Experimental implementation of a NMR entanglement witness

J. G. Filgueiras · T. O. Maciel · R. E. Auccaise · R. O. Vianna · R. S. Sarthour · I. S. Oliveira

Abstract  Entanglement witnesses (EW) allow the detection of entanglement in a quantum system, from the measurement of some few observables. They do not require the complete determination of the quantum state, which is regarded as a main advantage. On this paper it is experimentally analyzed an entanglement witness recently proposed in the context of Nuclear Magnetic Resonance experiments to test it in some Bell-diagonal states. We also propose some optimal entanglement witness for Bell-diagonal states. The efficiency of the two types of EW’s are compared to a measure of entanglement with tomographic cost, the generalized robustness of entanglement. It is used a GRAPE algorithm to produce an entangled state which is out of the detection region of the EW for Bell-diagonal states. Upon relaxation, the results show that there is a region in which both EW fails, whereas the generalized robustness still shows entanglement, but with the entanglement witness proposed here with a better performance.

1 Introduction

Entanglement is one of the central keys for quantum information processing, being associated with various puzzling quantum phenomena, such as Bell’s inequality violation and quantum teleportation, for example. It is also a main resource for the exponential speedup in some quantum algorithms [1]. Therefore, the detection of entanglement is important. For that, many tools have been developed, one of these are the entanglement witnesses.

Entanglement witnesses are tools designed to detect entanglement from direct measurements of observables. They can be used either to detect entanglement in a given state, or to quantify the entanglement for a specific state or class of states [2]. The main advantage of the use of entanglement witnesses is the possibility of detection of entanglement without performing Quantum State Tomography, which can significantly reduce the number of measurements performed in the system, in order to characterize some quantum effect due to the presence of entanglement.

During the last few years there have been proposals and experimental implementations of entanglement witnesses for various different quantum systems, like optical [3] and magnetic ones [4–6]. Although NMR techniques have been successfully used to implement quantum protocols [7], like quantum teleportation [8] and Shor’s [9] algorithm, besides several other quantum simulations [7], only recently a proposal of EW has been made for NMR quantum information processing experiments [10]. In this paper it is demonstrated the implementation of such a EW in a class of states, and it is also proposed some other entanglement witnesses.

2 Theory

Recently, a proposal for an EW has been made for NMR quantum information processing [10] which uses the superdense coding protocol, successfully implemented with NMR by Fang et al. [11]. The circuit for the superdense coding is given in the Fig. 1.

For a pure state, the circuit transmits two classical bits of information with only one qubit transmitted. The input state in the superdense coding, |00⟩, passes through an ERP gate [7], becoming the cat state, |Φ+⟩ (first part of Fig. 1). The encoded message is then chosen by a “message” operator, applied only at the first qubit, that transforms the cat state into one of the four states of the Bell basis (the operator $U_{xz}$ at the second part of Fig. 1). This operator is given by $X$, $Z$ or the product $XZ$. Then, the first qubit, which was modified by the message operator is sent to the other person which has the

![Fig. 1 Quantum circuit for superdense coding. In the first part of the circuit, the input state |00⟩ being transformed in the cat state, |Φ+⟩. After it, the “message” operator is applied, taking |Φ+⟩ into one of the four Bell basis states. The final part of the circuit indicates the measurement in the Bell basis](image)
Implementation of a NMR entanglement witness

other qubit of the entangled pair, and a measurement at the Bell basis is performed in each qubit (final part of the Fig. 1). The result of the readouts, measured at each qubit, is dependent of the “message” operator. By the knowledge of the sent message, the transmission of the two classical bits of information with only one qubit transmitted is completed.

In NMR systems one deals with not pure, but mixed states, due to the large number of molecules in a sample. Then, it is necessary to consider the above circuit in the context of mixed states. The equilibrium state of a NMR system containing two qubits can be written in form

$$\rho = (p_I |0\rangle\langle0| + q_I |1\rangle\langle1|) \otimes (p_S |0\rangle\langle0| + q_S |1\rangle\langle1|),$$

(1)

where

$$p_i = \frac{1 + \epsilon_i}{2}, \quad q_i = \frac{1 - \epsilon_i}{2},$$

(2)

and the indexes $I$ and $S$ label each of the nuclear spins used as qubits.

