ABSTRACT

The possible role of magnetorotational instability (MRI) and its driven magnetohydrodynamic (MHD) turbulence in the solar interior is studied on the basis of linear and non-linear theories coupled with physical parameters, assuming a solar rotation profile inverted from helioseismic observations and a standard model for the internal structure of the Sun. We find that the location of MRI is confined to the higher latitude tachocline and lower latitude near-surface shear layer. It is especially interesting that the MRI-active region around the tachocline closely overlaps with the area indicating a steep entropy rise, which is required from the thermal wind balance in the Sun. This suggests that the MRI-driven turbulence plays a crucial role in maintaining the thermal wind balance in the Sun via the exceptional turbulent heating and equatorward angular momentum transport. The warm pole existing around the tachocline might be a natural outcome of the turbulent activities energized by the MRI.

Key words: instabilities – MHD – Sun: rotation – stars: individual: Sun.

1 INTRODUCTION

Two important unsolved issues in solar physics are the mechanisms of the magnetic dynamo and angular momentum transport in the solar interior. These two processes essentially affect one another non-linearly, which makes the physical processes more difficult to resolve even using huge computer facilities. Despite the development of numerical and observational methods, we have not yet drawn a complete physical picture of these processes.

Solar physicists believe that two types of dynamo mechanisms operate in the solar interior. The flux transport type dynamo sustains the global, coherent, magnetic field by the stretching $\Omega$-effect around the tachocline (Parker 1993; Dikpati & Charbonneau 1999; Dikpati & Gilman 2006). The convective dynamo, in which the convective motion stores free energy, plays a role in generating relatively weak, small-scale magnetic fields (Parker 1955; Weiss 1994; Miesch et al. 2000; Brun & Toomre 2002; Brun, Miesch & Toomre 2004).

The solar rotation profile revealed by helioseismic observations tells us that our knowledge of angular momentum transport in the solar interior is still insufficient (Kosovichev et al. 1997; Schou et al. 1998; Thompson et al. 2003; Howe 2009). We have no consensus on how the differential rotation is physically developed and maintained in the convective zone (e.g. Kitchatinov & Ruediger 1995; Durney 1999; Rempel 2005; Miesch, Brun & Toomre 2006; Balbus 2009; Balbus et al. 2009).

There is a crucial magnetohydrodynamic (MHD) process related to these outstanding issues, which is magnetorotational instability (MRI) (Balbus & Hawley 1991, 1994; Menou, Balbus & Spruit 2004; Parfrey & Menou 2007). It is essentially of a local nature and destabilizes the differentially rotating magnetized system with a radially negative shear rate, that is $q \equiv \Delta \ln \Omega / \Delta \ln r < 0$, where $\Omega$ is the angular velocity and $r$ is the cylindrical radius. The typical spatial scale of the unstable MRI mode inversely cascades with its linear growth, and it finally operates the MHD turbulence. MRI-driven turbulence has been broadly investigated as a promising candidate for angular momentum transport in astrophysical accretion discs (Balbus & Hawley 1998).

The stability of the solar interior to MRI was studied first by Balbus & Hawley (1994) to understand why the solar radiative core rotates uniformly. Menou et al. (2004) constructed a linear theory of the MRI in the general form which is more suitable for the stellar interior (including heat, magnetic and viscous diffusivities). Recently, Parfrey & Menou (2007) have pointed out the possibility that the MRI-driven turbulence prevents global coherent dynamo activity in the MRI-active higher latitude tachocline.

Here we investigate, on the basis of the linear theory, where the MRI should be active in the convective zone and tachocline by taking account of the observed rotation profile inverted from helioseismic data and the standard solar structure. Then we discuss the role of the MRI-driven turbulence for maintaining the thermal wind balance that would be achieved in the solar interior.

