Abstract

Objective

To investigate whether the Garden index can determine the rotational displacement of femoral neck fracture.

Methods

Ten healthy human femoral specimens were obtained. A 2.0 mm diameter Kirschner-wire was placed in the center of the femoral head. The osteotomy was perpendicular in the middle of the femoral neck. The distal osteotomy surface was indicated the angle of rotation (pronation and supination to 90°, every 10° was an interval). The X-ray of anterior-posterior and lateral view was taken at different angles according to the mark. The Garden index and other relevant data were analyzed with the PCAS system. Meanwhile, the change of the area of the femoral head fovea at different rotation angles was observed.

Results

There was no significant difference in the Garden index in 0~30° at pronation and supination position (P>0.05). In range of 40°~90°, there was a statistical difference in the Garden index (P<0.05). With the increase of the pronation angle, the area of the femoral head fovea is gradually reduced; as the angle of the supination increases, the area of the femoral head fovea is gradually increased.

Conclusion

The Garden Index cannot accurately determine the rotational displacement of the femoral neck fracture during the pronation or supination range of 0~30°. Changes in the area of the femoral head fovea can help determine the rotational displacement of the femoral neck fracture.

Level of Evidence

Level V.

Introduction

Femoral neck fractures are one of the most common types of fractures in the clinic. Elderly patients with displaced femoral neck fractures can achieve good results by applying joint replacement surgery. In young people with femoral neck fractures, internal fixation operation is often chosen. However, certain complications often occur after internal fixation, such as traumatic femoral head necrosis, hip pain, function limitation, and fracture nonunion [1, 2], which result in a heavy economic and social burden to the patient and the family. Some scholars suggest that the quality of the reduction of the femoral neck fracture will affect the consequent of the internal fixator and the probability of secondary surgery after internal fixation of the femoral neck fracture [3-5]. Although the open reduction of the femoral neck
fracture can achieve anatomical reduction, there is a greater damage to the local blood supply, which easily damages the blood supply system of the femoral head, and lead to the postoperative avascular necrosis of the femoral head [6, 7]. Therefore, the current clinical reduction of femoral neck fractures is often based on intraoperative C-arm fluoroscopy for closed reduction [8].

How to accurately judge whether the reduction of the femoral neck fracture during surgery is good in the closed state. The previous literature proposed various methods, such as: the Garden Index [9], Lindquist and Tornkvist’s standard [10], the Western Infirmary Glasgow (WIG) Angle [11]. Among them, the Garden index is the most classic. The index was first proposed by Garden in the 1964, and it was mentioned again in the literature of 1971 [4] and 1974 [12]. It was later called the Garden Index. The anterior and lateral X-ray angle measurement is defined as: In the antero-posterior radiograph these the fan-shaped medial group of trabeculae in the head of the femur normally lie in alignment with their projections in the adjacent pelvis, and a line drawn through the long axis of the group forms an angle of approximately 160 degrees with the medial cortex of the femoral shaft (Fig. 1). In the lateral view the central axis of the head and the central axis of the neck lie in the same straight line (Fig. 1). The normal antero-posterior/lateral relationship of the two fragments can thus be expressed as an alignment index of 160/180. This reduction standard has been widely cited in the following clinical and literature and has become the most classic standard method for reduction of femoral neck fractures in clinical practice.

In the internal fixation operation of femoral neck fractures, anatomical reduction plays an important role in restoring blood supply after femoral neck fracture. Min et al [15] reported that the necrotic rate of unsatisfactory reduction after femoral neck fracture was 68.8%. Garden [12] also believes that malreduction of the femoral neck fracture will increase the rate of necrosis of the femoral head. Wang et al. [16] also found that Garden line index and necrosis rate of femoral head after internal fixation operation had a significant correlation (OR = 3.475, P = 0.006), indicating that the worse the garden index, the worse the patient's prognosis. All of the above studies suggest that we should undergo more fluoroscopy and repeated fluoroscopy during the operation, as soon as possible to achieve anatomic reduction, which can reduce the incidence of femoral head necrosis. However, Min et al [15] also reported that the satisfactory postoperative reduction of femoral neck fracture but still had a 20% femoral head necrosis rate. At the same time, the author also found some patients with a satisfactory Garden index after operation still suffered from traumatic femoral head necrosis in long-term follow-up. In addition to the commonly recognized factors (such as age, fracture classification, internal fixation options, etc.), is there still a rotatory displacement in the fracture line? Can the currently used Garden Index judge the rotatory displacement of the femoral neck? In this study, based on the anatomy of cadaver specimens, a rotatory displacement model of the femoral neck fracture was made. Then, according to the definition of the Garden Index angle measurement, it is clear whether it can judge the rotatory displacement of the femoral neck.

