ABSTRACT

Many present-day galaxies are known to harbor supermassive, ≥10$^6$ M$_\odot$, black holes. These central black holes must have grown through accretion from less massive seeds in the early universe. The molecules CO and H$_2$ can be used to trace this young population of accreting massive black holes through the X-ray irradiation of ambient gas. The X-rays drive a low-metallicity ion-molecule chemistry that leads to the formation and excitation of CO and H$_2$ in 100 K < T ≤ 1000 K gas. H$_2$ traces very low metallicity gas, ∼10$^{-2}$ solar or less, while some pollution by metals, ∼10$^{-2}$ solar or more, must have taken place to form CO. Strong CO J ≥ 15 and H$_2$ S(0) and S(1) emission is found that allows one to constrain ambient conditions. Comparable line strengths cannot be produced by FUV or cosmic-ray irradiation. Weak, but perhaps detectable, H$_2$ (2, 2)$\rightarrow$(1, 1) emission is found and discussed. The models predict that black hole masses larger than 10$^7$ M$_\odot$ can be detected with ALMA, over a redshift range of 5–20, provided that the black holes radiate close to Eddington.

Subject headings: cosmology: theory — galaxies: high-redshift — ISM: molecules

1. INTRODUCTION

Central to the study of galaxy evolution is the formation and evolution of the supermassive black holes in their nuclei. Accretion onto these black holes can provide the energy source for active galactic nuclei, which in turn impact the evolution of galaxies (Silk 2005). The processes believed to play a role in the formation of seed black holes, from which large black holes may form through accretion, involve (1) dynamical friction and collision processes in dense young stellar clusters (Portegies Zwart et al. 2004), (2) seeds as the remnants of the 300 Myr lifetimes of primordial stars ensure that the accreted gas is quickly polluted by a modest amount of dust and metals. If no star formation takes place, then the gas will remain metal-free. In either case, the accretion process will lead to the emission of X-rays that impact the thermal, ionization, and chemical balance of the gas in the halo, leading to an X-ray-dominated region (XDR; Maloney et al. 1996; Meijerink & Spaans 2005). For simplicity the black hole is taken to radiate at the Eddington luminosity.

For a baryonic number density $\rho_b$, halo masses of $M_h = 10^9$–$10^{10}$ M$_\odot$, and a characteristic size scale of $L = (3M_h/4\pi\rho)^{1/3}$, one has a typical mean density and column of $n_\rm{H}_2 = 0.05(1 + z)/10$ cm$^{-3}$ and $N_\rm{H}_2 = 10^{22}(1 + z)/10^2 (M_h/10^9$ M$_\odot)_{1/3}$ cm$^{-2}$, respectively. The work of Mo et al. (1998) shows that the subsequent formation of a disk occurs, with a collapse factor of 1/λ = 0.05. This yields densities that exceed 10$^2$ cm$^{-3}$ within 1 kpc. The above cosmology provides the boundary conditions for the ambient density and column density of individual models, and the metallicity is put in by hand.

The models of Meijerink & Spaans (2005) and Meijerink et al. (2007) are used to compute the thermal, chemical, and ionization balance of the irradiated gas self-consistently, for one-dimensional constant-density slabs of gas. The multizone escape probability method of Poelman & Spaans (2005, 2006) has been used to compute the line intensities presented here. The same radiative transfer is performed in relevant atomic (fine-structure) and molecular (rotational and vibrational) cooling lines. Cloud type “A” from Meijerink et al. (2007, their Table 1) is adopted, which is 1 pc in size. The interested reader is referred to the cited papers for a detailed description of all physical processes involved. There are four free parameters in the models: hydrogen density, hydrogen column density, metallicity, and X-ray flux. The latter parameterizes unknowns such as the accretion rate, turbulent viscosity, and the spectral