2 LOCATION OF MRI IN THE SOLAR INTERIOR

We indicate a promising location for the MRI in the solar interior. Considering an axisymmetric WKBJ plane wave perturbation with \( \exp [i(k_x x + k_z z - \omega t)] \) in the Boussinesq approximation, the stability of the system to the MRI is governed by the following local dispersion equation, in cylindrical coordinates \((\sigma, \phi, z)\):

\[
\frac{k^2}{k_z^2} \omega_{\psi}^2 - \frac{1}{\rho \omega} \frac{\partial}{\partial \zeta} \left[ \frac{D \rho}{D \ln P} \frac{\partial}{\partial P} \right] + \frac{\partial^2}{\partial \zeta^2} \omega \sigma + \frac{1}{\sigma \omega} \frac{\partial}{\partial \zeta} \left[ \frac{D \sigma}{D \ln \rho} \frac{\partial}{\partial \rho} \right] - 4 \Omega^2 (k \cdot v_A)^2 \omega = 0,
\]

(1)

where

\[
\omega_{\psi}^2 = \omega_{\psi} \omega_{\psi} - (k \cdot v_A)^2, \quad \omega_{\phi}^2 = \omega - (k \cdot v_A)^2,
\]

\[
\omega_{\zeta} = \omega + i \chi^2 (\chi = \sigma, \phi, \zeta), \quad D \equiv \left( \frac{k_z}{k_x} \frac{\delta}{\delta x} - \frac{\delta}{\delta x} \right).
\]

(see Menou et al. 2004 for details). Here \( k^2 = k_x^2 + k_z^2 \) is the wavenumber, \( v_A \equiv B/(4\pi \rho)^{1/2} \) is the Alfvén velocity, \( B \) is the magnetic field and \( \gamma \) is the adiabatic index of the gas. The heat, magnetic and viscous diffusivities are represented by \( \kappa, \eta \) and \( \nu \), respectively. Other symbols have their usual meanings.

Note that the dispersion equation (1) is obtained under the condition of stratified hydrostatic background, not limited only to the convectively stable background. The convectively unstable mode is also included in this dispersion equation. The instability in the form of thermal convection is treated on a footing equal to that of rotational instability in this Letter, as was done by Balbus (2009).

The strength of magnetic fields in the unperturbed state is assumed to be weak enough that it does not affect the hydrostatic balance.

We can search the most rapidly growing MRI mode at an arbitrary meridian point \((r, \theta)\) in the solar interior by numerically solving the linear dispersion equation (1) coupled with the observed rotation profile inverted from the helioseismic data of the SOHO Michelson Doppler Imager (MDI) and the standard model for the solar internal structure (Christensen-Dalsgaard et al. 1996). When searching for the fastest growing modes, we limit their wavelength to being sufficiently smaller than the typical width of the tachocline.

A promising location for the MRI is demonstrated by the colour map in Fig. 1. The colour scale represents the maximum growth rate of the MRI at each local meridian point. The vertical and horizontal axes denote polar and equatorial radii normalized by the solar radius. The rotation profile adopted in our analysis is overplotted on the MRI map with solid contours which increase by 15 nHz from 330 to 480 nHz. The angular velocity within \( \theta < 10^\circ \) is extrapolated by the cubic spline method from the lower latitude helioseismic data, where \( \theta \) is colatitude.

The local structure and the strength of magnetic fields are assumed to be vertical and weak, that is \( B_z = 1 \) G here. The MRI location is not drastically changed due to the field strength and structure as long as we give a weak, vertical component of the magnetic field. The destabilizing effect arising from the unstable internal gravity wave is eliminated so as to focus better on the destabilizing effect of the MRI modes on the system. In contrast, the stabilizing effect due to the density stratification on the MRI is consistently introduced in our analysis.

It is found that, in the solar interior, the MRI-active region is confined to the higher latitude tachocline and the lower latitude near-surface shear layer. The stabilizing effect due to the density stratification on unstable MRI modes is reduced significantly by the double diffusive effect in the convectively stable tachocline region (Menou et al. 2004; Masada, Sano & Shibata 2007). The MRI venue thus corresponds trivially to the differentially rotating zone with negative radial shear, \( q \equiv d \ln \Omega / d \ln \sigma < 0 \) here. In addition, the wavevector of the most unstable MRI mode tends to be parallel to the gravity vector in the convectively stable tachocline, as is suggested by Balbus & Hawley (1994). This is because such modes can grow in decoupling with the stabilization effect of the density stratification.

When focusing naively on the MRI mode by neglecting the effect of the convectively unstable mode, the MHD turbulence powered by MRI would operate in these MRI-active regions.