By applying an EPR gate [7] (first part of the circuit in Fig. 1) to this state the output will be a Bell-diagonal state:

$$\rho_1 = p_I p_S |\Phi^+\rangle\langle\Phi^+| + p_I q_S |\Psi^+\rangle\langle\Psi^+| + p_S q_I |\Phi^-\rangle\langle\Phi^-| + p_I p_S |\Psi^-\rangle\langle\Psi^-|,$$

(3)

where $|\Phi^+\rangle$, $|\Psi^+\rangle$, $|\Phi^-\rangle$ and $|\Psi^-\rangle$ are the states of the Bell basis. The parameter $\epsilon_i$ is the relation between the magnetic and thermal energies and is typically $\approx 10^{-5}$.

The spin magnetizations are measured at the end of the circuit and are proportional to the polarization of the state, $\epsilon$ (see the Sect. 4). They are given by

$$\langle Z_I \rangle = (-1)^z \epsilon_I, \quad \langle Z_S \rangle = (-1)^x \epsilon_S.$$

(4)

If the variables $x$ and $z$, the encrypted message, are known, the NMR implementation of the superdense coding is successful.

The statistical condition for success in the NMR implementation of superdense coding and the condition for the entanglement of the Bell-diagonal states are the same, and are given by [10]:

$$p_I p_S > \frac{1}{2}$$

(5)

This equation can be used to define an entanglement witness, as $F = 1/2 - p_I p_S$. Using the expressions for the probabilities and those for $p_i$ and $q_i$, we have

$$F = \frac{1}{2} - \frac{1}{4} (1 + |\langle Z_I \rangle|) (1 + |\langle Z_S \rangle|).$$

(6)
The measurements of the magnetizations $Z_I$ and $Z_S$ at the end of the circuit are equivalent to the measurements of $\rho_1$ (see Fig. 1) in the Bell basis, since

$$\langle Z_I \rangle = Tr(\rho_f(Z_I \otimes I_S)) = Tr(\rho_1(X_I \otimes X_S) \equiv \langle W_1 \rangle, \quad (7)$$

$$\langle Z_S \rangle = Tr(\rho_f(I_I \otimes Z_S)) = Tr(\rho_1(Z_I \otimes Z_S) \equiv \langle W_2 \rangle, \quad (8)$$

which yields:

$$F = \frac{1}{2} - \frac{1}{4}(1 + | \langle W_1 \rangle |)(1 + | \langle W_2 \rangle |). \quad (9)$$

This equation shows explicitly that $F$ is a measure of the correlations between the two qubits.

### 3 Decomposable optimal entanglement witnesses for NMR

In this section, we propose a set of optimal decomposable entanglement witnesses, which can detect the entanglement of states in the vicinity of the Bell states. In relation to the witness $F$, one pays the price of performing just one more local measurements, in order to have a finer description of the entanglement, as seen in Fig. 7 (see next section).

The new witnesses are of the form:

$$W = C_I I + C_x X_I \otimes X_S + C_y Y_I \otimes Y_S + C_z Z_I \otimes Z_S. \quad (10)$$

To guarantee that $W$ have a positive expectation value on all separable states $\sigma$, we have just to impose that the partial transpose of $W$ is a positive operator, i.e., $W^{TA} \geq 0$. This follows from the fact that if $\sigma$ is a bipartite separable state, so is its partial transpose, $\sigma^{TA}$. Therefore $Tr(W^{TA} \sigma) = Tr(W^{TA} \alpha) \geq 0$, which shows that $W$ is a valid entanglement witness.

Now, for a given Bell state $|\beta_{ii}\rangle$, an optimal witness in the form of Eq. (10) is obtained by solving the following semidefinite program (sdp): [12,13]:

$$\begin{align*}
\text{minimize} & \quad \langle \beta_{ii}|W|\beta_{ii}\rangle \\
\text{subject to} & \quad \begin{cases} W^{TA} \geq 0, \\
W \leq I. \end{cases} \quad (11)
\end{align*}$$

The sdp (Eq. 11) yields the witnesses in Table 1.

### 4 Experiment

NMR systems have been extensively used to test quantum information processing protocols. Most of the experiments deal with entanglement, and therefore the detection of entanglement by direct measurements is desirable. The main feature of
Table 1  Optimal entanglement witnesses for the Bell states in the form $W = C_I I + C_X X_I \otimes X_S + C_Y Y_I \otimes Y_S + C_Z Z_I \otimes Z_S$

| State | $I$ | $XX$ | $YY$ | $ZZ$ |
|-------|-----|------|------|------|
| $|\Phi^+\rangle$ | 0.5 | -0.5 | 0.5  | -0.5 |
| $|\Psi^+\rangle$ | 0.5 | -0.5 | -0.5 | 0.5  |
| $|\Phi^-\rangle$ | 0.5 | 0.5  | -0.5 | -0.5 |
| $|\Psi^-\rangle$ | 0.5 | 0.5  | 0.5  | 0.5  |