2. MODEL DESCRIPTION

We consider a high-redshift halo which already contains, by assumption, a seed black hole. Suppose further that an initially metal-free hydrogen gas is cooled by Ly$\alpha$ to $T \sim 10^4$ K and settles in the center of a halo close to the black hole. Part of the gas is likely to experience a period of Population III star formation. If Population III star formation occurs, then the short lifetimes of primordial stars ensure that the accreted gas is quickly polluted by a modest amount of dust and metals. If no star formation takes place, then the gas will remain metal-free. In either case, the accretion process will lead to the emission of X-rays that impact the thermal, ionization, and chemical balance of the gas in the halo, leading to an X-ray-dominated region (XDR; Maloney et al. 1996; Meijerink & Spaans 2005). For simplicity the black hole is taken to radiate at the Eddington luminosity.
shape of the X-ray radiation. For definiteness, a power-law radiation field with \( E^{-0.9} \) is adopted for energies \( E \) between 1 and 100 keV, appropriate for a self-absorbed Seyfert nucleus. This slope, if it is between \(-1.1\) and \(-0.7\), does not significantly impact the chemistries of \( \text{H}_2, \text{CO} \), and \( \text{H}^+ \); see also Meijerink & Spaans (2005) for the case of a 1 keV thermal spectrum. Solar elemental abundance ratios are adopted. As long as \([\text{O}/\text{C}] > 1\) this does not influence the \( \text{CO} \) results. Chemical equilibrium is assumed. At densities of \( \sim 10^3 \) cm\(^{-3}\) and for high X-ray fluxes, collisional and radiative timescales are short compared to the free-fall time. The chemical network comprises a few thousand reactions between 154 species with sizes up to 4 atoms (Wooddall et al. 2007). Polycyclic aromatic hydrocarbons and small grains are included in the charge balance and are assumed to scale with the elemental carbon abundance.

Following the above cosmology, we consider column densities of \( 10^{22} - 10^{26} \) cm\(^{-2}\) and densities of \( n = 10^3 - 10^5 \) cm\(^{-3}\). The X-ray flux takes values of \( F_X = 0.1 - 100 \) ergs s\(^{-1}\) cm\(^{-2}\). Results are shown in Figures 1, 2, and 3 for a density of \( 10^5 \) cm\(^{-3}\). Values below this density but above \( 10^3 \) cm\(^{-3}\) were found to lead to similar signal strengths for \( \text{H}_2 \) and \( \text{H}^+ \). For \( \text{CO} \), line intensities smaller by a factor of \( \sim \)10\(^{-5}\) were found. Recall that the Eddington luminosity is \( L_{\text{Edd}} \approx 1.3 \times 10^{38} M/\odot \) ergs s\(^{-1}\). So \( F_X \approx 100 \) ergs s\(^{-1}\) cm\(^{-2}\) corresponds to a \( 10^8 M/\odot \) black hole that emits \( \sim 10^{44} \) ergs s\(^{-1}\) through a surface with a radius of about 100 pc. The level to which Population III star formation pollutes the center of the primordial galaxy with metals through supernova explosions is a free parameter. Metallicities between \( 10^{-3}\) and 1.0 solar are considered since \( 10^{-3}\) solar is quite like a zero-metallicity gas as far as \( \text{H}_2 \) and \( \text{CO} \) are concerned, and supersolar values appear unlikely for the bulk of the very high redshift gas. Dust grains, with standard Milky Way properties (Mathis et al. 1977), are included and their abundance is assumed to scale with the overall metallicity. The velocity dispersion of the gas has a thermal contribution, equal to \( \Delta V = 12.9(7/10^4)^{1/2} \) km s\(^{-1}\), and a turbulent contribution, equal to \( \Delta v = 5 \) km s\(^{-1}\), for individual gas clouds on the scale of 1 pc. In the dense gas considered here, turbulence is expected to be maintained at a level similar to that in active galaxies.