### Materials And Methods
This study was done at the Second Affiliated Hospital and Yuying Children's Hospital of Wenzhou Medical University in Wenzhou, Zhejiang, China and permission was obtained from the hospital Ethics Committee.

Material

Five specimens of 10 upper femurs (no restrictions for men and women) are provided by the Department of Anatomy, Wenzhou Medical University. The specimens of the corpses in the area are all healthy adult cadaver specimens. The adult pelvis is visually observed and X-ray confirmed no obvious abnormalities, osteoporosis, old fractures and other abnormalities, and remove the surrounding soft tissues.

Specimen production method

A 2.0 mm diameter Kirschner wire was drilled into the center of the femoral head toward the lateral wall of the femur, parallel to the long axis of the femoral neck. Then, a marker line on the long axis of the femoral neck was made on the surface of the specimen, and the midpoint perpendicular line of the marker line was used as the osteotomy line to perform vertical femoral neck osteotomy (Figure 2). The intersection of the distal osteotomy surface of the femoral neck and the marked long axis of the femoral neck was used as a 0° scale line, and the protractor was used to measure on the osteotomy surface, 10° is an interval, marked to the left and right, from 0° to 90° (Figure 3). Then, the distal femur of the osteotomy surface was fixed with an acrylic resin on the standard anterior and lateral position, and the proximal femoral head of the osteotomy surface was sequentially rotated and rotated with the Kirschner wire as the center. A rotational model of the femoral neck fracture was made, with a clockwise rotation of the proximal femoral head of the osteotomy surface as the pronation; a counterclockwise rotation for supination (Fig. 4)

Measurement methods

Select the neutral position—pronation and supination 0°, 10°, 20°, 30°, 40°, 50°, 70°, 90° for the anterior and lateral X-ray photography, and the distal fragment was in the neutral position (Fig. 5, 30° after the pronation or supination). The image is uploaded and stored in our PACS imaging system, and its own angle measurement tool is used to measure and calculate the garden index for each angle of the x-ray film. At the same time, the area of the femoral head fovea was measured using the measurement function of the PACS during the rotation.

Data processing and analysis: All data were statistically processed using SPSS 19.0 statistical software package, and the practical mean ± standard deviation was expressed. There was a statistical difference between p<0.05. The garden index of multiple groups was compared by analysis of variance (ANOVA). After determining the statistical difference between the groups, the Tukey HSD method was further used for comparison.

Results
The garden index cannot determine the rotatory displacement of a femoral neck fracture within a certain range.

1. Anterior-posterior view: A total of 10 cadaver specimens, from 0° pronation to 90°, analysis of variance showed statistical differences between the garden indices (p<0.01). Further Tukey HSD method showed that there was no significant different in the garden index on the x-ray during the 0° to 30° process (p>0.05), and the values were all greater than 155°; During the rotation from 40° to 90°, the garden index showed a significant different (p<0.05), and the values were all less than 155°, as shown in Figure 6.

2. Anterior-posterior view: A total of 10 cadaver specimens, from 0° supination to 90°, analysis of variance showed statistical differences between the garden indices (p<0.01). Further Tukey HSD method showed that there was no significant difference in the garden index on the x-ray during the 0° to 30° supination (p>0.05), and the values were all greater than 155°; During the supination from 40° to 90°, the garden index showed a significant difference (p<0.05), and the values were all less than 155°, as shown in Figure 7.

3. Lateral view: A total of 10 cadaver specimens, from 0° pronation to 90°, analysis of variance showed statistical differences between the garden indices (p<0.01). Further Tukey HSD method showed that there was no significant change in the garden index on the x-ray during the 0° to 30° process (p>0.05); During the pronation from 40° to 90°, the garden index showed a significant difference (p<0.05), as shown in Figure 8.

4. Lateral view: A total of 10 cadaver specimens, from 0° supination to 90°, analysis of variance showed statistical differences between the garden indices (p<0.01). Further Tukey HSD method showed that there was no significant difference in the garden index on the x-ray during the 0° to 30° process (p>0.05); During the supination from 40° to 90°, the garden index showed a significant change (p<0.05), as shown in Figure 9.