It would be natural from a physical perspective to discuss the impact of convective motion on the MRI. Since the convective mode (unstable mode of internal gravity wave) has a growth rate which is at least an order of magnitude larger than that of the MRI, the profile of large-scale differential rotation drawn using a helioseismic time-averaging method should be modified by the vigorous convective motion and not be maintained during the typical evolutionary time of the MRI. The stationary background assumed for deriving the dispersion relation is thus not justified to be applied to the MRI in the Sun’s convective zone. When considering the vigorous convection, the growth of the MRI mode should be inhibited in the near-surface shear layer where there is one of the promising MRI locations.

In contrast, the tachocline which is a thin transition region between radiative and convection zones generally has a convectively stable nature with subadiabatic entropy gradient. The large-scale differential rotation should thus be maintained without being affected by the turbulent convection during the evolutionary phase of the MRI. The dispersion relation, adopting the stationary background as the unperturbed state, is applicable to the MRI mode (Parfrey & Menou 2007). In addition, as is denoted in this section, the stabilization effect due to the subadiabatic entropy gradient is reduced by diffusive relaxation and does not have a crucial role in suppressing the growth of the MRI. We can thus expect that, in the tachocline region, the local-scale MRI mode can evolve to the larger scale, leaving its character unchanged, and finally operates the MHD turbulence with a typical size comparable to the radial width of the tachocline. The non-linear interaction between the...
3 POTENTIAL RELATION BETWEEN THERMAL WIND BALANCE AND MRI-POWERED TURBULENT ACTIVITY

3.1 Entropy rise resulting from thermal wind balance

The effect of the MRI-driven turbulence on the global coherent dynamo has already been argued by Parfrey & Menou (2007). According to their logic, the coherent stretching process of the magnetic field by the $\Omega$-effect is prevented by the MRI-driven turbulence in the higher latitude tachocline. This implies that the flux transport type dynamo efficiently works only in the lower latitude tachocline. Parfrey & Menou insist that this prevention effect of the MRI-driven type dynamo efficiently works only in the lower latitude tachocline. Accordingly, we discuss here the role of the MRI-driven turbulence in maintaining the thermal wind balance in the solar interior. The thermal wind equation with a baroclinic term is

$$\nabla \frac{\partial^2 \Omega}{\partial z^2} = \frac{g}{y C_p} \nabla \frac{\partial S}{\partial \theta} \tag{2}$$

(Pedlosky 1987; Tassoul 2000), where $S$ is the specific entropy, $g$ is the gravity in hydrostatic equilibrium and $C_p$ is the constant pressure specific heat. This follows from the time-steady vorticity equation in conditions with small Rossby numbers. Equation (2) indicates that the latitudinal entropy variation drives the differential rotation and yields the deviation from the Taylor–Proudman state with $\nabla \Omega/\partial z = 0$.

When the observed rotation profile is given, we can directly calculate the left-hand side of equation (2) and derive the entropy gradient in the $\theta$ direction. Moreover, we can employ it to find the temperature deviation by using the thermodynamic relation $\partial T / \partial \theta \simeq T C_p \partial S / \partial \theta$ because of the quasi-incompressible plasma ($\partial P / \partial \theta \simeq 0$), where $T$ is the reference temperature varying only in the radial direction. This yields information about the latitudinal temperature inhomogeneity in the solar interior (e.g. Miesch 2005).

Fig. 2(a) illustrates the normalized latitudinal entropy gradient $-C_p \partial S / \partial \theta$ consistent with the thermal wind balance. Fig. 2(b) demonstrates the latitudinal temperature deviation $\Delta T \equiv \Delta T \left( \theta \simeq 90^\circ \right) = 0$ K in Fig. 2(b). Note that the temperature obtained from the standard solar structure (Christensen-Dalsgaard et al. 1996) is adopted as the reference temperature $T$ at each radius. The isorotation contour is overplotted on both maps.

The specific entropy is found to rise steeply towards the pole between $\theta \simeq 20^\circ$ and $60^\circ$ at around the tachocline depth. This suggests that an exceptional heat production is maintained in this area. In addition the temperature deviation $\Delta T$ increases with increasing latitude and reaches up to $\Delta T \sim 10$ K at the polar region around the tachocline. We interpret physically this steep entropy rise and the temperature enhancement around the higher latitude tachocline in relation to turbulent activities powered by MRI in the following.

