Transverse-longitudinal coupling by space charge in cyclotrons

C. Baumgarten*

Paul Scherrer Institute, Switzerland

(Received 12 September 2011; published 28 November 2011)

A method is presented that enables one to compute the parameters of matched beams with space charge in cyclotrons with emphasis on the effect of the transverse-longitudinal coupling. Equations describing the transverse-longitudinal coupling and corresponding tune shifts in first order are derived for the model of an azimuthally symmetric cyclotron. The eigenellipsoid of the beam is calculated and the transfer matrix is transformed into block-diagonal form. The influence of the slope of the phase curve on the transverse-longitudinal coupling is accounted for. The results are generalized and numerical procedures for the case of an azimuthally varying field cyclotron are presented. The algorithm is applied to the PSI injector II and ring cyclotron and the results are compared to TRANSPORT.

I. INTRODUCTION

There is continuous interest in the understanding of space charge effects in isochronous cyclotrons [1–9]. The area is of special relevance for the conceptual designs of cyclotrons as energy-efficient drivers for accelerator driven systems (ADS) [10,11]. Nevertheless, there is no self-consistent first order theory of matched bunched beams with space charge in cyclotrons to date known to the author. Bertrand and Ricaud showed that it is possible to set up and solve linearized equations of motion for a simple cyclotron model [9], but they did not determine the parameters of matched beams in cyclotrons and they did not generalize their results in order to find a numerical method to compute matched beams for sector-focused cyclotrons. Information on the matched ellipsoid is of special interest for modern high-performance codes like OPAL, that enable one to simulate high intensity beams in the space charge dominated regime [12,13].

First, we describe the usual simplified azimuthally symmetric cyclotron model (see, for instance, [14] or [15]), but include the linearized space charge forces. The model neglects possible effects of rf acceleration and is restricted to the description of a coasting beam. A modified version of Teng’s method to decouple longitudinal and horizontal motion will be presented and applied to the simplified analytical model [16,17]. Later we describe how this method can be applied in an iterative numerical procedure to determine the parameters of matched beams with space charge in sector-focused cyclotrons. Finally, we present some results as computed for the cyclotrons of the PSI high intensity accelerator facility.

II. THE SIMPLIFIED CYCLOTRON MODEL

The simplest relativistic cyclotron model is based on a magnetic field with cylindrical and midplane symmetry. The nominal orbital frequency of an ion beam coasting in an isochronous cyclotron is

$$\omega_0 = \frac{q}{m\gamma} B = \frac{q}{m\gamma} B_0 \gamma,$$

where $q$ is the charge and $m$ the rest mass of the ions. The axial magnetic field is $B = B(r) = B_0 \gamma$. We define a cyclotron length unit $a = \frac{\omega_0}{\omega}$ using the orbital frequency $\omega_0$. The particle velocity is $v = \omega_0 r$ so that $\beta = v/c = r/a$. Hence, the relativistic factor $\gamma$ can be written as

$$\gamma = \frac{1}{\sqrt{1 - (r/a)^2}}. \quad (2)$$

The axial magnetic field in dependence of the radius $r$ is then given by

$$B(r) = B_0 \frac{1 + \varepsilon(r)}{\sqrt{1 - \frac{v^2}{c^2}}}, \quad (3)$$

where $\varepsilon$ is a small distortion of the isochronism ($\varepsilon \ll 1$). The radial field increase compensates the relativistic mass increase and the cyclotron is strictly isochronous for $\varepsilon(r) = 0$. The field index $n = \frac{d\ln B}{d\ln r}$ is given by

$$n = \frac{r \frac{dB}{dr}}{B} = \frac{r \frac{d\varepsilon}{dr}}{r} + \gamma^2 - 1, \quad (4)$$

so that

$$1 + n = \gamma^2 + r \frac{d\varepsilon}{dr}. \quad (5)$$

The phase shift per turn $\Delta\phi \equiv \frac{d\phi}{dr}$ is (see, for instance, [14])

\[
\Delta \phi = T \frac{d \phi}{dt} = T \left( \frac{d \phi_{bf}}{dt} - N_h \frac{d \theta}{dt} \right) = \frac{2 \pi}{\omega_c} \left( \omega_{bf} - N_h \omega_c \right) = \frac{2 \pi}{\omega_c} (N_h \omega_c - N_h \omega_c) = 2 \pi N_h \left( \frac{\omega_c}{\omega_c} - 1 \right), \quad (6)
\]

