ABSTRACT

Metric based comparison operations such as finding maximum, nearest and farthest neighbor are fundamental to studying various clustering techniques such as \( k \)-center clustering and agglomerative hierarchical clustering. These techniques crucially rely on accurate estimation of pairwise distance between records. However, computing exact features of the records, and their pairwise distances is often challenging, and sometimes not possible. We circumvent this challenge by leveraging weak supervision in the form of a comparison oracle that compares the relative distance between the queried points such as ‘Is point \( u \) closer to \( v \) or \( w \) closer to \( x \)?’.

However, it is possible that some queries are easier to answer than others using a comparison oracle. We capture this by introducing two different noise models called adversarial and probabilistic noise. In this paper, we study various problems that include finding maximum, nearest/farthest neighbor search under these noise models. Building upon the techniques we develop for these comparison operations, we give robust algorithms for \( k \)-center clustering and agglomerative hierarchical clustering. We prove that our algorithms achieve good approximation guarantees with a high probability and analyze their query complexity. We evaluate the effectiveness and efficiency of our techniques empirically on various real-world datasets.

1 INTRODUCTION

Many real world applications such as data summarization, social network analysis, facility location crucially rely on metric based comparative operations such as finding maximum, nearest neighbor search or ranking. As an example, data summarization aims to identify a small representative subset of the data where each representative is a summary of similar records in the dataset. Popular clustering algorithms such as \( k \)-center clustering and hierarchical clustering are often used for data summarization [25, 39]. In this paper, we study fundamental metric based operations such as finding maximum, nearest neighbor search, and use the developed techniques to study clustering algorithms such as \( k \)-center clustering and agglomerative hierarchical clustering.

Clustering is often regarded as a challenging task especially due to the absence of domain knowledge, and the final set of clusters identified can be highly inaccurate and noisy [7]. It is often hard to compute the exact features of points and thus pairwise distance computation from these feature vectors could be highly noisy. This will render the clusters computed based on objectives such as \( k \)-center unreliable.

To address these challenges, there has been a recent interest to leverage supervision from crowd workers (abstracted as an oracle) which provides significant improvement in accuracy but at an added cost incurred by human intervention [20, 55, 57]. For clustering, the existing literature on oracle based techniques mostly use optimal cluster queries, that ask questions of the form ‘do the points \( u \) and \( v \) belong to the same optimal cluster?’ [6, 17, 42, 57]. The goal is to minimize the number of queries aka query complexity while ensuring high accuracy of clustering output. This model is relevant for applications where the oracle (human expert or a crowd worker) is aware of the optimal clusters such as in entity resolution [20, 55]. However, in most applications, the clustering output depends highly on the required number of clusters and the presence of other records. Without a holistic view of the entire dataset, answering optimal queries may not be feasible for any realistic oracle. Let us consider an example data summarization task that highlights some of the challenges.

Example 1.1. Consider a data summarization task over a collection of images (shown in Figure 1). The goal is to identify \( k \) images (say \( k = 3 \)) that summarize the different locations in the dataset. The images 1, 2 refer to the Eiffel tower in Paris, 3 is the Colosseum in Rome, 4 is the replica of Eiffel tower at Las Vegas, USA, 5 is Venice and 6 is the Leaning tower of Pisa. The ground truth output in this case would be \{1, 2\}, \{3, 5, 6\}, \{4\}. We calculated pairwise similarity between images using the visual features generated from Google Vision API [1]. The pair (1, 4) exhibits the highest similarity of 0.87, while all other pairs have similarity lower than 0.85. Distance between a pair of images \( u \) and \( v \), denoted as \( d(u, v) \), is defined as \( 1 - \text{similarity between } u \text{ and } v \). We ran a user experiment by querying crowd workers to answer simple Yes/No questions to help summarize the data (Please refer to Section 6.2 for more details).

In this example, we make the following observations.

Figure 1: Data summarization example
• Automated clustering techniques generate noisy clusters. Consider the greedy approach for k-center clustering [27] which sequentially identifies the farthest record as a new cluster center. In this example, records 1 and 4 are placed in the same cluster by the greedy k-center clustering, thereby leading to poor performance. In general, automated techniques are known to generate erroneous similarity values between records due to missing information or even presence of noise [19, 56, 58]. Even Google’s landmark detection API [1] did not identify the location of images 4 and 5.