NMR quantum information processing is the excellent control of unitary transformations over qubit states, provided by the use of radiofrequency pulses, which results in high fidelity. Our experiment is performed on a liquid-state enriched carbon-13 Chloroform sample at room temperature in a Varian 500 MHz shielded spectrometer. This sample exhibits two qubits encoded in the $^1H$ and $^{13}C$ 1/2-spin nuclei. The two qubit state is represented by a density matrix in the high temperature limit, which takes the form $\rho_{AB} = \frac{1}{4} + \epsilon \Delta \rho_{AB}$, where $\epsilon = \hbar \omega_{L} / 4k_B T \approx 10^{-5}$ is the ratio between the magnetic and thermal energies and $\Delta \rho_{AB}$ is the deviation matrix [7]. Another form to write the density matrix of the NMR system is:

$$\rho_{AB} = \frac{1 - \epsilon}{4} \mathbb{I} + \epsilon \rho_1,$$

where $\rho_1$ is a density matrix. The matrix $\rho_1$ is directly related to the NMR observables, since $\rho \propto Tr \{ (I_x \pm i I_y) \rho_1 \}$.

By having the two entanglement witness well-defined, we can look at three classes of NMR states:

- entangled states which can be detected by $F$,
- entangled states which can not be detected by $F$,
- separable states.

These three classes of states will be considered using Bell-diagonal states, which are described by the equation:

$$\rho = \frac{1}{4} \mathbb{I} + \sum_{i=1}^{3} c_i I_i \otimes I_i,$$

where $c_i \in [-1, 1]$ and $I_i = 2\sigma_i$, where $\sigma_i$ are the well known Pauli matrices. For this class of states, the region of detection of entanglement by $F$ is given in the shadowed volume of Fig. 2. In the figure, the empty volume inside the lefthand side tetrahedron represents the $F$-non-detected states. The separable states being inside the octahedron in the righthand side figure. The entanglement witnesses $F$ and $W$ can detect the presence of entanglement not only for Bell-diagonal states, but for any class of states. In this paper, it will be shown the detection of entanglement by these two EW on the decoherence process of NMR, the relaxation.
Fig. 2 In the righthand side is shown the geometry of the Bell-diagonal states, where the internal octahedron is the region of the separable states, with the entangled states being outside this tetrahedron. In the lefthand side, the Bell-diagonal states detected by F are in the shadowed volume. The empty volume represents the set of Bell-diagonal states such that $F \geq 0$, i.e., the entangled states that are not detected by $F$ and the separable ones. The figure on the righthand side is credited to [21].

The measurements of the magnetizations have been made by observing the NMR spectra directly. The NMR spectra of a two qubit spin-1/2 molecule gives the measurements of four projectors of the Hilbert-Schmidt space, by combining the intensities of the two lines of the spectra of each nucleus [14]. The projectors measured in the first nucleus (with a very similar equation for the projectors measured in the second nucleus) are given by [14]:

$$\begin{pmatrix}
Tr(\rho \tilde{I}_- \otimes \mathbb{I}) \\
Tr(\rho \tilde{I}_- \otimes \tilde{Z})
\end{pmatrix} = \begin{pmatrix}
1 & 1 \\
1 & -1
\end{pmatrix} \begin{pmatrix}
S(\omega_1 - \omega_{12}) \\
S(\omega_1 + \omega_{12})
\end{pmatrix},$$  (14)

where $\tilde{I}_- = U(X - iY)U^\dagger$ and $\tilde{Z} = UZU^\dagger$, with $U$ being a preparatory pulse that transforms four desired observables of the Hilbert-Schmidt space basis into $I_- \otimes \mathbb{I}$ and $I_- \otimes Z$, the four basis elements observable in the NMR spectra. $S(\omega_1 - \omega_{12})$ and $S(\omega_1 + \omega_{12})$ are the line intensities (Fig. 3).

The preparatory pulse that leads the desired basis elements into the observable ones is a $(\pi/2)$ pulse in the $x$ or $y$ directions in one or both spins. For example, to read the two desired correlation functions, $\langle Z \otimes Z \rangle$ and $\langle X \otimes X \rangle$, the preparatory pulse necessary is a $(\pi/2)_y$ pulse in the second qubit, the $13C$ nucleus in this case. These two correlation functions will be present in the second line of the lefthand side of Eq. (14), i.e., the difference between the normalized intensities in the NMR spectra of each nucleus. The correlation function $\langle X_I \otimes X_S \rangle$ is observed in the real part of the $^1H$ spectra, while $\langle Z_I \otimes Z_S \rangle$ is observed in the real part of the $^{13}C$ spectra. The measurements were obtained after the phase adjustment, using the equilibrium state as reference, and the removal of the background signal present at the NMR spectra.