where \( \theta \) is the azimuthal angle, \( \omega_c = \theta \) is the real orbital frequency, and \( \omega_{bf} = N_h \omega_c \) the frequency of the accelerating high frequency system operated at the harmonic number \( N_h \). The bending radius \( r \) of a particle with charge \( q \) in a magnetic field \( B \) is given by \( r = \frac{q B}{\gamma} \) and, hence, \( \omega_c \) can be written as

\[
\omega_c = \frac{v}{r} = \frac{m c \gamma \beta}{m \gamma r} = \frac{p}{m \gamma r} = \frac{q B(r)}{m \gamma r} = \frac{q B_0 \gamma (1 + \varepsilon)}{m \gamma},
\]

so that

\[
\frac{\omega_c}{1 + \varepsilon} = 1 - \varepsilon = - \frac{\Delta \phi}{2 \pi N_h} = - \left( \frac{\omega_c}{\omega_c} - 1 \right). \quad (8)
\]

Hence, \( \frac{\Delta \phi}{\omega_c} \) is proportional to the change of the phase shift per turn with radius. The reference orbit corresponding to the kinetic energy \( E = m c^2 (\gamma - 1) = E_0 (\gamma - 1) \) is a circle with the radius

\[
r(E) = a \sqrt{\gamma^2 - 1}. \quad (9)
\]

We will use \( x = r - r(E) \) as the horizontal coordinate of a specific orbit relative to the reference orbit, \( y \) as the axial deviation from the median plane, and \( z \) as the longitudinal coordinate.

### III. SOME GENERAL REMARKS

From the assumption of midplane symmetry it follows that the axial coordinate \( y \) is neither coupled to the horizontal nor to the longitudinal coordinate. Therefore it is sufficient to describe the coupling of horizontal and longitudinal motion. Since we assume azimuthal symmetry, the matched beam ellipse must also be azimuthally symmetric, i.e., constant along the orbital length coordinate \( s \). If the matched beam is constant, then the forces are constant—even if space charge is taken into account.

The vector describing the (horizontal and longitudinal) displacement of an orbit at position \( s \) relative to the reference orbit is \( \mathbf{x} = (x, x', z, \delta)^T \), where \( x' = \frac{dx}{ds} \) is the horizontal direction angle with the reference orbit and \( \delta = \frac{L - L_0}{\gamma} \) is the relative momentum deviation. We use the formalism of linear Hamiltonian systems as for instance described by Talman [18] including the method of Wolski to compute the matched beam matrix [19]. The equations of motion (to first order) can be written as

\[
\mathbf{x}'(s) = \mathbf{Fx}(s), \quad (10)
\]

where \( \mathbf{F} \) is a constant \( 4 \times 4 \) matrix. The general solution is

\[
\mathbf{x}(s) = \exp(\mathbf{Fs})\mathbf{x}(0) = \mathbf{M}(s)\mathbf{x}(0), \quad (11)
\]

where \( \mathbf{M}(s) \) is the transfer matrix. The matrix exponential \( \mathbf{M}(s) \) is

\[
\mathbf{M}(s) = \exp(\mathbf{Fs}) = 1 + \mathbf{F} s + \frac{(\mathbf{Fs})^2}{2!} + \frac{(\mathbf{Fs})^3}{3!} + \cdots. \quad (12)
\]

Let \( S \) be the skew-symmetric matrix with \( S^2 = -1 \),

\[
S = \begin{pmatrix}
0 & 1 & 0 & 0 \\
-1 & 0 & 0 & 0 \\
0 & 0 & 0 & 1 \\
0 & 0 & -1 & 0
\end{pmatrix}, \quad (13)
\]

so that—since \( \mathbf{M} \) is symplectic—the following relation holds:

\[
\mathbf{M}^T S \mathbf{M} = S. \quad (14)
\]

If there exists an invertible transformation matrix \( \mathbf{E} \) and a diagonal matrix \( \lambda \) such that

\[
\mathbf{F} = \mathbf{E} \lambda \mathbf{E}^{-1}, \quad (15)
\]

then it is easy to show that the following relation holds:

\[
\mathbf{M} = \mathbf{E} \exp(\lambda s) \mathbf{E}^{-1} = \mathbf{E} \lambda \mathbf{E}^{-1}. \quad (16)
\]