### 3. Results

The main goal is to compute the expected columns of \( \text{H}_2 \), \( \text{CO} \), and \( \text{H}^+ \), and their associated emission strengths. For simplicity, a fiducial column of \( 10^{23.5} \) cm\(^{-2}\) is adopted for the predicted line emissivities. This is driven by the theoretical considerations above, but also by recent observations of massive galaxies at \( z \approx 2 \) (Daddi et al. 2007a, 2007b). A significant fraction (20%–30%) of the systems appear to contain heavily obscured AGNs with columns in excess of \( 10^{24} \) cm\(^{-2}\). These massive systems appear to be a somewhat later stage of the...
concerted bulge–black hole mass forming systems studied here. The X-ray luminosities of these lower redshift counterparts are $(1-4) \times 10^{33} \text{ erg s}^{-1}$ in the 2–8 keV band. The precise value of the total obscuring hydrogen column does not impact our emissivity results as long as it exceeds $10^{23} \text{ cm}^{-2}$, i.e., includes all $T > 100 \text{ K}$ gas.

3.1. $\mathrm{H}_2$ and $\mathrm{H}_3^+$

In the absence of dust grains, $\mathrm{H}_2$ is formed in the gas phase through the $\mathrm{H}^-$ route, $\mathrm{H}^- + \mathrm{H} \rightarrow \mathrm{H}_2 + e^-$. This leads to high abundances of $\mathrm{H}_2$, $10^{-2}$ to $10^{-3}$, even for low metallicities (Fig. 1). So, contrary to far-ultraviolet (FUV; 6–13.6 eV) illumination, X-ray irradiation constitutes a form of positive feedback for $\mathrm{H}_2$ (Haiman et al. 1997). The models with a modest metallicity of $>10^{-3}$, and thus dust grains, follow the $\mathrm{H}_2$ formation prescription as in Cazaux & Spaans (2004), which includes both physisorbed and chemisorbed hydrogen atoms. The columns of $\mathrm{H}_2$ that are reached at low metallicities are as large as $10^{23} \text{ cm}^{-2}$—this while temperatures exceed 100 K over the bulk of this column, and reach $10^4 \text{ K}$ at its edge, sufficient to excite (Fig. 9) the $500 \text{ K} S(0)$ line at 28 $\mu$m and $800 \text{ K} S(1)$ line at 17 $\mu$m. The $S(1)$ line is typically weaker than the $S(0)$ line, while both lines are optically thin and in LTE. High molecular gas temperatures are reached in XDRs because of efficient ionization and Coulomb heating, rather than photoelectric heating from dust grains (Meijerink & Spaans 2005). Interestingly, an increase in metallicity decreases the $\mathrm{H}_2$ line strength. This is a direct consequence of enhanced cooling in fine-structure lines and a lower resulting temperature. Hence, the pure rotational $\mathrm{H}_2$ lines are particularly well suited to detect the earliest stages of black hole accretion, prior to significant metal pollution by star formation. Metallicities below $10^{-3}$ were found to lead to quite similar $\mathrm{H}_2$ emissivities since all $\mathrm{H}_2$ is formed in the gas phase and fine-structure cooling is modest.

Figure 2 (see § 4 for its details) shows rest-frame line intensities of $\sim 10^{-3} \text{ ergs s}^{-1} \text{ cm}^{-2} \text{ sr}^{-1}$ at a metallicity of $10^{-3}$ solar. For the numbers below, the ALMA sensitivity tool on the ESO Web site has been used and the concordance model, with the latest WMAP results, is adopted. With a source size of $0.2^\prime$, or $600 \text{ pc}$ at $z = 15$, this yields an $S(0)$ flux density of $39(1 + z)^3$ Jy, for a fiducial galaxy-center velocity dispersion of $20 \text{ km s}^{-1}$ ($\sim 200 \text{ pc}$ from a $10^9 \text{ M}_\odot$ central mass). For the $S(0)$ line from $z = 15$, so at 0.45 mm, and for 10 km s$^{-1}$ spectral resolution, this is detectable with ALMA (50 antennas, beam size = source size) at the 6 $\sigma$ level in 4 hr of integration. Hence, despite the fact that the line falls in the less sensitive band 9, spectrally resolved detection is possible. The pure rotational $\mathrm{H}_2$ lines are intrinsically very bright, because of the strong contribution from the X-ray-driven $\mathrm{H}^-$ route, and are accessible to ALMA for redshifts above 10, for $S(0)$ 28 $\mu$m, and above 16 for $S(1)$ 17 $\mu$m.

