Abstract

Leishmaniasis is a neglected disease caused by protozoan parasites of the *Leishmania* genus spread around the world. Benzyl farnesyl amine mimetics are known class of compounds selectively designed to inhibit the squalene synthase (SQS) enzyme that catalyzes the first committed reaction on the sterol biosynthesis pathway. Herein, we studied seven new benzyl farnesyl amine mimetics (SBC 37 - 43) against *Leishmania amazonensis*. After the first initial screening of cell viability, two inhibitors (SBC 39 and SBC 40) were selected for further studies. Against intracellular amastigotes, SBC 39 and SBC 40 presented selectivity indexes of 117.7 and 180, respectively, indicating that they are highly selective. Analyses of free sterol showed that SBC 39 and SBC 40 inhibit two enzymes, sterol $\Delta^8 \rightarrow \Delta^7$ isomerase and SQS, resulting in depletion of endogenous 24-methyl sterols. Physiological analysis and electron microscopy revealed three main alterations: 1) in the mitochondrion ultrastructure and function; 2) the presence of lipid bodies and autophagosomes; and 3) the appearance of projections in the plasma membrane and extracellular vesicles inside the flagellar pocket. In conclusion, our results support the notion that benzyl farnesyl amine mimics have a potent effect against *Leishmania amazonensis* and should be an interesting novel pharmaceutical lead for the development of new chemotherapeutic alternatives to treat leishmaniasis.

1. Introduction

Leishmaniasis is an endemic neglected disease caused by several species of *Leishmania* genus. The leishmaniasis transmission was reported in a total of 98 countries and 3 territories on 5 continents. The estimated world prevalence for all clinical manifestations of the disease is 12 million, with 58,000 of visceral leishmaniasis (VL) cases and 220,000 cutaneous leishmaniasis (CL) cases per year [1, 2]. In the New World, multiple species, including *L. amazonensis* and *L. braziliensis*, are the causative agents of the CL. Furthermore, *L. amazonensis* can also cause mucocutaneous leishmaniasis (MCL), which results in a progressive destruction of the naso-oropharyngeal mucosa, and diffuse cutaneous leishmaniasis (DCL), the most severe cutaneous form of the disease that is characterized by a diffuse infiltration in the skin of the patients and highly resistant to all kind of chemotherapy available [3, 4]. Besides of the severe clinical manifestations of the leishmaniasis, there are few drugs available for its treatment.

Pentavalent antimonials are the first choice of treatment for more than 70 years in some countries around the world, despite the parenteral route of administration, high toxicity and cost [5]. Second-line treatments are based on the use of amphotericin B formulations and pentamidine. In some countries in Asia, Africa, and Europe, Miltefosine (Impavido) is currently the first line-treatment [5, 6]. Among the chemotherapeutic agents available, miltefosine is the only orally available treatment, however it is teratogenic and not indicated for woman of fertile age [7, 8]. None of the available drugs can be considered ideal due to their high toxicity, long duration of treatment, and severe side effects, which often lead to treatment abandonment. Furthermore, these treatments do not be eliminate the parasite completely in the infected individuals [9, 10].
Trypanosomatids and fungi have an endogenous requirement of ergosterol and other 24-alkylated sterols for growth and survival, which are absent in mammal cells. Thus, the enzymes of sterol biosynthesis pathway are interesting targets for new treatments and several works have shown the effect of different sterol biosynthesis inhibitors (SBIs) in trypanosomatids [11–17]. Benzyl farnesyl amine mimetics are one class of selective inhibitors of the squalene synthase (SQS), an important enzyme that catalyzes the condensation of two molecules of farnesyl pyrophosphate to produce squalene. This is the first committed step in the sterol biosynthesis, and its inhibition does not affect the synthesis of isoprenoids that are also important molecules for eukaryotic cells. For years, the research for specific squalene synthase inhibitors (SQSi) has involved intensive efforts of industrial and academic investigators, because of the potential use of these inhibitors in the treatment of coronary heart disease and hypercholesterolemia [18–20].

Among the selective inhibitors of the SQS [21–23], we early investigated the antiprotozoal potential of BPQ-OH (3-biphenyl-4-yl-3-hydroxyquinuclidine), an arylquinuclidine, with significant biological activity against *T. cruzi* and *L. mexicana*, resulting in growth inhibition, cell lysis and complete depletion of endogenous squalene and 24-methyl sterols [27]. Against *L. amazonensis*, BPQ-OH presented a potent growth inhibition effect against both developmental stages of the parasite leading to several changes in the ultrastructure of promastigotes [28]. Furthermore, other two quinuclidine derivatives, E-5700 and ER-119884, also showed potent antiproliferative effects against *T. cruzi* [30] and *L. amazonensis*, also in combination with C14α-demethylase inhibitors [azoles] [17, 23].

In this work, the effect of another class of selective SQS inhibitors, novel mimetics of benzyl farnesyl amine, were evaluated against *Leishmania amazonensis*. Several aspects of the anti-*Leishmania* activity of these compounds were investigated in different times of treatment, such as antiproliferative, ultrastructural and biochemical effects. Moreover, we found one derivative that is among the most selective compounds for the parasite with low toxicity for the mammalian cells.