\( \mathbf{E} \) is the matrix of columnwise eigenvectors and \( \lambda \) is the (diagonal) matrix of the corresponding eigenvalues of \( \mathbf{F} \). The (imaginary) eigenvalues of \( \mathbf{F} \) are the betatron frequencies of the orbital motion. \( \mathbf{F} \) and \( \mathbf{M} \) have the same eigenvectors—and the eigenvalues of \( \mathbf{M} \) are the exponentials of the eigenvalues of \( \mathbf{F} \). The eigenellipsoid \( \sigma_E \), defined by

\[
\sigma_E = \mathbf{M}\sigma_E \mathbf{M}^T, \quad (17)
\]

can then be written as follows [19]:

\[
\sigma_E = - \mathbf{E} \mathcal{D} \mathbf{E}^{-1} S, \quad (18)
\]

where \( \mathcal{D} \) is the diagonal matrix with the eigenvalues of \( \sigma_E S \)—which are the emittances (apart from factors \( \pm i \)).

### IV. THE EQUATIONS OF MOTION (EQOM)

The Hamiltonian is given by

\[
H = \frac{x'^2}{2} + \frac{\delta^2}{2 \gamma^2} + \frac{k_c - K_c}{2} x^2 - \frac{\gamma^2 K_c}{2} l^2 - h x \delta, \quad (19)
\]

where the canonical coordinates are \( x \) and \( l \) and the momenta are given by \( x' \) and \( \delta \). The EQOM (in first order) are

\[
\frac{dx}{ds} = \begin{pmatrix}
0 & 1 & 0 & 0 \\
\frac{1}{2} k_c + K_c & 0 & 0 & \frac{h}{\gamma} \\
0 & 0 & 0 & \frac{1}{2} K_c \gamma^2 \\
-\frac{1}{2} h & 0 & 0 & 0
\end{pmatrix} \begin{pmatrix}
x \\
x' \\
l \\
\delta
\end{pmatrix}, \quad (20)
\]

where \( h = \frac{1}{\gamma} \) is the inverse bending radius and \( k_c = h^2 (1 + n) \) is the horizontally restoring force. \( K_c \) and \( K_c \) represent the
strength of the horizontal and longitudinal space charge forces [20]:

\[
K_x = \frac{K_3(1 - f)}{(\sigma_x + \sigma_y)\sigma_x\sigma_z}, \quad K_3 = \frac{3qI\lambda}{20\sqrt{5}\pi\epsilon_0mc^3B^2}\gamma^3
\]

\[
K_z = \frac{K_3f}{\sigma_x\sigma_y\sigma_z} = \frac{\sqrt{\sigma_x\sigma_y}}{3\gamma\sigma_z}, \quad K_y = \frac{K_3(1 - f)}{(\sigma_x + \sigma_y)\sigma_x\sigma_z}.
\]

The eigenvalues of \( \mathbf{F} \) and \( \mathbf{M} \) are

\[
\lambda = \text{Diag}(i\Omega, -i\Omega, i\omega, -i\omega)
\]

\[
\Lambda = \text{Diag}(e^{i\Omega}, e^{-i\Omega}, e^{i\omega}, e^{-i\omega}) \quad a \equiv \frac{k_x - K_x - K_z}{2}
\]

\[
b = K_z(K_x + h^2\gamma^2 - k_z)
\]

\[
\omega = \sqrt{a - \sqrt{a^2 - b}}.
\]

(22)

The inverse matrix \( \mathbf{E}^{-1} \) is given by

\[
\mathbf{E}^{-1} = \frac{1}{2(A - B)} \begin{pmatrix}
-B & \frac{ib}{\Pi} & -i & \frac{1}{\Gamma K_z}\gamma^2 \\
-i\Omega & i\Omega & -i\omega & -i\omega \\
-i\omega & i\omega & -1 & \frac{1}{\Gamma K_z}\gamma^2 \\
A & -\frac{ib}{\Pi} & \frac{1}{\Gamma K_z}\gamma^2 & \frac{1}{\Gamma K_z}\gamma^2
\end{pmatrix},
\]

(25)

where

\[
A = \frac{h}{\Omega^2 + K_z}, \quad B = \frac{h}{\omega^2 + K_z}.
\]

The transfer matrix \( \mathbf{M} \) can be computed by using Eq. (16) and one obtains

\[
\mathbf{M} = \frac{1}{A - B} \begin{pmatrix}
Ac - BC & \frac{\Delta s}{\omega} - \frac{BS}{\Pi} & \frac{\Pi}{\Omega} - \frac{s}{\omega} & AB(C - c) \\
\Omega B S - \omega A \bar{s} & Ac - BC & C - c & AB(\omega \bar{s} - \Omega S) \\
AB(\Omega S - \omega \bar{s}) & AB(c - C) & AC - Bc & AB(\omega \bar{s} - A \Omega S) \\
c - C & \frac{\bar{s}}{\omega} - \frac{S}{\Omega} & \frac{S}{\Omega} - \frac{\Pi}{\Omega} - \frac{\bar{s}}{\omega} & AC - Bc
\end{pmatrix},
\]

