Introduction

Skull base surgery is an integral part of neurosurgical endeavor, the presence of vital neural structures located there as well as exit/entry foramina for cranial nerves and blood vessels poses a great challenge to the neurosurgeon who must do all possible to preserve this structures during neurosurgical intervention and as well as the neuroanaesthetist who had to continuously monitored neuro-vital signs which guide the surgeon in view of structure such as the brainstem which controls cardiorespiratory activities located in the skull base. These vital structures regulate the dynamic body reflexes (cardiorespiratory center) and cranial nerves important for control of body function. The trigeminal nerve, which is the largest cranial nerve with mainly sensory supply to the craniofacial structure is involved in the trigeminocardiac reflex. Trigeminocardiac reflex is a well known entity consisting of bradycardia, arterial hypotension, apnea and gastric hypermotility [1]. In skull base surgeries, awareness of a rapid drop in pulse rate, mean arterial pressure more than 20% of baseline values following stimulation of the peripheral or central branches of trigeminal nerves or the structure it supplies should be recognized [1-3] and could avert calamity during neurosurgical intervention.

Literature Review

Trigemino-cardiac Reflex (TCR) is defined as sudden drop in heart rate, mean arterial pressure of 20% or more compared with baseline values before stimulation and coinciding with manipulation of trigeminal nerve (peripheral or central) or structures supply by it excluding pathological contributions. TCR occur with a frequency of 8-18% in adult patient during different surgical procedure involving the skull base [2-4]. It is not a pathological event, but can be a neuroprotective phenomenon [5] in calling for attention to prevent or combat it, thereby preventing far reaching consequences on the patient. Despite triumph in micro neurosurgical technique by Yasargil in the 1960s, occurrence of TCR is traced to structural changes in brainstem [6]. TCR has evolved over time, first described in 1870 by Kratchner, Kumada et al [7] until recently when Schaller popularized it [2]. Several surgical procedures involving the craniofacial areas, skull base, percutaneous procedure related to trigeminal nerve have been found to be associated with bradycardia, arterial hypotension and asystole with far reaching devastating sequelae [8-12].

Manipulation at or near the trigeminal nerve distribution or structures that it supplies has been traced as a cause of TCR [13]. Mechanism of TCR is poorly understood and elusive, but current theoretical bases is a reflex manipulation of trigeminal nerve at different level or structures that are innervated by this nerve [14]. It may induce neuronal signal to sensory trigeminal nucleus through the gasserian ganglion which constitute an afferent pathway of their reflex arc [14]. Others have suggested that afferent impulses are transmitted to the peripheral sensory nucleus of the trigeminal nerve and spinal nucleus of trigeminal nerve [14]. The sensory nuclei connect with the autonomic vagal motor nucleus through short internuncial fibre to the vagal motor nucleus of the medulla [14]. The vagal parasympathetic nerve fibre cell bodies with descending cardiac fibers are located within the dorsal motor
nucleus of the vagus and the nucleus ambiguous, from where cardioinhibitory fibers arise and terminate in the myocardium causing bradycardia, asystole and rarely arrhythmia. Oculocardiac reflex (a variant of TCR) is induced by mechanical stimulation of ocular and periorcular structure innervated by CNV1, is elicited by stimulation of the afferent pathway of the long ciliary nerve (CNV2), submucosa of the nose by nasociliary branch of CNV1, sensory branch of CNV2 or V3 [15,16].

Premedication with Anticholinergic drugs [such as atropine] can lead to cessation of irritation from surgical manipulation so as to disrupt the reflex that trigger the response [13]. Appropriate selection of Anticholinergic is needed in cases in which manipulation of the cavernous sinus is inevitable. Glycopyrrolate has been found to be has been found to be superior to atropine in managing TCR in view of central anticholinergic syndrome of atropine as it crosses blood brain barrier [17]. Atropine has been found to be effective in treating refractory TCR, while glycopyrrolate has been found to be has been found to be superior to atropine as it crosses blood brain barrier [17]. Atropine has been found to be effective in treating refractory TCR, while glycopyrrolate has been found to be has been found to be superior to atropine as it crosses blood brain barrier [17]. Atropine has been found to be effective in treating refractory TCR, while glycopyrrolate has been found to be has been found to be superior to atropine as it crosses blood brain barrier [17]. Atropine has been found to be effective in treating refractory TCR, while glycopyrrolate has been found to be has been found to be superior to atropine as it crosses blood brain barrier [17]. Atropine has been found to be effective in treating refractory TCR, while glycopyrrolate has been found to be has been found to be superior to atropine as it crosses blood brain barrier [17]. Atropine has been found to be effective in treating refractory TCR, while glycopyrrolate has been found to be has been found to be superior to atropine as it crosses blood brain barrier [17].

Management of TCR involved early detection of bradycardia and or hypotension with continuous monitoring of hemodynamic stability, stoppage of all surgical manipulation. In the work by Koerbel et al, 80% of the patient had TCR during Skull Base Surgery for identification. Every skull base surgeon should be aware of the important determining factor is cavernous sinus thrombosis (Transsphenoidal Surgery) has been elusive. No correlation of age, sex, tumor history, method of anesthesia, duration and distribution of clinical symptoms have been traced to TCR. Reports have shown that important determining factor is cavernous sinus thrombosis manipulation. Another predicting factor of the doubtful acceptance is intravenous anesthesia surfactants potentiating TCR [18], but now clear evidence has been found.

Conclusion

TCR should be discussed with all team members included the anesthetists involved in Skull Base Surgery in view of preparation for identification. Every skull base surgeon should be aware of the occurrence of TCR and strive to prevent it or treat it when it occurs with available pharmacological agents.