### 2. Material And Methods

#### 2.1. Ethics statements.

The experiments using BALB/c mice to isolate macrophages and maintained *Leishmania* parasite were approved by the Ethics Committee for Animal Experimentation of the Health Sciences Centre, Federal University of Rio de Janeiro (Protocols n. IBCCF 096/097/106), according to the Brazilian federal law (11.794/2008, Decreto no 6.899/2009). All animals received humane care in compliance with the “Principles of Laboratory Animal Care” formulated by the National Society for Medical Research, and the “Guide for the Care and Use of Laboratory Animals” prepared by the National Academy of Sciences, USA.

#### 2.2. Parasites
The MHOM/BR/75/Josefa strain of *L. amazonensis* used in this study was gently provided by the Leishmania Collection of the Instituto Oswaldo Cruz (code IOCL 0071-FIOCRUZ). It has been maintained via inoculation into the base of BALB/c mouse tails. Amastigotes were obtained from the lesions of infected mice and transformed into promastigotes that were maintained in Warren's medium [brain heart infusion plus hemin and folic acid] [24] supplemented with 10% fetal bovine serum (FBS) at 25°C. Infective metacyclic promastigotes were used to obtain intracellular amastigotes in macrophage culture. Firstly, peritoneal macrophages from BALB/c mice were harvested by washing them with Hanks' solution and plated in 24-well tissue culture chamber slides, allowing them to adhere to the slides for 24 h in RPMI medium (Gibco) supplemented with 10% FBS at 37°C in 5% CO₂. After this, adherent macrophages were infected with metacyclic promastigotes at a macrophage-to-parasite ratio of 1:10 at 35°C in 5% CO₂ for 2 h. These cultures were maintained for 24 h in RPMI medium supplemented with 10% FBS for the assays with intracellular amastigotes.

2.3. Drugs.

The benzyl farnesyl amine mimetics, SBCs 37 - 43, were prepared by chemical synthesis at IQ-UNICAMP according to an experimental procedure previously described by Cämmerer and Souza [25]. Structures of those *N*[4-[benzyloxy] benzyl]-benzene-methaneamine derivatives, SBCs 37 - 43, are displayed in scheme 1. These compounds have been recently reported to exhibit significant biological activity against intracellular amastigotes of *Trypanosoma cruzi* [25]. Compounds were used as hydrochloride salts, which were purified by one recrystallization from analytical grade ethanol and dried in high vacuum at room temperature.

2.4. Cell viability and cytotoxicity assays

For primary screening of the antileishmanial effects of the SBCs 37-43, we evaluated the cell viability and cytotoxicity effects in *L. amazonensis* promastigotes and peritoneal macrophages by CellTiter 96® Aqueous MTS Assay (Promega, United States) [16, 29]. For analysis in promastigotes, we started the culture at cell density of 1 x 10⁶ cells/ml in Warren's medium supplemented with 10% FBS. After 24 h, different concentrations of SBC37-43 were added to the cultures. Cell viability and the cytotoxic effects were measured at 24, 48, and 72 h of treatment, when all groups, including untreated, were transferred to clear 96-well plate in triplicate. MTS/PMS assay reaction was quantified by optical density measurement at 490 nm in a microplate reader and SpectraMax M₂/M₂e spectrofluorometer (Molecular Devices, United States). As a negative control, parasites were fixed with 0.4% nascent formaldehyde for 10 min at room temperature before the incubation. Cytotoxicity effects of SBCs 37 - 43 in murine macrophages were also evaluated using the same MTS/PMS assay reaction described above. Murine macrophages were obtained from BALB/c mouse after washing with Hanks's solution and cultivated in a clear 96-well plate with RPMI medium supplemented with 10% FBS and maintained at 37°C in 5% CO₂. After 24 h of cultivation, SBCs 37 - 43 were added at different concentrations. Macrophages viability was measured at 24, 48, and 72 h of treatment. MTS/PMS assay reaction was also quantified by optical density measurement at 490 nm in a microplate reader and SpectraMax M₂/M₂e spectrofluorometer (Molecular
Devices, United States). The cytotoxicity concentration to reduce 50% of viable macrophages (CC_{50}) was determined.