(27)

where

\[
C = \cos(\Omega s) \quad S = \sin(\Omega s) \quad c = \cos(\omega s) \quad \bar{s} = \sin(\omega s).
\]

\]

(28)

**V. THE EIGENELIPSOID**

The matrix \( \mathcal{D} \) is explicitly given by \( \mathcal{D} = \text{Diag}(i\epsilon_1, -i\epsilon_1, -i\epsilon_2, i\epsilon_2) \) [19]. The matched eigenellipsoid can then be calculated using Eq. (18):

\[
\sigma_L = \frac{1}{B - A}
\]

\[
\begin{pmatrix}
\frac{B\epsilon_1 + A\epsilon_2}{\omega} & 0 & 0 & \frac{\epsilon_1}{\Pi} + \frac{\epsilon_2}{A}\omega \\
0 & B\epsilon_1 + A\epsilon_2 \omega & \frac{\epsilon_1 \Omega + \epsilon_2 \omega}{\Pi \gamma \gamma^2} & 0 \\
0 & \frac{\epsilon_1 \Omega + \epsilon_2 \omega}{K_z \gamma^2} & A\epsilon_1 \Omega + B\epsilon_2 \omega & 0 \\
\frac{\epsilon_1}{\Pi} + \frac{\epsilon_2}{A}\omega & 0 & 0 & \frac{\epsilon_1}{\Pi} + \frac{\epsilon_2}{A}\omega
\end{pmatrix}.
\]

(29)
where $\varepsilon_1 = \varepsilon_x$ and $\varepsilon_2 = \varepsilon_z$ are identified with the horizontal and longitudinal emittance, respectively. The axial motion can be treated separately and one finds

$$\sigma_y^2 = \frac{\varepsilon_y}{\sqrt{h^2 \nu_y^2 - K_y}}. \quad (31)$$

If one considers Eq. (21) together with Eqs. (30) and (31), then it is obvious that this result does not enable one to start a straightforward calculation, since the beam sizes depend on the space charge forces and vice versa in an algebraically complicated way. But with the additional assumption of a spherical beam, it is possible to derive a 4th order equation for the beam size as will be shown in Sec. VIII.

VI. DECOUPLING LONGITUDINAL AND TRANSVERSE MOTION

If sectors are considered, then the azimuthal symmetry is broken and, hence, the force terms in the EQOM and consequently the beam ellipsoid depend on the position $s$. The vertical beam dynamics can still be treated separately, but it has to be taken into account that the periodic change of the vertical beam size influences the space charge factors $K_x$ and $K_z$. The design orbit usually has to be computed numerically as described by Gordon [21]. If this has been done, it is possible to compute the transfer matrix for known starting conditions, since the equations of motion are known and can be integrated. The problem is to find the correct beam dimensions for a given beam current and given emittances such that the beam is matched, i.e., such that Eq. (17) is fulfilled.

Teng and Edwards described a parametrization for coupled motion in two and more dimensions that allows one to find the decoupling matrix [16,17]. They called their method symplectic rotation. We will give a brief summary of the method and apply it to the problem of decoupling longitudinal and transverse motion.

Given two $2 \times 2$ symplectic matrices $\mathcal{A}$ and $\mathcal{B}$ that form a block-diagonal (i.e. decoupled) transfer matrix $T_0$,

$$T_0 = \begin{pmatrix} \mathcal{A} & 0 \\ 0 & \mathcal{B} \end{pmatrix}$$

$\mathcal{A}(\mu_1) = \cos(\mu_1) \mathbb{1} + \sin(\mu_1) \begin{pmatrix} \alpha_1 & \beta_1 \\ -\gamma_1 & -\alpha_1 \end{pmatrix}$ \quad (32)

$\mathcal{B}(\mu_2) = \cos(\mu_2) \mathbb{1} + \sin(\mu_2) \begin{pmatrix} \alpha_2 & \beta_2 \\ -\gamma_2 & -\alpha_2 \end{pmatrix}$.