• Answering pairwise optimal cluster query is infeasible. Answering whether 1 and 3 belong to the same optimal cluster when presented in isolation is impossible unless the crowd worker is aware of other records present in the dataset, and the granularity of the optimum clusters. Using the pair-wise Yes/No answers obtained from the crowd workers for the $\binom{5}{2}$ pairs in this example, the identified clusters achieved 0.40 F-score for $k = 3$. Please refer to Section 6.2 for additional details.

• Comparing relative distance between the locations is easy. Answering relative distance queries of the form ‘Is 1 closer to 3, or is 5 closer to 6?’ does not require any extra knowledge about other records in the dataset. For the 6 images in the example, we queried relative distance queries and the final clusters constructed for $k = 3$ achieved an F-score of 1.

In summary, we observe that humans have an innate understanding of the domain knowledge and can answer relative distance queries between records easily. Motivated by the aforementioned observations, we consider a quadruplet comparison oracle that compares the relative distance between two pairs of points $(u_1, u_2)$ and $(v_1, v_2)$ and outputs the pair with smaller distance between them breaking ties arbitrarily. Such oracle models have been studied extensively in the literature [11, 17, 24, 32, 34, 48, 49]. Even though quadruplet queries are easier than binary optimal queries, some oracle queries maybe harder than the rest. In a comparison query, if there is a significant gap between the two distances being compared, then such queries are easier to answer [9, 15]. However, when the two distances are close, the chances of an error could increase. For example, ‘Is location in image 1 closer to 3, or 2 to 6?’ maybe difficult to answer.

To capture noise in quadruplet comparison oracle answers, we consider two noise models. In the first noise model, when the pairwise distances are comparable, the oracle can return the pair of points that are farther instead of closer. Moreover, we assume that the oracle has access to all previous queries and can answer queries by acting adversarially. More formally, there is a parameter $\mu > 0$ such that if $\max \{d(u_1, u_2), d(v_1, v_2)\} \leq (1 + \mu)\min \{d(u_1, u_2), d(v_1, v_2)\}$, then adversarial error may occur, otherwise the answers are correct. We call this the ‘Adversarial Noise Model’. In the second noise model called ‘Probabilistic Noise Model’, given a pair of distances, we assume that the oracle answers correctly with a probability of $1 - p$ for some fixed constant $p < \frac{1}{2}$. We consider a persistent probabilistic noise model, where our oracle answers are persistent, i.e., query responses remain unchanged even upon repeating the same query multiple times. Such noise models have been studied extensively [9, 10, 20, 24, 42, 46] since the error due to oracles often does not change with repetition, and in some cases increases upon repeated querying [20, 42, 46]. This is in contrast to the noise models studied in [17] where response to every query is independently noisy. Persistent query models are more difficult to handle than independent query models where repeating each query is sufficient to generate the correct answer by majority voting.

1.1 Our Contributions

We present algorithms for finding the maximum, nearest and farthest neighbors, k-center clustering and hierarchical clustering objectives under the adversarial and probabilistic noise model using comparison oracle. We show that our techniques have provable approximation guarantees for both the noise models, are efficient and obtain good query complexity. We empirically evaluate the robustness and efficiency of our techniques on real world datasets.

(i) Maximum, Farthest and Nearest Neighbor: Finding maximum has received significant attention under both adversarial and probabilistic models [4, 9, 15, 18, 21–23, 38]. In this paper, we provide the following results.

• Maximum under adversarial model. We present an algorithm that returns a value within $(1 + \mu)^3$ of the maximum among a set of $n$ values $V$ with probability $1 - \delta^3$ using $O(n \log^2 (1/\delta))$ oracle queries and running time (Theorem 3.6).

• Maximum under probabilistic model. We present an algorithm that requires $O(n \log^2 (n/\delta))$ queries to identify $O(n \log^2 (n/\delta))$th rank value with probability $1 - \delta$ (Theorem 3.7). In other words, in $O(n \log^2 (n))$ time we can identify $O(\log^2 (n))$th value in the sorted order with probability $1 - \frac{1}{\sigma^2}$ for any constant $\sigma$.

