_1 \) until we reach the point, \( q \), where the distances to the third nearest object (\( \vec{x}_3 \)) is the same as that to object 1, then the distance between object 2 and \( q \) is also the same that the previous two (See figure A3). Then we need to solve:

\[
| \vec{x}_1 - q(w_0) | = | \vec{x}_3 - q(w_0) |
\]  
(A1)

where

\[
q(w) = \left( \frac{\vec{x}_1 + \vec{x}_2}{2} + w \vec{j} \right)
\]  
(A2)

and

\[
\vec{j} = \frac{\vec{x}_{13} - (\vec{x}_{13} \cdot \vec{x}_{12}) \vec{x}_{12}}{|\vec{x}_{13} - (\vec{x}_{13} \cdot \vec{x}_{12}) \vec{x}_{12}|} 
\]  
(A3)

where

\[
\vec{x}_{12} \equiv \frac{\vec{x}_1 - \vec{x}_2}{|\vec{x}_1 - \vec{x}_2|}, \quad \vec{x}_{13} \equiv \frac{\vec{x}_1 - \vec{x}_3}{|\vec{x}_1 - \vec{x}_3|} 
\]  
(A4)

with \( w_0 \in (-2R_0, 2R_0) \), \( R_0 \) is the radius of the trial sphere.

Now, we repeat the same procedure described above but taking into account the fourth object, i.e. we move from \( q(w_0) \) perpendicularly to the plane of the figure A1 until we reach the point \( \vec{P}(t) \) where the distance between \( \vec{P}_4 \) and \( \vec{P}(t) \) is the same as the distance from \( \vec{x}_1 \) to \( \vec{P}(t) \). So,

\[
\vec{P}(t) = q(w_0) + t \vec{n}
\]  
(A5)

where

| Sample | Box: | 100 Mpc |
|--------|-----|---------|
| 1000   |     |         |
| Radius Mpc | \( N_{HB} \) | \( N_{CELLS} \) |
| 10.0   | 23  | 25      |
| 11.0   | 15  | 15      |
| 12.0   | 7   | 7       |
| 10000  |     |         |
| 5.5    | 69  | 73      |
| 6.0    | 20  | 21      |
| 6.5    | 3   | 3       |
| 7.0    | 1   | 1       |
Figure A2. Sequence of steps in our HB Void Finder: a) we throw a sphere of fixed radius (dotted circle) over the observed sample of objects, b) if this sphere is empty of objects defining the void (filled dots), we then grow the sphere (dashed circle) until its surface contains the four nearest objects (three in 2-D, see Appendix A). This is a potential maximal sphere. We throw another random sphere (dotted circle). Again, if this one is empty, we obtain the potential maximal sphere (dashed circle in panel c). d) Finally, we check if the new maximal sphere overlaps with another one; if so, we keep the largest sphere. This is our void (filled circle). See text for details.
\( \vec{n} = \vec{e}_{12} \wedge \vec{e}_{13} \) \hspace{1cm} (A6)

Solving

\[ |\vec{x}_1 - \vec{P}(t)| = |\vec{x}_4 - \vec{P}(t)| \] \hspace{1cm} (A7)

with \( t \in (-2R_0, 2R_0) \), we finally obtain the coordinates of the center of the maximal sphere, \( \vec{P}(t) \), and its radius \( R \), which is simply given by \( |\vec{x}_1 - \vec{P}(t)| \).