2.5. Growth inhibition of promastigotes and amastigotes of \textit{L. amazonensis}

After the evaluation of the cell viability and cytotoxic effects by MTS assay in promastigote forms, we also analyzed the effects of the SBCs 37 - 43 in the growth of promastigotes. For this, promastigote cultures were initiated at a cell density of 1.0 \times 10^6 cells/ml. After 24 h of growth, SBCs 37 - 43 were added at different concentrations from concentrated stock solutions, and cell densities were evaluated daily over 96 h of growth using a Neubauer chamber. Based on the analysis of CC_{50} and IC_{50} in promastigotes, and the cytotoxic effects in murine macrophages, three of the benzyl farnesyl amine mimetics (SBCs 37, 39 and 40) were chose for evaluation against amastigotes infected macrophages. To evaluate the effects of compounds on \textit{L. amazonensis} intracellular amastigotes, macrophages were infected as described previously and incubated with different concentrations of compounds after 24 h of infection. Fresh medium was added daily until 3 days (24, 48, and 72 h of treatment). After this time, cultures were fixed in Bouin's solution \cite{17}, and washed with 70% ethanol, distilled water and then stained with Giemsa solution for 1 h. The number of intracellular amastigotes was obtained after count in light microscopy. Association indexes ((mean number of parasites internalized \times percentage of infected macrophages) / total number of macrophages) were determined and used as a parameter to calculate the percentage of infection for each condition used in this study. The concentration that inhibited 50% of growth (IC_{50}) and selective index (SI) were calculated.

2.6. Estimation of the mitochondrial transmembrane electric potential

Mitochondrial transmembrane electric potential (\Delta \psi_m) of the untreated and treated promastigotes was analyzed using the JC-1 fluorochrome (Molecular Probes, United States), a lipophilic and cationic mitochondrial vital dye that accumulates in the mitochondria in response to \Delta \psi_m, since its fluorescence is considered an indicator of an energized mitochondrial state \cite{15}. JC-1 exits as a J-monomer that in absence of \Delta \psi_m accumulate in low concentration with emission wavelength at 530 nm (green fluorescence), however, in presence of \Delta \psi_m JC-1 accumulated as J-aggregates with emission at 590 nm (red fluorescence). Parasites were prepared as previously described \cite{15,16}. For each sample, 1 \times 10^7 parasites were incubated with 10 \mu g/mL JC-1 for 25 min, with readings made every minute using a microplate reader and spectrofluorometer SpectraMax M2/M2e (Molecular Devices, United States). Cells were incubated in the presence of 2 \mu M FCCP (a mitochondrial protonophore) during the initial 20 min of experiment as positive control for the mitochondrial membrane depolarization. After 20 min of readings, 2 \mu M FCCP was added at all samples to abolish the \Delta \psi_m. The relative \Delta \psi_m values were obtained calculating the ratio between the reading at 590 nm and 530 nm (590:530 nm). Experiments were
independently repeated at least three times in triplicate, and graphic shows the mean and standard deviation of one representative experiment.

2.7. Evaluation of ROS production

Intracellular ROS levels were evaluated in control and compound-treated promastigotes as described previously [17]. For this, $3 \times 10^7$ promastigotes were harvested, washed twice in PBS (pH 7.2) and incubated with 10 µg/ml H$_2$DCFDA [a cell-permeable green probe; Molecular Probes, United States] in PBS for 1h at 25°C. After 1 h, cells were washed and resuspended in PBS, added in a black 96-well plate, and then analyzed in a microplate reader and spectrofluorometer SpectraMax M2/M2e (Molecular Devices, United States), using the pair of 507 nm and 530 nm wavelengths as emission and excitation wavelengths, respectively.

2.8. Lipid bodies accumulation

For analysis of lipid bodies accumulation, $1.0 \times 10^6$ cells were harvested, washed in PBS (pH 7.2), and incubated with 10 µg/ml Nile Red (Sigma, Brazil) for 20 min. After this step, cells were washed twice in PBS, resuspended in 200 µl of PBS and then added to a black 96-well plate. Readings were taken in a microplate reader and spectrofluorometer SpectraMax M2/M2e (Molecular Devices, United States), using the wavelengths 485 and 538 nm for excitation and emission, respectively.

2.9. Electron microscopy

First, control and treated promastigotes and intracellular amastigotes were fixed in 2.5% glutaraldehyde in 0.1 M cacodylate buffer (pH 7.2) for 1 h at room temperature. Second, the samples were postfixed in a solution containing 1% OsO$_4$, 1.25% potassium ferrocyanide, and 5 mM CaCl$_2$ in 0.1 M cacodylate buffer (pH 7.2) for 30 min. For scanning electron microscopy, promastigotes were dehydrated in ethanol (30, 50, 70, 90 and 100%) and critical point-dried in CO$_2$. After that, samples were sputtered with a thin gold layer, and then observed under a FEI Quanta 250 scanning electron microscope. For transmission electron microscopy, cells were dehydrated in acetone and embedded in epoxy resin. After that, ultrathin sections were stained with uranyl acetate and lead citrate and observed under a Zeiss 900 electron microscope.

2.10. Electron tomography

For electron tomography, ribbons of 200 nm thick serial sections were produced from transmission electron microscopy blocks described above. These ribbons were collected in a formvar-coated copper slot grids. After that, colloidal gold particles (10 nm) were deposited on both surfaces of the sections, being used as fiducial markers for alignment of the tilted views. Single-axis tilt series ($\pm 60^\circ$ with $1^\circ$ increments) were produced from samples using Xplore3D software and a Tecnai-G2 (FEI Company, Eindhoven, Netherlands) electron microscope operating at 200 kV. 3D reconstruction was performed using the IMOD software package [27]. Furthermore, tomogram generation by R-weighted back-projection was performed using ETOMO, and virtual slices were manually segmented using 3DMOD that was also used to produce 3D models.
2.11. Extraction, separation of neutral lipids and free sterol analysis.