3.2 MRI-powered turbulent activity

The higher latitude tachocline where the entropy steeply rises is reminiscent of the MRI-active region denoted in Fig. 1, although the governing equations for each map are completely different. Then we attempt to reveal a potential relationship between the steep entropy rise and the MRI-powered activities around the solar tachocline.

A non-linear outcome of the MRI activity in astrophysical systems is the enhancement of turbulent viscous heating. We can expect that the viscous heating maintained by the MRI-driven turbulence plays an essential role in inducing the exceptional heat production around the higher latitude tachocline which is required from the thermal wind balance.

In addition the angular momentum tends to be transported equatorward by the MRI-driven turbulence in the stably stratified tachocline (Balbus & Hawley 1994). Then the gaseous matter would advect towards the pole by absorbing the heat generated by the MRI-driven turbulence. The warm pole is thus expected to be formed at around the tachocline depth as a natural consequence of the MRI-powered turbulent activities.

For simplicity, we assume that the differential rotation in the tachocline is maintained long enough to balance the angular momentum transport entirely in the solar interior. Then we can evaluate the turbulent heating rate provided by the MRI-driven turbulence in the tachocline region.

The Maxwell stress $M_{\omega, \phi}$ resulting from the MRI-driven turbulence acts into the fraction of free energy stored in the differential rotation $e_{\text{diff}}$ and is given by

$$M_{\omega, \phi} = \frac{B_{\omega} B_{\phi}}{4\pi} = f e_{\text{diff}}, \tag{3}$$

where $f$ is an arbitrary parameter ranging from 0.01 to 0.1 (Masada et al., in preparation). The free energy stored in the differential rotation $e_{\text{diff}}$ is given by

$$e_{\text{diff}} = \rho_0 \int \left[ \Omega^2_{\text{diff}}(\sigma) - \Omega^2_{\text{rigid}}(\sigma) \right] d\sigma d\phi dz \int d\sigma d\phi dz \simeq \rho_0 |q| \Omega^2_{\text{diff}}(\sigma_0, \Delta \sigma), \tag{4}$$

where

$$\Omega_{\text{diff}}(\sigma) = \Omega_0 (\sigma / \sigma_0)^y, \quad \Omega_{\text{rigid}} = \Omega_0 (\sigma_0 + \Delta \sigma / 2) / \sigma_0)^y.$$  

Here $\Omega_{\text{diff}}(\sigma)$ is the angular velocity in the differentially rotating state with maximum free energy, and $\Omega_{\text{rigid}}$ shows the constant angular velocity in the rigidly rotating state with minimum free energy. Note that $\sigma_0$ is the fiducial radius, $\Omega_0$ is the angular velocity at the fiducial radius, $\Delta \sigma$ is the radial width of the shear layer and $\rho_0$ is the averaged density around $\sigma_0$.

The viscous heating rate resulting from the MRI-driven turbulence is thus, at around the fiducial radius $\sigma_0$,

$$\epsilon \simeq \xi \left( \frac{d\Omega}{d\ln r} \right)^2 = \rho_0 |q| \Omega^2_{\text{diff}}(\sigma_0, \Delta \sigma), \tag{5}$$

where $\xi \equiv M_{\omega, \phi} / |\Omega_0|$ is the viscous energy deposition rate. Note that the turbulent viscosity is then given by $\nu_{\text{turb}} \simeq \xi / \rho$.