Figure 1, for a density of $10^5 \text{ cm}^{-3}$, shows that the $\mathrm{H}_3^+$ abundance increases with ionization parameter $F_{\rm Ly}/n$ for metallicities below $10^{-2}$ of solar. A higher X-ray ionization rate leads to a larger $\mathrm{H}_3^+$ abundance, through $\mathrm{H}_2$ secondary ionizations, and boosts the formation rate $\mathrm{H}_2 + \mathrm{H}_3^+ \rightarrow \mathrm{H}_3^+$. The $\mathrm{H}_3^+$ abundance is thus key since no $\mathrm{H}_3^+$ can be formed without it. Too large values of $F_{\rm Ly}/n$ lead to a decrease in the $\mathrm{H}_3^+$ abundance, driven by dissociative recombination.

The best candidate for an $\mathrm{H}_3^+$ detection is the optically thin $(2, 2) \rightarrow (1, 1)$ line at 95 $\mu$m, as suggested by Pan & Oka (1986). The critical density of the $(2, 2) \rightarrow (1, 1)$ transition is about $2 \times 10^9 \text{ cm}^{-3}$ and the excitation energy $\sim 150 \text{ K}$. Col-

3.2. CO

Any metallicity larger than $10^{-3}$ solar leads to significant, $\sim 10^{-3}$ to $10^{-6}$, abundances of CO. X-rays, because of their large energy, do not dissociate CO directly. FUV photons are produced through collisional excitation of $\mathrm{H}$ and $\mathrm{H}_2$ by electrons, followed by radiative decay. This UV flux is generally modest and thus CO can survive even in strong X-ray radiation fields. Given the high molecular gas temperatures in XDRs, $10^3$ to $10^4 \text{ K}$, rotational levels with are excited (Meijerink et al. 2006, 2007). This very high CO emission requires densities $>10^3 \text{ cm}^{-3}$ because the critical densities of these lines are about $10^3 \text{ cm}^{-3}$. Metallicities in excess of $10^{-2}$ of solar further raise the CO emissivities, even though the higher abundances of C, O, Si, and Fe also enhance the cooling of the gas (Santoro & Shull 2006). The CO emissivities below $10^{-3}$ solar are negligible.

One finds from Figure 2 that, at a metallicity $>10^{-2}$ solar, rest-frame CO line intensities reach $\sim 10^{-3} \text{ ergs s}^{-1} \text{ cm}^{-2} \text{ sr}^{-1}$, which yields a flux density of $-1.4/(1 + z)^3$ Jy for a 0.2$''$ source size, or 850 pc at $z = 10$, and a fiducial galaxy-center velocity dispersion of 20 km s$^{-1}$. For the rest-frame peak in the CO line spectral energy distribution (SED) at 3000 GHz (see Fig. 2), 10 km s$^{-1}$ velocity resolution, and $z = 10$, ALMA detects such a source at 5 $\sigma$ in 8 hr of integration (50 antennas, beam size = source size). Spectrally resolved detection is possible. ALMA covers 0.3–3.0 mm, fortuitously matching most of the X-ray-driven CO line SED for $z = 5–20$.

4. DISCUSSION

Figure 2 shows how the rest-frame spectral line distribution of CO, pure rotational $\mathrm{H}_2$, and $\mathrm{H}_3^+$ evolves with irradiation and metallicity for an ALMA beam that is filled with 1 pc clouds at $\sim 10^3 \text{ cm}^{-3}$. These clouds are in Keplerian orbit around the central black hole and are randomly distributed over a spherical region with a linear size of 1 kpc in such a way that there is about one cloud along each line of sight. This central region is slowly enriched in metals as indicated. The total column density is on average $\sim 10^{23.5} \text{ cm}^{-2}$ along each line of sight. The total intensity is then found by a ray trace on the level populations of the individual clouds. More complicated geometries are not an issue as long as the cloud covering factor is of the order of unity and the bulk of the emitted X-rays are absorbed.