Changes in the Fovea area of femoral head can indicate a rotator displacement in the femoral neck fracture

1. Changes in the fovea area of femoral head in the anterior-posterior view: During the rotation from 0° to 90° pronation, the fovea area of the femoral head gradually became smaller until it finally disappeared. After 60° of the pronation, the existence of the fovea of femoral head was not observed, and the area measurement could not be performed (Figure 10).

2. Changes in the fovea area of femoral head in the anterior-posterior view: During the rotation from 0° to 90° supination, the fovea area of femoral head gradually increases until it is “embedded” inside the femoral head, and the trend is reduced (Figure 11).

Discussion

After internal fixation of femoral neck fracture, traumatic necrosis of the femoral head is still a major complication. How to reduce the rate of necrosis is a major problem in Orthopaedic Trauma[17, 18]. The
blood supply of the femoral head is mainly from the medial and lateral femoral circumflex artery. The fracture is usually accompanied by the distortion, deformation and obstruction of the blood vessels in the femoral neck region. At the same time, the pressure increase in the joint capsule after the fracture which further reduces the blood supply to the femoral head, avascular necrosis of the femoral head occurs when residual blood supply is not compensated [19,20]. Therefore, the quality of the reduction of the femoral neck fracture is related to the blood supply of the femoral head. The anatomical reduction of the femoral neck fracture can provide the best environment for the revascularization of the femoral head [21]. How to improve the quality of fracture reduction during surgery is particularly important [5].

The garden index was first proposed by Garden [9] in 1964 and is still the classic standard for clinical reduction of femoral neck fractures. The specific content is: In the antero-posterior radiograph these the fan-shaped medial group of trabeculae in the head of the femur normally lie in alignment with their projections in the adjacent pelvis, and a line drawn through the long axis of the group forms an angle of approximately 160 degrees with the medial cortex of the femoral shaft. In the lateral view the central axis of the head and the central axis of the neck lie in the same straight line. The normal antero-posterior/lateral relationship of the two fragments can thus be expressed as an alignment index of 160/180. At the same time, Garden [4] also pointed out that regardless of the anterior-posterior or lateral position, the femoral head necrosis rate of the garden index between 155 ° and 180 ° is 6.6% (16/242), less than 155 °, or more than 180 °, will greatly increase the incidence of femoral head necrosis, from 65.5% (53/81) to 100% (26/26). As a classic rule for evaluating the reduction quality of femoral neck fractures, the garden index is still adopted by most orthopaedic surgeons.

However, the Garden Index is a measurement based on a two-dimensional plane, and it does not make explicit provisions for rotatory displacement of the femoral neck in three-dimensional space. Therefore, we used imaging studies of cadaver specimens to determine whether the garden index can determine the rotatory displacement of femoral neck fractures. We found that within the range of pronation 30 ° or supination 30 °, the garden index did not change significantly, and there was no statistical difference. Therefore, we believe that the rotatory displacement of femoral neck fractures within 30 °, the garden index cannot be accurately judged. The rotatory displacement from 40 ° to 90 ° shows a significant change in the garden index no matter whether it is pronation or supination. According to our analysis, X-ray is a two-dimensional planar image, but the femoral neck rotatory displacement in three-dimensional space cannot be accurately judged. Only when the rotatory angle increases to a certain degree and there is obvious misalignment, the garden index will change to some extent. This also prompts us to use the garden index to evaluate the reduction quality is not completely reliable. We need more accurate instruments such as intraoperative 3D CT to more accurately display the reduction quality of femoral neck fractures.

We have also found some imaging markers in repeated research, in order to assist in determining the rotatory displacement of femoral neck fractures during surgery. We initially found that during the proximal rotation of the femoral neck fracture, the fovea area of femoral head on the anterior-posterior view showed a certain change law, which can help judge the rotation of the femoral neck fracture during
the operation. The fovea of femoral head is located at the center of the femoral head and connects the round ligament. With the rotation of the femoral head, the fovea of femoral head appears on the two-dimensional image of the X-ray, showing an increase or decrease in area. In the process of femoral neck fracture reduction, it can be used to help judge the change of rotation.

However, how many degrees of rotatory displacement will affect the blood supply of the femoral head and then cause necrosis of the femoral head? There are currently no relevant literature reports. We will use animal experiments and clinical case follow-up studies for further verification in future studies.