For the analysis of the effects of SBC 39 and SBC 40 on the free sterol composition of the promastigotes, total lipids were extracted from control and drug-treated \textit{L. amazonensis} promastigotes, as described previously [17, 28]. Neutral lipids were analyzed by MS and mass spectra were obtained by electron ionization (EI) at 70 eV according to the protocol published previously [17, 28]. The assignment of structures was based on relative chromatographic behaviors, as well as the characteristic fragmentation patterns in MS and by comparison of the mass spectra with those available in the National Institute of Standards and Technology (NIST) Research Library located at the NIST Mass Spectrometry Data Center.

2.12. Calibration for cholesterol and ergosterol determination.

A set of five calibration standards was prepared from the pure standard of cholesterol and ergosterol purchased from Sigma-Aldrich Co. Different calibration solutions were prepared using ethyl acetate as solvent. For the quantification of cholesterol and ergosterol, standards were used at different concentrations of 0.08, 0.10, 0.25, 0.50 and 1.0 mM to plot the standard curve. From each calibration solution, 1 µL was injected (run in triplicate) into the GC-MS system to achieve the regression plot of various concentrations versus their peak area.

2.13. Statistical analysis

All the graphics in the figures were created using the means of three independent experiments, and the bars represent the standard deviations of the means. The statistical significance of differences among the groups was assessed using the one-way or two-way analysis of variance (ANOVA) test, followed by Bonferroni’s multiple-comparison test in the GraphPad Prisma 5 software. Results were considered statistically significant when \( P \) was < 0.05(\*), <0.01(\*\*), and <0.001(\*\*\*).

3. Results

3.1. The cytotoxic and antiproliferative effects of benzyl farnesyl amine mimetics (SBC 37 - 43) against macrophages and \textit{Leishmania amazonensis}

Figure 1 shows the cytotoxic effects of seven benzyl farnesyl amine mimetics (SBC 37 - 43) by MTS/PMS assay in promastigotes of \textit{Leishmania amazonensis}. Six of them had \( CC_{50} \) lower than 5 µM (SBC 37, SBC 39, SBC 40, SBC 41, SBC 42, and SBC 43), indicating a promising effect against \textit{L. amazonensis}. These inhibitors were used to evaluate their potential antiproliferative effects against promastigotes of \textit{L. amazonensis}. Figure 2 shows that the most potent inhibitors were SBC 37, SBC 39, SBC 40, and SBC 43 with \( IC_{50} \) of 557 nM, 560.05 nM, 303.78 nM, and 536.85 nM, respectively, after 72 h of treatment.
We also evaluated the cytotoxic effects of the SBCs 37 - 43 against murine macrophages using MTS/PMS assay after 72 h of treatment. Figure 3 shows that SBC 37, SBC 38, SBC 39, and SBC 40 presented low cytotoxicity to mammalian cells, with CC\textsubscript{50} of 33.94 µM, 40.53 µM, 40.65 µM, and 39.15 µM, respectively. Based on the results obtained for macrophage and promastigotes, we decided to evaluate the effects of three of them (SBCs 37, 39 and 40) against intracellular amastigotes. Figure 4 shows the antiproliferative effects of SBC 37, SBC 39, and SBC 40 after 72h of treatment, presenting IC\textsubscript{50} values of 740.48 nM, 345.35 nM, and 217.5 nM, respectively (Fig. 4A-C). Thus, the selectivity index obtained was 45.83, 117.7, and 180, respectively, after 72 h of treatment.

3.2. SBC 39 and SBC 40 alter the morphology of promastigotes

Scanning electron microscopy revealed important changes in the morphology of promastigotes treated with SBC 39 and SBC 40 for 48 h (Fig. 5A-F). Figure 5A shows a control \textit{L. amazonensis} promastigote without any alteration in the morphology of cell body, surface and flagellum (Fig. 5A). Treatment with lower concentrations of SBCs induced several alterations such as the presence of parasites rounded and swollen (Fig. 5B, C, F), also presenting vesicles budding from the region near the flagellar pocket (Fig. 5E) and sometimes more than two flagella (Fig. 5C, D). After 48 h of treatment with 300 nM SBC 40, all parasites were completely rounded (Fig. 5F). These results indicate the potent effect of these inhibitors to alter the morphology of promastigotes.

3.3. SBC 39 and SBC 40 alter mitochondrion function and induce lipid bodies accumulation

Nanomolar concentrations of SBC 39 and SBC 40 were able to reduce significantly the mitochondrial membrane potential (ΔΨ\textsubscript{m}) after 48 h of treatment (Fig. 6A). This effect was similar to those observed for the positive control group treated with FCCP, a mitochondrial protonophore. The readings were done 25 min after addition of JC-1 in all groups, when both forms of the fluorochrome (monomer and J-aggregate) are stabilized in inner portion of the mitochondrion. Although both inhibitors were able to reduce potential, only SBC 40 was able to increase significantly the ROS production at low concentrations (Fig. 6B).