To contrast our results with the state of the art, Ajtai et al. [4] study a slightly different additive adversarial error model where the answer of a maximum query is correct if the compared values differ by $\theta$ (for some $\theta > 0$) and otherwise the oracle answers adversarially. Under this setting, they give an additive 30-approximation with $O(n)$ queries. Although, our model cannot be directly compared with theirs, we note that our model is scale invariant, and thus, provides a much stronger bound when distances are small. As a consequence, our algorithm can be used under additive adversarial model as well, and obtaining the same approximation guarantees (Theorem 3.10).

For the probabilistic model, after a long series of works [9, 21, 23, 38], only recently an algorithm is proposed with query complexity $O(n \log n)$ that returns an $O(\log n)$th rank value with probability $1 - \frac{1}{n}$ [22]. Previously, the best query complexity was $O(n^{3/2})$ [23]. While our bounds are slightly worse than [22], our algorithm is significantly simpler.

Rest of the work in finding maximum allow repetition of queries and assume the answers are independent [15, 18]. As discussed earlier, persistent errors are much more difficult to handle than independent errors. In [18], the authors present an algorithm that finds maximum using $O(n \log 1/\delta)$ queries and succeeds with probability $1 - \delta$. Therefore, even under persistent errors, we obtain guarantees close to the existing ones which assume independent error. The algorithms of [15, 18] do not extend to our model.

• Nearest Neighbor. Nearest neighbor queries can be cast as “finding minimum” among a set of distances. We can obtain bounds

$\delta$ is the confidence parameter and is standard in the literature of randomized algorithms.
similar to finding maximum for the nearest neighbor queries. In the
adversarial model, we obtain an \((1 + \mu)^3\)-approximation, and in the
probabilistic model, we are guaranteed to return an element with
rank \(O(n \log^2(1/\delta))\) with probability \(1 - \delta\) using \(O(n \log^2(1/\delta))\) and
\(O(n \log^2(n/\delta))\) oracle queries respectively.

Prior techniques have studied nearest neighbor search under
noisy distance queries [41], where the oracle returns a noisy es-
imate of a distance between queried points, and repetitions are
allowed. Neither the algorithm of [41], nor other techniques de-
veloped for maximum [4, 18] and top-

(ii): Under adversarial noise, we show a
Hierarchical Clustering
approximation ratio of
in practice [5]. Clustering points using
are widely used [15]. For the problem of finding nearest neighbor,
are generated according to a normal distribution. These techniques
form average linkage in which the unobserved pairwise similarities
in each merge operation and has an overall query complexity of
clustering technique that loses only a multiplicative factor of

• **Farthest Neighbor.** Similarly, the farthest neighbor query can
be cast as finding maximum among a set of distances, and the
results for computing maximum extends to this setting. However,
computing the farthest neighbor is one of the basic primitives for
more complex tasks like \(k\)-center clustering, and for that, the existing
bounds under the probabilistic model that return an \(O(\log n)\) rank
element is insufficient. Since distances on a metric space satisfies
triangle inequality, we exploit it to get a constant approximation
to the farthest query under the probabilistic model and a mild
distribution assumption (Theorem 3.10).

(ii) **\(k\)-center Clustering:** \(k\)-center clustering is one of the funda-
mentals models of clustering and is very well-studied [52, 59].

• **\(k\)-center under adversarial model** We design algorithm that
returns a clustering that is a \(2 + \mu\) approximation for small values
of \(\mu\) with probability \(1 - \delta\) using \(O(nk^2 + nk \log^2(k/\delta))\) queries (Theorem 4.2). In contrast, even when exact distances are known, \(k\)-
center cannot be approximated better than a 2-factor unless \(P = NP\)
[52]. Therefore, we achieve near-optimal results.

• **\(k\)-center under probabilistic noise model.** For probabilistic
noise, when optimal \(k\)-center clusters are of size at least \(\Omega(\sqrt{n})\), our
algorithm returns a clustering that achieves constant approximation
with probability \(1 - \delta\) using \(O(nk \log^2(n/\delta))\) queries (Theorem 4.4).

To the best of our knowledge, even though \(k\)-center clustering
is an extremely popular and basic clustering paradigm, it hasn’t been
studied under the comparison oracle model, and we provide the
first results in this domain.