The $F$-detected entangled state which has been prepared is the $|\Phi^-\rangle = \frac{1}{\sqrt{2}}(|00\rangle - |11\rangle)$ state, for which we measured $\langle Z_I \otimes Z_S \rangle = 1.00 \pm 0.01$ and $\langle X_I \otimes X_S \rangle = -1.01 \pm 0.01$. These values give us $F = -0.51 \pm 0.01$, in excellent agreement with the theoretical values, given by $\langle Z_I \otimes Z_S \rangle = 1.00$, $\langle X_I \otimes X_S \rangle = -1.00$ and $F = -0.50$. The Bell-diagonal state that is not detected by $F$ is given by $c_1 = -0.20$, $c_2 = 1.00$ and $c_3 = 0.20$. For this state, we measured $\langle Z_I \otimes Z_S \rangle =$
Implementation of a NMR entanglement witness

Fig. 3 The NMR spectra used to measure the correlation functions $\langle X_I \otimes X_S \rangle$ and $\langle Z_I \otimes Z_S \rangle$ for each of the implemented states. The $^1$H spectra is at lefthand side, while the $^{13}$C spectra is at the righthand side. 

(i) the NMR spectra for the $|\beta_{10}\rangle$ state. To illustrate the measurement of the correlation functions, $\langle X_I \otimes X_S \rangle$ is measured by looking at the difference between the normalized line intensities of lines 1 and 2 at the lefthand side. 

(ii) the NMR spectra for the identity. 

(iii) the NMR spectra for the nondetected entangled state.

Fig. 4 Quantum state tomographies of the three states. The real parts are multiplied by a factor of 4 to make the experimental errors more clear, and the imaginary parts are too small in all cases. 

(a) The tomographed $|\Phi^-\rangle$ state. 

(b) The quantum state tomography of the identity, the separable state. 

(c) The tomographed Bell-diagonal state that is entangled and $F$-non-detected state.

$0.22 \pm 0.01$ and $\langle X_I \otimes X_S \rangle = -0.17 \pm 0.01$, which give us $F = 0.15 \pm 0.01$. While the theoretical values are $\langle Z_I \otimes Z_S \rangle = 0.20$ and $\langle X_I \otimes X_S \rangle = -0.20$, resulting in $F = 0.14$. As an example of separable state, we prepared the identity, which is the state of maximum statistical mixture. For this state we measured $\langle Z_I \otimes Z_S \rangle = 0.01 \pm 0.01$ and $\langle X_I \otimes X_S \rangle = 0.00 \pm 0.01$, giving $F = 0.25 \pm 0.01$. The theoretical expectation values of the correlation functions are null for the identity, with $F = 0.250$. The fidelity of the tomographed states were found to be of order of 0.99, 0.97 and 0.98, respectively. The tomographed states can be seen in the Fig. 4.

Since the entanglement witnesses $W$ need the measurement of one more projector, it is needed another reading pulse to perform the measurement of $\langle Y_I \otimes Y_S \rangle$. In
Fig. 5  Pulse sequence employed for the preparation of the entangled nondetected state. The first stage (A) is the passage from the thermal equilibrium state to the pseudo-pure state $|00\rangle$, after the GRAPE pulse (B), the pseudo-EPR (C), the reading pulse (D) and the measurement. This is the sequence for the measurement in the $^{13}$C nucleus. For measurements at the $^1$H nucleus, the pulse sequence is the same, but with the corresponding lines of both nucleus interchanged. Above each box that indicates the radiofrequency pulses is the phase of the pulse, with the angle of rotation below the box.

In this case, the $(\pi/2)_{x}$ in the $^{13}$C nucleus. The values of $\langle Y_{I} \otimes Y_{S} \rangle$ for the prepared states are given by $0.96 \pm 0.01, 0.96 \pm 0.01$ and $0.00 \pm 0.01$, respectively. The theoretical values are, respectively, 1.00, 1.00 and 0.00. For the $|\Phi^{-}\rangle$ state, it is needed to use the witness given by the values in the third line of the Table 1, since the $F$-nondetected entangled state is at the same region of the tetrahedron (see Fig. 2), the same entanglement witness is adequate to evaluate the entanglement for this state. The measured values for the entanglement witnesses are $W_{|\Phi^{-}\rangle} = -1.01 \pm 0.01$, for $|\Phi^{-}\rangle$, $W_{|\Phi^{-}\rangle} = -0.20 \pm 0.01$, which shows that this state is detected by $W$. For the identity, $W_{|\Phi^{-}\rangle} = 0.50 \pm 0.01$.