Furthermore, both inhibitors were able to induce lipid bodies accumulation after 48 h of treatment (Fig. 7). However, for SBC 39 the concentration to increase the presence of lipid bodies was 3-times higher than those for SBC 40.

3.4. SBC 39 and SBC 40 alters the ultrastructure of promastigotes

Transmission electron microscopy was used to analyze the ultrastructural alterations induced by SBC 39 and SBC 40. Figure 8A shows a control promastigote presenting a structural organization without any alteration for the nucleus (N), mitochondrion (M), kinetoplast (k), flagellum (f) and cell surface. After 48 h
of treatment with 500 nM or 1 µM SBC 39, several alterations were observed, such as: 1) loss of the mitochondrial matrix content and vesiculation of its inner membrane (Fig. 8C, D, F); 2) presence of several large vacuoles similar to autophagosomes engulfing parts of the cytosol (Fig. 8B, E); 3), increased number of lipid bodies (Fig. 8E); and 4) disorganization of the kinetoplast (Fig. 8C-E). For the treatment with SBC 40, in concentrations much lower, the ultrastructural alterations were similar for those with SBC 39. A significant accumulation of lipid bodies randomly distributed throughout the cytosol were observed (Fig. 9C, D). The presence of glycosomes were easily observed in ultrathin sections of treated-promastigotes, probably indicating an increase number of them, since they are difficult to observe in control parasites (Fig. 9C). Furthermore, several extracellular vesicles inside the flagellar pocket (Fig. 9D), and the presence of autophagosome-like vacuoles in close association with nucleus and mitochondrion (Fig. 9A, E, F) were observed. Alterations in the trans-Golgi network (Fig. 9E), disorganizing of the kinetoplast (Fig. 9B), and intense mitochondrial swelling (Fig. 9B, F) were also induced by the treatments.

Trying to understand better the ultrastructural effects induced by SBs, we decided to carry out treatments with high concentrations and short time of incubation. For this, we used the concentration of 5 µM for just 6 h. The results obtained indicated significant alterations showing that these new compounds present a potent activity against *Leishmania*. Plasma membrane projections were observed after treatment with 5 µM SBC 39 (Fig. 10B-D, arrowhead). Interesting, these projections appeared frequently in regions of the membrane close to endoplasmic reticulum (Fig. 10D, arrowhead). Therefore, we decided to observe these projections by electron tomography. Figure 11A-D shows a serial section tomography of *L. amazonensis* promastigotes treated with 5 µM SBC 39 for 6 h. From these sections, a specific area of the parasite surface was reconstructed (Fig. 11E, F) revealing the ultrastructure of this plasma membrane projection. Images confirmed the presence of the endoplasmic reticulum profile near the projection, and the absence of microtubules associated to this projection. The alignment of the electron tomograms allows us to observe the relation between projection and endoplasmic reticulum (Suppl. Figs. 1 and 2 – movies).

Furthermore, the treatment with SBC 39 and SBC 40 for short time caused several other alterations in the ultrastructure of the promastigotes such as: mitochondrial swelling with an increased numbers of mitochondrial cristae (Fig. 10B, C, F); presence of large vacuoles and myelin-like figures (Fig. 10B-F); and disorganization of kinetoplast (Figure 11E). After alignment of several electron tomograms, it is possible to observe some of these changes in a movie containing a large volume of one treated promastigote with 5 µM SBC 39 (Suppl. Fig. 3 – movie).

### 3.5. Effects of SBC 40 on the fine structure of intracellular amastigotes

Transmission electron microscopy was also used to study the fine structure of intracellular amastigotes and the effects induced by the treatments. Figure 12 shows the ultrathin sections of *L. amazonensis* intracellular amastigotes treated with 1 µM SBC 40 for 48 h. Several alterations in the ultrastructure were observed, which are absent in the control parasites (Fig. 12A) such as: mitochondrial swelling (Fig. 12C);
presence of autophagosome-like vacuoles containing membrane profiles (Fig. 12C-D); alterations in the plasma membrane ultrastructure (Figure 12B-D, arrowhead); and disorganization of the kinetoplast (Figure 12D). Together, these images suggest the potent effect of benzyl farnesyl amine mimetics in L. amazonensis intracellular amastigotes.

### 3.6. Identification and quantification of the free sterol

Analyses of the free sterol composition of control and treated Leishmania amazonensis promastigotes (Table 1) revealed that the major sterols of control (untreated) promastigotes were ergosta-5,7,24(24’)-trien-3β-ol (5-dehydroepisterol) and ergosta-7,24(24’)-dien-3β-ol (episterol), both synthesized de novo, which accounted for 8 % and 2 %, respectively, of the total sterols. While other minority sterols such as zymosterol, cholesta-5,8,24-trien-3β-ol, ergosta-5,7,9(11)-22-tetraen-3β-ol, ergosta-5,8,22-trien-3β-ol, 14α-methyl-ergosta-8,24(24’)-dien-3β-ol, ergosta-8,24(24’)-trien-3β-ol, ergosta-5,7,9(10)-24(24’)-tetratrien-3β-ol, lanosterol, stigmastera-5,7,22-trien-3β-ol, stigmasta-7,22-trien-3β-ol were detected, and the sum of them represented 14 % (Table 1). Additionally, cholesterol, taken by endocytosis from the growth medium, accounted for 6%.