Overall, X-ray fluxes of $>1 \text{ ergs s}^{-1} \text{ cm}^{-2}$, corresponding to black hole masses of $>10^9 \text{ M}_\odot$ and a region with a size of $>600 \text{ pc}$, yield detectable lines, provided the black hole is radiating at its Eddington luminosity. This mass value is comparable to that of black holes present in cosmological simulations of $10^8$–$10^9 \text{ M}_\odot$ halos collapsing at 10 $< z < 20$ (Pelupessy et al. 2007). Black holes that are emitting below the Eddington luminosity by a factor of $x$ are detectable with ALMA only if their masses
exceed $10^3 M_{\odot}$. Also, the Eddingtone time of $\sim 10^8$ yr is 25\% of the Hubble time at $z = 10$, yielding a fair probability for detection of these systems in the ALMA frequency window. Finding sources is best done in the continuum (e.g., the James Webb Space Telescope), with ALMA follow-up. Since the molecular lines are optically thin, they trace the kinematics of all irradiated gas. Multiple CO and H$_2$ lines further allow one to determine the ambient density, temperature, and X-ray flux.

[O~i] 63 $\mu$m and [C~ii] 158 $\mu$m fine-structure lines can be important coolants of X-ray-irradiated gas as well. At a metallicity of $\sim 10^2$, fine-structure line cooling contributes about half of the total cooling. These lines could also be observed with ALMA, but FUV or cosmic-ray irradiation boosts them as well (Meijerink et al. 2007), diminishing their diagnostic value for tracing black hole accretion. In addition, the 149 $\mu$m ($J = 1-0$, $v = 0$) rotational line of HeH$^+$ is shown in Figure 2, because it was suggested by Maloney et al. (1996) as a useful XDR tracer. It is found that this line is typically much weaker than the H$_2$ and CO lines, and HeH$^+$ abundances do not exceed $10^{-9}$.

Fast ($\sim 50$ km s$^{-1}$) shocks can lead to similar CO and H$_2$ emissivities, albeit over much smaller regions so that beam dilution would be an issue. Also, shocks should produce CO line profiles with strong non-Gaussian wings. At redshifts of a few, CO emission with upper levels from massive tori in active galaxies is also accessible to ALMA. This has been studied by Kawakatu et al. (2007) for the case where FUV photons drive the chemistry. Narayanan et al. (2008a) look at simulations of $z \sim 6$ quasars in $10^{12}-10^{13} M_{\odot}$ halos and find that the CO is highly excited by starbursts, peaking at $J = 5-8$. Narayanan et al. (2008b) further find that AGN-driven winds may leave signatures in the CO line emission profile in the form of high-velocity peaks at a few times the circular velocity. Also, Lintott & Viti (2006) and Meijerink et al. (2007) find an increase in HCN emission with X-ray flux, but this effect is suppressed at low metallicity and for densities $\geq 10^4$ cm$^{-3}$. The X-ray-driven lines presented here complement these efforts. Finally, Figure 3 shows a CO comparison between an AGN (XDR) and a starburst (PDR) model, for the same impinging flux by energy of 100 ergs s$^{-1}$ cm$^{-2}$, typical of a $10^{44}$ ergs s$^{-1}$ Seyfert nucleus or $10^8$ B0 stars within a 200 pc region. Solar metallicity is assumed, merely because it favors the PDR. It is obvious that star formation can never compete with an XDR, for the same illuminating flux by energy, in terms of the very high J CO line intensities that are produced.

The authors are grateful to Paul van der Werf for his comments on H$_2^+$ destruction, to Joe Silk for discussions on CO emission, and to the anonymous referee for his/her very helpful comments.