where $\alpha_i$, $\beta_i$, and $\gamma_i$ are the familiar Twiss parameters. Then a general symplectic transfer matrix $M$ of coupled motion can be written as

$$M = \begin{pmatrix} M & n \\ m & N \end{pmatrix} = R T_0 R^{-1},$$

where $M$, $N$, $m$, and $n$ are $2 \times 2$ matrices and $R$ is the symplectic rotation matrix. Teng suggested to write $R$ in the form

$$R = \begin{pmatrix} I \cos(\phi) & D^{-1} \sin(\phi) \\ -D \sin(\phi) & I \cos(\phi) \end{pmatrix} \quad \text{and} \quad R^{-1} = \begin{pmatrix} I \cos(\phi) & -D^{-1} \sin(\phi) \\ D \sin(\phi) & I \cos(\phi) \end{pmatrix}.$$ \quad (34)

The rotation angle $\phi$ can be computed using

$$\frac{1}{2} \text{Tr}(M - N) = \cos(2\phi) \left[ \cos(\mu_1) - \cos(\mu_2) \right]$$

$$2 \text{Det}(m) + \text{Tr}(nm) = \sin^2(2\phi) \left[ \cos(\mu_1) - \cos(\mu_2) \right]^2.$$ \quad (36)

If we apply this method to the transfer matrix computed according to Eq. (16), we obtain

$$\frac{1}{2} \text{Tr}(M - N) = \frac{B + A}{B - A} \left[ \cos(\Omega s) - \cos(\omega s) \right]$$

$$2 \text{Det}(m) + \text{Tr}(nm) = -\frac{4AB}{(B - A)^2} \left[ \cos(\Omega s) - \cos(\omega s) \right]^2.$$ \quad (37)

Comparison of Eqs. (36) and (37) yields

$$\cos(2\phi) = \frac{B + A}{B - A} \sin^2(2\phi) = -\frac{4AB}{(B - A)^2}.$$ \quad (38)

From Eq. (26) we find that $A > 0$ and $B > 0$ and $B > A$ since $\Omega^2 > \omega^2$, so that the method fails in the case under study. The method of symplectic rotation is not generally applicable and has to be extended. A workaround solution was found by replacing trigonometric by hyperbolic functions.2

$$R = \begin{pmatrix} I \cosh(\psi) & D^{-1} \sinh(\psi) \\ D \sinh(\psi) & I \cosh(\psi) \end{pmatrix} \quad \text{and} \quad R^{-1} = \begin{pmatrix} I \cosh(\psi) & -D^{-1} \sinh(\psi) \\ -D \sinh(\psi) & I \cosh(\psi) \end{pmatrix}.$$ \quad (39)

2Formally this extension is a rotation about an imaginary angle, similar to a Lorentz boost in Minkowski space.
with $\text{Det}(D) = -1$, i.e. $D$ is not symplectic—but $R$ is symplectic. Table I compares the formulas of the symplectic rotation and of the symplectic Lorentz boost. Applying this method to the case under study then gives

$$\sin(2\psi) = \frac{2\sqrt{AB}}{B-A} \quad \text{cosh}(2\psi) = \frac{B+A}{B-A}$$

$$\tanh(2\psi) = \frac{2\sqrt{AB}}{B+A} \quad \sinh(\psi) = \sqrt{\frac{A}{B-A}}$$

$$\cosh(\psi) = \sqrt{\frac{B}{B-A}} \quad \tanh(\psi) = \sqrt{\frac{A}{B}}$$

which can be solved. The matrices $\mathcal{A}$ and $\mathcal{B}$ are then given by

$$\mathcal{A} = \begin{pmatrix} \cos(\Omega s) & \sin(\Omega s)/\Omega \\ -\Omega \sin(\Omega s) & \cos(\Omega s) \end{pmatrix}$$

$$\mathcal{B} = \begin{pmatrix} \cos(\omega s) & -AB\omega \sin(\omega s) \\ \sin(\omega s)/(AB\omega) & \cos(\omega s) \end{pmatrix}$$

$$D = \begin{pmatrix} 0 & \sqrt{AB} \\ 1/\sqrt{AB} & 0 \end{pmatrix}.$$ (40)

The signs in $\mathcal{B}$ suggest a negative $\beta_2$, but this can be compensated by using either a negative emittance or a negative frequency $\omega$, since the transfer matrix is invariant against a change of the sign of $\omega$, while $\sigma_E$ is not.