Fig. 3 shows the viscous heating rate $\epsilon$ which would be sustained by the MRI-driven turbulence around the tachocline as a function of colatitude $\theta$ in the cases $f = 0.01, 0.05$ and 0.1. The fiducial parameters $\Omega_0, q, \sigma_0$ and $\Delta \sigma$ are systematically determined from
Impact of MHD turbulence on thermal wind balance in the Sun

The typical travelling time $\tau_{\text{travel}}$ of the poleward advecting matter due to the turbulent angular momentum transport is estimated by the diffusion time, that is $\tau_{\text{travel}} \simeq \delta l / v_{\text{turb}}$, where $\delta l$ is the typical size of the MRI-active region measured along the latitude. Then the total energy gain $\psi$ of the advecting matter through the MRI-active region can be evaluated as, without depending on the arbitrary parameter $f$,

$$
\psi = \epsilon \tau_{\text{travel}} = \rho_0 |g|^2 \Omega_\text{a}^2 l^2
$$

$$
\simeq 5 \times 10^6 \text{erg cm}^{-3} \left( \frac{g}{0.5} \right)^2 \left( \frac{\Omega_\text{a}}{\Omega_\text{a}^0} \right)^2 \left( \frac{l}{l_{\text{active}}} \right)^2.
$$

where $\Omega_\text{a} = 2.69 \times 10^{-6} \text{s}^{-1}$ is the angular velocity at the tachocline. The typical size of the MRI-active region is chosen as $l_{\text{active}} = 2\pi \times 0.7 R_\odot / 8$ here. The poleward advection flow is thus heated up by $\Delta T = \psi / (\rho k_B / m) \simeq O(10) \text{K}$ during which it goes through the MRI-active region around the tachocline.

We stress that the typical propagation time-scale of the poleward flow through the MRI-active region becomes

$$
\tau_{\text{travel}} \simeq 3.2 \times 10^8 \text{s}
$$

$$
\times \left( \frac{f}{0.05} \right)^{-1} \left( \frac{\sigma_0}{0.7 R_\odot} \right)^{-1} \left( \frac{\Delta \sigma_0}{0.01 R_\odot} \right)^{-1} \left( \frac{\Omega_0}{\Omega_\text{a}} \right)^{-1} \left( \frac{l}{l_{\text{active}}} \right)^2.
$$

This is almost comparable to one solar cycle. Then we can predict that the poleward flow resulting from the MRI-driven turbulence has a propagating velocity $O(100) \text{cm s}^{-1}$ ($\simeq l_{\text{active}} / \tau_{\text{travel}}$) in the higher latitude tachocline. The physical picture we have arrived at here is more or less speculative, but provides new insight into the role of the MHD turbulence driven by the MRI in the solar interior. Further numerical study on non-linear properties of the MRI around the tachocline should be encouraged to make this picture robust.

Based on current understanding, roughly the upper third of the tachocline is the overshoot layer and the remaining lower two-thirds have the same thermal properties as the radiative zone (cf. Gilman 2000; Miesch et al. 2005). It would thus be expected that the MRI-driven turbulence non-linearly interacts with the convective overshoot (i.e. overshooting plumes) in the upper third of the tachocline region.

The impact of the convective hydrodynamic turbulence on the MRI-driven turbulence has been studied by Workman & Armitage (2008). They found that the convective turbulence modifies the properties of the MRI-driven turbulence with the effects varying depending on the spatial scale of hydrodynamic forcing. Large-scale forcing surprisingly boosts the intensity of the MHD turbulence, leaving the character of the MRI unchanged. Low-amplitude small-scale forcing may modestly suppress the MRI.

This implies that the non-linear properties of the MRI in the overshoot layer also depend on the characteristics of the overshooting plumes (such as the overshooting velocity, its latitude-dependence and/or the filling factor of plumes which is the volume occupancy of the turbulent plume in the total volume of the system), although they still remain unsettled in the solar interior because the numerical

Figure 2. (a) Specific entropy gradient in the $\theta$ direction obtained from the thermal balance equation (2) coupled with the observed rotation profile. The normalization is chosen as $-10^{-8} C_F (3 = S / C_F)$ here. (b) Temperature deviation $\Delta T$ from the equatorial plane calculated from the thermodynamic relation $\delta T = TC_F^{-1} f / \delta S$. The vertical and horizontal axes have same meanings as Fig. 1. The isorotation contour is overplotted just for reference on both plots.

Figure 3. Turbulent viscous heating rate $\epsilon$ sustained by the MRI-driven turbulence as a function of colatitude $\theta$ in the cases with $f = 0.01$, 0.05 and 0.1. The region with turbulent heat production closely overlaps the area indicating the entropy rise required from the thermal wind balance.