The entanglement measured on each state is given by $0.96 \pm 0.01, 0.14 + 0.01$ and $0.00 \pm 0.01$, respectively. The quantification of entanglement have been made using the generalized robustness of entanglement [15–17], a well-known measure of entanglement based on the notion of “distance” between an entangled state and the set separable ones in the Hilbert-Schimdt space. An advantage of this measure of entanglement is the fact that even for multipartite systems, it can identify the various types of entanglement that these systems can exhibit.

The preparation of the $F$-detected and the identity states was made by using transfer gates [18], while the entangled and $F$-nondetected state was produced using the technique known as GRAPE [19], which takes the state $|00\rangle$ into the state $\sqrt{0.6}|00\rangle + \sqrt{0.4}|11\rangle$. A gradient pulse is applied to kill the coherences of this state, and the desired state is obtained after the application of a pseudo-EPR gate (see Fig. 5). The quantum state tomography employed here was the variational quantum state tomography proposed by Maciel et al. [20].

As an extension of the above study, the detection of entanglement by $F$ in the relaxation (decoherence) process, for the initial state $|\Phi^{-}\rangle$, was studied. Using the generalized robustness [15] to quantify the entanglement, it is possible to compare the detection of entanglement by the two methods. As can be seen in the Fig. 6, the EW stops detecting the entanglement at the time $\tau_{c} = 0.32\text{s}$, near the transverse relaxation time of the hydrogen, given by $0.31(2)\text{s}$ for this sample, while the generalized robustness still shows the presence of entanglement for a few milliseconds after this time. But, as it is clear from the figure, the EW has a large range of detection during the decoherence. Another feature that comes from the data analysis of detection
Implementation of a NMR entanglement witness

Fig. 6 Detection of entanglement by $F$ and generalized robustness under relaxation. The figure shows explicitly that there are states that are entangled but not detected by $F$ not only for Bell-diagonal states, since the transversal relaxation takes the state $|Φ^−⟩$ outside the class of the Bell-diagonal states. This region is localized between the times near to 0.3 s until approximately 0.4 s. At the figures, $τ_R$ and $τ_W$ are the characteristic times of the curves of detection of entanglement by the generalized robustness and by the EW, respectively. The time $τ_C$ is the approximate time which indicates the end of detection of the entanglement by the EW.

In Fig. 7, we compare the witnesses $F$ and $W$ for the entanglement of the state $|Φ^−⟩$ under relaxation. In one hand, we see that $W$ is more sensitive than $F$ and is a better quantifier, but on the other hand they detect entanglement in the same region.
Fig. 7 Detection of entanglement by $F$ and $W$ under relaxation. The two witnesses detect entanglement in the same region, but $W$ quantifies entanglement better than $F$.

5 Conclusions

In this paper, it has been made the experimental implementation of the EW proposed by Rahimi et al. [10] in the NMR context. It was shown explicitly the detection of entanglement, by this EW, for two different situations. First, it has been shown the region of detection by the EW for the class of Bell-diagonal states, with examples of entangled states that are detected and are not detected by the EW and a separable state. It was also shown how is the detection of the entanglement by the EW in the NMR decoherence process, the transversal relaxation. In this case, it was clearly shown the presence of a time interval which has a little presence of entanglement that is not detected by the EW. Instead of the fact that the EW can not be used to quantify entanglement for the two classes of states studied in this paper, this EW can detect entanglement for a large number of states in these two situations with the application of only one preparatory pulse to measure the EW. While the complete quantum state tomography, necessary to calculate entanglement quantifiers such as the generalized robustness and the concurrence, demands the application of four pulses to reconstruct the density matrix.

It was also proposed by a simple method other entanglement witnesses, $W$, that are optimal for each region of the entangled Bell-diagonal states. As could be seen by an example, these EW can detect the entangled Bell-diagonal states that are not detected by $F$. In the context of relaxation, the comparison of the two entanglement witnesses $W$ and $F$ shows that both detects the presence of entanglement in the same region, but $W$ with the advantage of a better quantification of entanglement in this region.

A possible next step would be the development of an EW that is optimal in the context of relaxation for a given state. Another advance would be the development in the context of NMR experiments of EW for the detection of multipartite entanglement for systems with larger number of qubits, where there is a considerable experimental cost to implement quantum state tomography.