The transformation matrices are explicitly given by

$$R = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 1/B & 0 \\ 0 & A & 1 & 0 \\ 1/B & 0 & 0 & 1 \end{pmatrix}$$

$$R^{-1} = \begin{pmatrix} 1 & 0 & 0 & -A \\ 0 & 1 & -1/B & 0 \\ 0 & -A & 1 & 0 \\ -1/B & 0 & 0 & 1 \end{pmatrix}.$$ (42)

The matched beam ellipsoid can be computed for given emittances according to Eq. (18) as soon as the diagonalization of the transfer matrix $M$ is known.

The fact that we have to extend the decoupling method of Teng and Edwards raises the question, whether the description of decoupling is now complete or if there are other cases that require further modifications or extensions. The answer to this question requires a proper two-dimensional extension of the Courant-Snyder theory and a complete survey of all possible symplectic transformations as presented in an accompanying paper [22].

### VII. THE ITERATION PROCESS AND EXAMPLES

We have shown for the symmetrical analytical example that a modified version of the method of Teng and Edwards enables one to bring the transfer matrix in block-diagonal form according to Eq. (32). The diagonalization of the block-diagonal matrices is given by Eq. (43) and, hence, the matrix of eigenvectors $E$ and the matched beam ellipsoid can be constructed.

In order to take advantage of this method for the case of sectored cyclotrons, the method has to be applied iteratively. The goal is to compute the properties of a matched beam. Assuming that the beam emittances and the current are given as boundary conditions, one proceeds as follows:

1. Provide an initial guess of the beam dimensions $\sigma_x(s)$, $\sigma_y(s)$, and $\sigma_z(s)$.
2. Compute the driving terms of the space charge forces $K_x(s)$, $K_y(s)$, and $K_z(s)$.
3. Compute the one-turn transfer matrix $M(s)$ for all azimuthal angles.
4. Compute the eigenvectors of $M(s)$ by diagonalization.
5. Use the beam emittances to obtain the eigenellipsoid $\sigma_E$ according to Eq. (18).
6. Take the beam sizes from $\sigma_E$ and go back to step (ii), if beam sizes changed significantly compared to the previous iteration.

Optionally, one can start the iteration with a reduced beam current and increase it either during the iteration process or use the result of the reduced beam current as an initial guess for higher currents. The (speed of) convergence strongly depends on the assumptions about beam current and emittance. In the following examples, the process converged typically after less than 20 iterations.

### A. Example: PSI injector II

The PSI high intensity proton accelerator facility [23,24] consists of a Cockcroft-Walton preaccelerator, a four-sector injector cyclotron (injector II, 72 MeV), and the
eight sector ring cyclotron (590 MeV). In routine operation
the beam current is 2.2 mA.

The injector II cyclotron can be modeled reasonably
well by a hard edge approximation of the sector magnets.
This has the advantage that the computed matched beam
parameters can be compared to TRANSPORT [25–27].
We have computed the matched beam parameters for
injector II. The results have then been used as input
parameters for TRANSPORT (with space charge). The
results are shown in Fig. 1.

\begin{figure}
\centering
\includegraphics[width=\textwidth]{figure1.png}
\caption{Transport (re)computation of a matched beam in injector II for a circulating beam of 2.2 mA at low energy. The boxes indicate the position of the sector magnets SM1–SM4. The horizontal beam width is plotted as a negative value. The longitudinal beam size is plotted as $2\sigma_L$.}
\end{figure}

\section*{B. Example: PSI ring cyclotron}

The PSI ring cyclotron is a separated sector isochronous
cyclotron with eight sectors. But since the field of
the magnets does not fall off as sharp as it does in injector II,
a hard edge approximation does not work equally well.
Furthermore, the sectors are much more spiralled. For the
sake of precision we used the measured field map $B(r, \theta)$ to
compute the equilibrium orbits (EO) on a radial grid [28].
The radius $R_{eo}(\theta)$ of the equilibrium orbit (EO) is then
given as a function of the angle and of the starting radius
$R_{eo}(\theta_0)$. Besides the pure geometry of the orbit, one also
obtains a precise value for $e = 1 - \frac{\omega_0}{\omega}$ for each EO [21],
which then allows one to compute $\frac{dx}{dt}$. In order to obtain the
force matrix according to Eq. (20), the following additional
calculations have been done. (i) Inverse bending radius
$h = \frac{1}{\rho} = \frac{B(r, \theta)}{K_0 F}$. (ii) Local field index
\begin{align}
n &= \frac{\rho}{B} \frac{dB}{dx} = B_0 \frac{dB}{B^2} \left( \frac{dB}{dr} \frac{\rho}{\rho} - \frac{dB}{rd\theta} \frac{\rho}{\rho} \right).
\end{align}
(iii) Path length element $\Delta s = \sqrt{\Delta r^2 + \Delta r^2 \Delta \theta}$. (iv) Horizontal (vertical) focusing $k_x = \frac{1 + n(E, \theta)}{\rho^2}$ ($k_z = \frac{\gamma(E)}{\rho^2}$).
(v) $h(E, \theta)$, $n(E, \theta)$, $\gamma(E)$ and the space charge forces $K_x$, $K_z$. (vi) The exponential series allows one to compute
the transfer matrix for a (short) interval $[\theta, \theta + \Delta \theta]$: (vii) Multiplication of all matrices yields the one-turn transfer matrix $M$.
(viii) Diagonalize $M$ and compute eigenellipse $\sigma_E$.
(ix) The average beam sizes are obtained from the eigenellipsoid and used to recompute the force coefficients.
(x) The convergence is then checked and either the next
iteration starts with step (v) or is stopped.