The typical travelling time $\tau_{\text{travel}}$ of the poleward advecting matter through the MRI-active region becomes

$$
\tau_{\text{travel}} \simeq 3.2 \times 10^8 \text{s}
$$

$$
\times \left( \frac{f}{0.05} \right)^{-1} \left( \frac{\sigma_0}{0.7 R_\odot} \right)^{-1} \left( \frac{\Delta \sigma_0}{0.01 R_\odot} \right)^{-1} \left( \frac{\Omega_0}{\Omega_\text{a}} \right)^{-1} \left( \frac{l}{l_{\text{active}}} \right)^2.
$$

This is almost comparable to one solar cycle. Then we can predict that the poleward flow resulting from the MRI-driven turbulence has a propagating velocity $O(100) \text{cm s}^{-1}$ ($\simeq l_{\text{active}} / \tau_{\text{travel}}$) in the higher latitude tachocline. The physical picture we have arrived at here is more or less speculative, but provides new insight into the role of the MHD turbulence driven by the MRI in the solar interior. Further numerical study on non-linear properties of the MRI around the tachocline should be encouraged to make this picture robust.

Based on current understanding, roughly the upper third of the tachocline is the overshoot layer and the remaining lower two-thirds have the same thermal properties as the radiative zone (cf. Gilman 2000; Miesch et al. 2005). It would thus be expected that the MRI-driven turbulence non-linearly interacts with the convective overshoot (i.e. overshooting plumes) in the upper third of the tachocline region.

The impact of the convective hydrodynamic turbulence on the MRI-driven turbulence has been studied by Workman & Armitage (2008). 4 SUMMARY

The MRI-active location is clarified on the basis of linear theory coupled with the observed rotation profile and the standard solar model. It is found that the MRI activity is confined to the higher latitude tachocline and the lower latitude near-surface shear layer. It is especially interesting that the MRI-active tachocline region closely overlaps with the area indicating a steep entropy rise, which is required from the thermal wind balance in the solar interior.

MRI-driven turbulence would play a crucial role in achieving the Sun’s thermal wind balance by sustaining the exceptional heating and equatorward angular momentum transport. The warm pole with $\Delta T \simeq \mathcal{O}(10)$ K would be the natural outcome of the MRI-energized turbulent activities in the tachocline region.

The impact of the latitudinal entropy inhomogeneity on the solar rotation profile has been investigated numerically by adding the mechanical/thermal forcing effects on the bottom of the convective zone (Rempelo 2005; Miesch et al. 2006). These commonly indicate that the warm pole in the tachocline is key to explaining the rotational features of the Sun. MRI-energized turbulence could maintain the warm pole expected from the thermal wind balance and numerical studies.

Recently, Balbus et al. (2009) have found that, by assuming a coincidence between the isorotation surface and isocontour of $\delta S \equiv S - S'$, we can obtain the exact solution of the thermal wind equation (3) by the characteristic method, where $S$ and $S'$ are regarded as the entropy distributions with and without rotational effects. We stress that the characteristic curves they obtained can correctly reproduce the rotation profile of the mid-convective zone (see also Balbus 2009). This implies that, at the quasi-steady state, the baroclinic effect has a main role in sustaining the observed rotation profile.

The role of the baroclinic effect is very controversial at present. Although the importance of the Reynolds stress in the convective zone is indicated by large-scale simulations (e.g. Bru et al. 2004), consensus has not been reached yet because the smallest size of the convective cell and the turbulence cascading process are inevitably restricted by the grid size even with current huge computational facilities. A global MHD simulation which can capture the localized MRI-growth and other local-scale phenomena will help us to correctly understand the physical origin of the solar rotation profile and the related magnetic dynamo process in the future.

The rotation profile of the Sun reflects enough physical information on the solar interior. A helioseismic study covering the Sun’s polar region will reveal further details of the internal flow properties and the roles of MRI in the thermal wind balance of the solar interior.

ACKNOWLEDGMENTS

A special note of thanks to T. Sekii who provided YM with a lot of information on the solar interior and the inverted MDI data of the solar rotation profile. YM thanks the anonymous referee for constructive comments. YM also thanks S. Tsuneta, K. Kusano, T. Sano and T. Hanawa for scientific discussions and constructive comments.