Incubation of L. amazonensis promastigotes with increasing concentrations of SBC 39 (300 nM – 1 µM) or SBC 40 (30 nM – 300 nM) for 48 h induced reduction of the relative level of the main endogenous sterol 5-dehydroepisterol in about 50%. However, promastigotes in presence of SBC 39 followed displayed a significant accumulation of ergosta-8, 24(24’)-dien-3β-ol (fecosterol) in 40%, while in the case of SBC 40 to the highest concentration, fecosterol reached only 16% (Table 1). Episterol is not significantly affected. These changes in the relative percentages of endogenous sterols are compensated with an increase in the percentage of cholesterol, which account for ca. 19% and 26% for SBC 39 and SBC 40 respectively.

When performing the quantitative analysis of cholesterol and endogenous sterol (Table 2), it can be seen that both drugs induce a concomitant 10 and 14 - fold (from 5.12 µg/ X 10^8 control cells to 0.4 or 0.5 µg/ X 10^8 treated cells; ≥ 90%) reduction of the content of endogenous sterols when compared with untreated cells. While cholesterol mass reduction is related to the decrease in cell density and not by the drugs actions.

### 4. Discussion

Although leishmaniasis has a number of treatment options, its therapy has a lot of problems as extensive toxicity, lack of efficacy, parenteral route of administration affecting compliance, high costs, and emerging drug resistance [29]. Visceral, cutaneous and mucocutaneous leishmaniasis remain some of the most devastating neglected tropical diseases. Thus, there is an urgent need for development of the new anti-leishmanial compounds that have more efficacy, low toxicity and cost, and preferentially administrated by oral or topic routes.

Sterol biosynthesis (SB) is an important metabolic pathway in Leishmania sp. For many years, several SB inhibitors have been studied against both developmental stages of the parasite in vitro [15–17, 23, 28,
Table 2

Free and total cholesterol and endogenous sterol contents in mass (µg) present in *L. amazonensis* growth in absence or presence of SBC 39 and SBC 40.

|                | Cholesterol (µg) | Endogens sterol (µg) |
|----------------|------------------|----------------------|
| Control        | 0.116            | 5.12µg               |
| 300 nM SBC 39  | 0.078            | 2.12                 |
| 500 nM SBC 39  | 0.062            | 1.18                 |
| 1.0 µM SBC 39  | 0.052 / 2-fold less | 0.54 / 10 fold less |
| 30 nM SBC 40   | 0.108            | 3.56                 |
| 100 nM SBC 40  | 0.078            | 0.92                 |
| 300 nM SBC 40  | 0.054 / 2-fold less | 0.38 / 14-fold less |

Some of them have also been tested *in vivo* against *Trypanosoma cruzi*, inducing a potent suppressive effect in models of acute Chagas’ disease [30, 33–35]. An important step of the SB is catalyzed by the enzyme squalene synthase (SQS). SQS is responsible for the reaction that catalyze the first committed step in the SB pathway; thus, not interfering with isoprenoid production and its metabolites [11, 36]. Several classes of squalene synthase inhibitors, such as quinuclidine derivatives, have been studied as potent SB inhibitors. The first quinuclidine derivatives tested against *Leishmania* sp. was BPQ-OH, ER-119884 and E5700 inducing cell death in association with the depletion of the parasite's endogenous sterols [23, 31]. Furthermore, other quinuclidine derivative, WSP 1267, showed potent effect against *Candida albicans*, *C. parapsilosis*, and *C. tropicalis*, with a MIC$_{50}$ of 2 µg/ml [37]. Some quinuclidine derivatives were also able to inhibit the recombinant *L. major* SQS at submicromolar concentrations, exhibiting selectivity action for the parasite enzyme [20–21]. Benzyl farnesyl amine mimics were also reported as to be selective inhibitors of human SQS. They were explored for their potential use for development of cholesterol lowering treatment options for hypercholesterolemia in man [38].
In this study, we report the activity of several benzyl farnesyl amine mimetics against *Leishmania amazonensis*. The compounds SBC 39 and SBC 40 showed the most pronounced effects on the growth of *L. amazonensis* intracellular amastigotes, associated with a low cytotoxicity in mammal cells and a higher selectivity index of 117.7 and 180, respectively. These selectivity indexes are higher than those found after treatment with posaconazole and itraconazole, two potent inhibitors of the growth of *L. amazonensis* [16]. Herein, the antiproliferative activities of SBC 39 and SBC 40 were in the nanomolar range against both extracellular promastigotes and intracellular amastigotes. The biological activity against *Leishmania amazonensis* was lower than those found for E5700 and ER-119884, two SQS inhibitors from Eisai Pharmaceutical Company, previously studied against *Leishmania* [17, 26]. Nevertheless, it is noteworthy to mention, that further development of E5700 and ER 119884 has been stopped, because it caused testicle atrophy in a small animal experiment. Beyond this, quinuclidine derivatives often bear a certain risk of neurological side effects (neurotoxicity of antimalarial drug quinine and other quinuclidine containing drugs). Therefore, medicinal chemistry has today an increasing interest, to avoid the quinuclidine moiety in early phase drug development. Last but not least, benzyl farnesyl amine mimetics have a much lower production cost, what is especially highly attractive for antiinfectious drug design in tropical emerging countries, where cost restrictions play sometimes a limiting factor in pharmaceutical development. Thus, these results should regarded as a highly valuable contribution to SB inhibitors research in tropical parasites with a high potential for further drug development.