\begin{figure}
\centering
\includegraphics[width=\textwidth]{figure2.png}
\caption{Top: Phase shift per turn for the ring cyclotron computed from the measured magnetic field map. Middle: Horizontal and vertical betatron tunes of the ring cyclotron as computed by EO code (gray solid lines), the transfer matrix method over the EO (black solid lines), and with space charge (dashed lines). Bottom: Longitudinal betatron tune as induced by transverse-longitudinal coupling. The region with a negative slope of the phase shift is indicated by vertical lines. Without further field trimming, the longitudinal focusing is suppressed by the term $-h \frac{dB}{dt}$ and the longitudinal beam size may increase. The calculation has been performed for a beam current of 2.2 mA and $(e_x, e_y, e_z) = (1.5, 2.5, 0.5) \pi$ mm mrad.}
\end{figure}

The first item in the described algorithm is to provide an
initial guess of the beam dimensions. In the following we
show how to obtain a possible choice of the initial guess for
“nearly” spherical beams. If the horizontal-longitudinal
coupling is strong enough, the beam will usually be ap-
proximately circular in this plane [29]. The axial size
depends mainly on the vertical emittance and tune.
From Eqs. (22) and (26), one quickly derives
\[
\Omega^2 \omega^2 = K_z (K_z + h^2 \gamma^2 - k_z)
\]
\[
\Omega^2 + \omega^2 = k_z - K_z - k_z
\]
\[
\Omega^2 - \omega^2 = \sqrt{(k_z - K_z + k_z)^2 - 4 h^2 \gamma^2 K_z}
\]
\[
\frac{1}{B - A} = \frac{\gamma^2 h K_z}{\sqrt{(k_z - K_z + k_z)^2 - 4 h^2 \gamma^2 K_z}}.
\] (45)

With the assumption of an isochronous cyclotron \((k_z = h^2 \gamma^2)\) and spherical symmetry, i.e.,
\[
\sigma = \sigma_x = \sigma_y = \sigma_z = \gamma
\]
\[
\varepsilon = \varepsilon_x = \varepsilon_y = \varepsilon_z \rightarrow K = K_x = K_y = K_z = \frac{K_3 \gamma}{3 \sigma^3}.
\] (46)

one finds
\[
\Omega^2 \omega^2 = \frac{K^2}{\Omega^2 + \omega^2} = k_z - 2K
\]
\[
\Omega^2 - \omega^2 = \frac{1}{B - A} = \frac{K}{h \sqrt{1 - 4 K/k_z}}.
\] (47)

The beam size \(\sigma\) then yields using Eq. (30)
\[
\sigma^4 = \varepsilon^2 \frac{(B \omega + A \Omega)^2}{(\Omega \omega)^2} = \frac{4 \varepsilon^2}{k_z - 4 K}.
\] (48)

so that one obtains
\[
\sigma^4 - \frac{4 K_3 r^2}{3 \gamma} \sigma - \frac{4 \varepsilon^2 r^2}{\gamma^2} = 0.
\] (49)

If one defines \(\sigma_0 = \sqrt{\frac{2 \varepsilon}{\gamma}}\), then Eq. (49) can be written as
\[
x^4 - \alpha x - 1 = 0,
\] (50)

where
\[
\alpha = \frac{\sigma}{\sigma_0} = \frac{4 K_3 r^2}{3 \gamma \sigma_0^3} = \frac{K_3 \sqrt{2 \varepsilon}}{3 \varepsilon^{3/2}} > 0.
\] (51)