To analyze morphological and ultrastructural alterations, we used scanning and transmission electron microscopy, respectively. Some morphological alterations such as the swollen of the cell body and the presence of several flagella were observed. Although the number of flagella in treated promastigotes was altered, we did not observe arrest of the cell cycle or presence of multiple numbers of nucleus and kinetoplast, similar to those observed by our group with other SB inhibitors [16, 17, 28]. Transmission electron microscopy images indicated that mitochondrion ultrastructure was dramatically altered after treatment with SBC 39 and SBC 40 (Figures 8 and 9). Using fluorescence markers for mitochondrial membrane potential and ROS production, as JC-1 and H$_2$DCF分别 respectively, it was possible to confirm the mitochondrial damage provoked by the treatments (Fig. 6). Alterations in the mitochondrion structure and function could be related to significant changes in the lipidic composition of the mitochondrial membranes, since previous studies showed that the unique and ramified mitochondrion of the trypanosomatid have a special composition of 24-methyl sterols [14]. Interestingly, in some images, several glycosomes were observed after treatment with SBC 40 (Fig. 9C), which could indicate an effort of the treated parasite to supply the mitochondrial damages and a possible decrease in the oxidative phosphorylation. An increase number of glycosomes could help the parasite to compensate the ATP production using the glycolytic pathway.

Another important alteration was observed in the plasma membrane (Fig. 5), which could be consequence of 24-methyl sterols depletion that was replaced by toxic intermediates of the sterol biosynthesis. This phenotype was also observed after treatment with several other SB inhibitors in
*Leishmania* [15–17, 26–27, 38]. Moreover, several projections on plasma membrane were observed after only 6 h of treatment, which were better observed by electron tomography (Figure 10, 11). Projections could also be related with the secretory pathway, since in some images, as shown in figure 9D, we observed several extracellular vesicles secreted by treated promastigotes. The presence of several giant vacuoles containing portions of the cytosol, damaged organelles and membranes could be related with an intense autophagic process, which could increase the secretory activity by the treated promastigotes.

After analyses of sterol composition, our results suggest that the compounds SBC 39 and SBC 40 have at least two mechanisms of action, both affecting the integrity of the plasma membrane. The first one, both act as inhibitors of the enzyme sterol $\Delta^8 \rightarrow \Delta^7$ isomerase, being the SBC 39 better inhibitor. The second mechanism of action would be the blockade of endogenous sterol biosynthesis at the level of SQS, where the SBC 40 has the greatest effect.

In conclusion, our results support the notion that SBC 39 and SBC 40 are promising new chemotherapeutic agents against *Leishmania* sp, since they presented a very high specificity for the parasite. Furthermore, our findings justify future studies to better understand the mode of action and also using in combination therapy with other SB inhibitors as a new therapeutic strategy that could reduce toxicity, but increase efficacy of treatment.

**Figures**

**Figure 1**

**Evaluation of cytotoxicity effects of SBCs on Leishmania amazonensis promastigotes.** Cell viability and cytotoxicity were evaluated against promastigotes using the MTS/PMS assay after 72 h of treatment. The cytotoxicity concentration to reduce 50% of viable promastigotes (CC$_{50}$) was determined. SBC37, SBC39, SBC40, SBC41, SBC42, and SBC43 presented CC$_{50}$ lower than 5 µM. Bars represent standard deviation, *p*<0.05, **p**<0.01, and ***p***<0.001.
Figure 2

*Evaluation of antiproliferative effects of SBCs on *Leishmania amazonensis* promastigotes.* Parasites were treated with SBCs for 72 h to evaluate the parasite growth. The inhibitors were added at different concentrations after 24 h of growth. The most potent inhibitors were SBC37 (A), SBC39 (B), SBC40 (C), and SBC43 (F) with IC$_{50}$ of 557 nM, 560.05 nM, 303.78 nM, and 536.85 nM, respectively, after 72 h of treatment.

Figure 3

*Evaluation of cytotoxicity effects of SBCs on murine macrophages.* The MTS/PMS assay was used to evaluate the cytotoxicity against murine macrophages after 72 h of treatment. The compounds SBC37 (A), SBC38 (B), SBC39 (C), and SBC40 (D) presented low cytotoxicity to mammalian cells, with CC$_{50}$ of 33.94 µM, 40.53 µM, 40.65 µM, and 39.15 µM, respectively. Bars represent standard deviation; *$p<0.05$, **$p<0.01$, and ***$p<0.001$.