A polynomial of 4th order has four solutions, namely, the solutions of Eq. (50) are
\[
x = \frac{1}{26^{1/3}} \left( \sqrt{Y} \pm \sqrt{\frac{12 \alpha}{\sqrt{Y}} - Y} \right),
\] (52)

where the abbreviations used are defined by
\[
Y = 2^{1/3} Z - \frac{8^{3/3}}{Z} \geq 0
\]
\[
Z = \left( 9 \alpha^2 + \sqrt{3 \gamma^2 h K_z} + 27 \alpha^2 \right)^{1/3} > 768^{1/6}.
\] (53)

The minus sign in the square root of Eq. (52) belongs to a pair of complex conjugate solutions and may not be used. Starting from low values of \(\alpha\), \(Y\) monotonically increases starting from zero so that we have to take the plus in front of the square root as well in order to obtain positive solutions also for small values of \(\alpha\), so that
\[
x = \frac{1}{26^{1/3}} \left( \sqrt{Y} + \sqrt{\frac{12 \alpha}{\sqrt{Y}} - Y} \right).
\] (54)

Analyzing Eq. (50), one finds that
\[
\lim_{\alpha \to 0} x(\alpha) = 1 \quad \lim_{\alpha \to \infty} x(\alpha) = \alpha^{1/3},
\] (55)

so that the function \(x(\alpha) = (1 + \alpha)^{1/3}\) is a reasonable approximation. The maximal relative deviation of about \(-0.035\) appears at \(\alpha = 3/2\). Therefore we suggest to use the approximations
\[
\sigma = \begin{cases} 
\sigma_0 \left( 1 + \frac{\pi}{2} - \frac{\alpha^2}{32} \right) & \text{for } 0 \leq \alpha \leq 5/2 \\
\sigma_0 \left( 1 + \alpha \right)^{1/3} & \text{for } 5/2 \leq \alpha.
\end{cases}
\] (56)

Using the normalized emittance \(\tilde{\varepsilon} = \beta \gamma \varepsilon\), the wavelength \(\lambda = h / \varepsilon = 2 \pi c / \omega_0 \), the cyclotron radius \(a = \omega_0 / \beta\), and the relation \(\varepsilon_0 e^2 = \frac{1}{\mu_0}\), the values of \(K_3\), \(\alpha\), and \(\sigma_0\) can be written as follows:
\[
K_3 = \frac{3 q \mu_1}{20 \sqrt{5} \pi e_0 m c^3 \beta^2 \gamma^3} = \frac{3 q \mu_0 \lambda}{10 \sqrt{5} m c^2 \beta^2 \gamma^3 N_h},
\]
\[
\alpha = \frac{q \mu_0 \lambda \sqrt{2 \gamma}}{10 \sqrt{5} m c \beta^2 \gamma^3 e^{3/2} N_h} = \frac{q \mu_0 \lambda}{5 \sqrt{5} m c \gamma N_h} \left( \frac{a}{\lambda} \right)^{3/2},
\]
\[
\sigma_0 = \sqrt{\frac{2 \varepsilon}{\gamma}} = \sqrt{\frac{2 a \beta \gamma \varepsilon}{\gamma}} = \sqrt{2 a \tilde{\varepsilon}}.
\] (57)

Equations (56) and (57) describe the matched beam sizes for a spherical beam in a perfectly isochronous cyclotron. The real beam sizes will usually differ from these values since the spherical symmetry requires that the vertical tune roughly equals the horizontal tune, while in most cyclotrons the vertical tune is below the horizontal tune. Nevertheless the equations derived for the special case of a spherical beam can be used as starting conditions for the described iterative matching procedure.

IX. SUMMARY

A method has been developed that allows one to compute the parameters of a matched beam with space charge in cyclotrons in linear approximation for given beam current and known emittances. As an example, a matched beam in the PSI injector II cyclotron has been computed. The result has been used as input to TRANSPORT and it has been shown that the beam is matched.

Furthermore, it has been shown that the longitudinal focusing as induced by the space charge forces depends on the isochronism of the cyclotron. In the case of the PSI ring cyclotron, the negative slope of the phase shift per turn may reduce or even destroy the longitudinal focusing effect. The results are important for the design of high
intensity cyclotrons. If beam emittance and current are chosen accordingly, then the space charge induced longitudinal focusing allows one to replace flattop cavities by accelerating cavities and thus increase the energy gain per turn and the turn separation significantly. This is important to minimize beam losses and activation of components. The flattop cavities of the PSI injector II cyclotron are already operating as accelerating cavities and a complete replacement is planned [29,30].