Figure 4

*Evaluation of antiproliferative effects of SBC37, SBC39, and SBC40 on *Leishmania amazonensis* intracellular amastigotes.* Parasites were treated with different concentrations of the inhibitors for 72 h to evaluate the parasite growth. After 72 h of treatment, the IC$_{50}$ was determined for each inhibitors tested and the values were 740.48 nM, 345.35 nM, and 217.5 nM, respectively. Thus, the selectivity index obtained was 45.83, 117.7, and 180, respectively. Bars represent standard deviation; *$p<0.05$, **$p<0.01$, and ***$p<0.001$. 

Figure 5
Scanning electron microscopy (SEM) of *L. amazonensis* promastigotes treated with SBCs for 48 h. (A) Control. (B, C) 500 nM SBC39. (D) 1 µM SBC39. (E) 100 nM SBC40. (F) 300 nM SBC40. The images show several changes at morphology of the parasite. Promastigotes appeared rounded and swollen (B, C, F), with vesicles next to flagellar pocket (E). Sometimes more than two flagella could be observed (C, D).

**Figure 6**

Evaluation of the mitochondrial physiology and function of *L. amazonensis* promastigotes, control and treated with SBC39 and SBC40 for 48 h. (A) Measurement of $\Delta \psi_m$ using JC-1 marker. (B) Determination of intracellular ROS by incubating the cells with H$_2$DCFDA. The decrease in the $\Delta \psi_m$ value indicates a collapse in the mitochondrial transmembrane potential when parasites were treated with SBC39 and SBC40. Treatment with 100 nM and 300 nM SBC40 induced a significant increase of ROS. FCCP and H$_2$O$_2$ were used as positive control. The experiments were performed three times, each time in triplicate, and the figures shown are representative of these three experiments. Bars represent standard deviation. *$p<0.05$, **$p<0.01$, and ***$p<0.001$.

**Figure 7**

Analysis of Nile Red accumulation. Fluorometric analyses indicate that there is a significant increase in Nile Red accumulation after treatment with 300 nM SBC39 and 100 nM SBC40. Bars represent standard deviation. *$p<0.05$, **$p<0.01$, and ***$p<0.001$.

**Figure 8**

Ultrathin sections of *Leishmania amazonensis* promastigotes, control (A) and treated with 500 nM (B, C) or 1 µM SBC39 (D-F) for 48 h. Several alterations were observed such as: loss of the matrix content and vesiculation of the inner mitochondrial membrane (C, D, F); presence of several larges vacuoles similar to autophagosomes engulfing portions of the cytoplasm (B, E); presence of lipid bodies (E); and disorganization of the kinetoplast structure (C-E). N: nucleus; m: mitochondrion; f: flagellum; k: kinetoplast; asterisks: lipid bodies; v: autofagosome-like vacuole.
Ultrathin sections of *Leishmania amazonensis* promatigotes treated with 100 nM SBC40 (A-C) or 300 nM SBC40 (D-F) for 48h. SBC40 also induced alterations in the parasite ultrastructure such as: mitochondrial swelling and structural disorganization (A, B, F); presence of many lipid bodies electron dense and electron lucent (stars, C-D); high number of extracellular vesicles inside flagellar pocket (D); presence of several vacuoles similar to autophagosomes containing portions of the cytoplasm and membranes (A, E, F). Panel E shows a dilation at the trans-Golgi network. N: nucleus; m: mitochondrial; f: flagellum; k: kinetoplast; asterisks: lipid bodies; v: autophagosome-like vacuole; g: glycosome.

Ultrathin sections of *Leishmania amazonensis* promastigotes, control (A) and treated with 5 µM SBC39 (B-D) or SBC40 (E, F) for 6 h. After a short time of incubation with the compounds, promastigotes also presented several alterations such as: mitochondrial swelling with a significant increase number of cristae (B-C, E-F); plasma membrane projections (B-D, arrowhead); disorganization of kinetoplast (E); and presence of large vacuoles and a myelin like-figure in close association with endoplasmic reticulum (B-C, E-F, arrow). N: nucleus; m: mitochondrion; f: flagellum; k: kinetoplast; asterisks: lipid bodies; v: vacuole.

Electron microscopy tomography and 3D reconstruction showing a projection of the plasma membrane of *L. amazonensis* promastigotes treated with 5 µM SBC39 for 6h. The images confirmed the presence of the endoplasmic reticulum profile near the projection, and the absence of microtubules associated to it.
Ultrathin section of *L. amazonensis* intracellular amastigotes treated with 1 µM of SBC40 for 48 h. Parasites treated with SBC40 appeared with drastic alterations in plasma membrane (B-D, arrowhead), mitochondrial swelling (C), presence of autofagosome-like vacuoles (C-D), and disorganization of the kinetoplast (D). N: nucleus; m: mitochondrion; f: flagellum; k: kinetoplast; v: autofagosome-like vacuole.