(iii) **Single Linkage and Complete Linkage– Agglomerative Hierarchical Clustering.** Under adversarial noise, we show a clustering technique that loses only a multiplicative factor of \((1 + \mu)^3\) in each merge operation and has an overall query complexity of \(O(n^3)\). Prior work [24] considers comparison oracle queries to perform average linkage in which the unobserved pairwise similarities are generated according to a normal distribution. These techniques do not extend to our noise models.

1.2 **Other Related Work** For finding the maximum among a given set of values, it is known that techniques based on tournament obtain optimal guarantees and are widely used [15]. For the problem of finding nearest neighbor, techniques based on locality sensitive hashing generally work well in practice [5]. Clustering points using \(k\)-center objective is NP-hard and there are many well known heuristics and approximation algorithms [59] with the classic greedy algorithm achieving an approximation ratio of 2. All these techniques are not applicable when pairwise distances are unknown. As distances between points cannot always be accurately estimated, many recent techniques
leverage supervision in the form of an oracle. Most oracle based
clustering frameworks consider ‘optimal cluster’ queries [13, 28, 33, 42, 43] to identify ground truth clusters. Recent techniques for
distance based clustering objectives, such as \(k\)-means [6, 12, 36, 37]
and \(k\)-median [3] use optimal cluster queries in addition to distance
information for obtaining better approximation guarantees. As
‘optimal cluster’ queries can be costly or sometimes infeasible, there
has been recent interest in leveraging distance based comparison
oracles for other problems similar to our quadruplet oracles [17, 24].

Distance based comparison oracles have been used to study a wide range of problems and we list a few of them – learning
fairness metrics [34], top-down hierarchical clustering with a dif-
f erent objective [11, 17, 24], correlation clustering [49] and classi-
f ication [32, 48], identify maximum [30, 53], \(k\)-top elements [14–
16, 38, 40, 45], information retrieval [35], skyline computation [54].

To the best of our knowledge, there is no work that considers
**quadruplet** comparison oracle queries to perform \(k\)-center clustering
and single/complete linkage based hierarchical clustering.

Closely related to finding maximum, sorting has also been well
studied under various comparison oracle based noise models [8, 9].

The work of [15] considers a different probabilistic noise model
with error varying as a function of difference in the values but they
assume that each query is independent and therefore repetition can
help boost the probability of success. Using a quadruplet oracle, [24]
studies the problem of recovering a hierarchical clustering under a
planted noise model and is not applicable for single linkage.

2 **PRELIMINARIES**

Let \(V = \{v_1, v_2, \ldots, v_n\}\) be a collection of \(n\) records such that each record maybe associated with a value \(val(v_i), \forall i \in [1, n]\). We as-
ume that there exists a total ordering over the values of elements
in \(V\). For simplicity we denote the value of record \(v_i\) as \(v_i\) instead
of \(val(v_i)\) whenever it is clear from the context.

Given this setting, we consider a comparison oracle that com-
pares the values of any pair of records \((v_i, v_j)\) and outputs \(Yes\) if
\(v_i \leq v_j\) and \(No\) otherwise.

**Definition 2.1 (Comparison Oracle).** An oracle is a function
\(O : V \times V \rightarrow \{Yes, No\}\). Each oracle query considers two values as
input and outputs \(O(v_1, v_2) = Yes\) if \(v_1 \leq v_2\) and \(No\) otherwise.

Note that a comparison oracle is defined for any pair of values.

Given this oracle setting, we define the problem of identifying the
maximum over the records \(V\).

**Problem 2.2 (Maximum).** Given a collection of \(n\) records \(V = \{v_1, \ldots, v_n\}\) and access to a comparison oracle \(O\), identify the
arg max\(_{v_i \in V}\) \(v_i\) with minimum number of queries to the oracle.

As a natural extension, we can also study the problem of identi-
fying the record corresponding to the smallest value in \(V\).

2.1 **Quadruplet Oracle Comparison Query**

In applications that consider distance based comparison of records
like nearest neighbor identification, the records \(V = \{v_1, \ldots, v_n\}\)
are generally considered to be present in a high-dimensional metric
space along with a distance \(d : V \times V \rightarrow \mathbb{R}^+\) defined over pairs of
records. We assume that the embedding of records in latent space is not known, but there exists an underlying ground truth [5]. Prior techniques mostly assume complete knowledge of accurate distance metric and are not applicable in our setting. In order to capture the setting where we can compare distances between pair of records, we define quadruplet oracle below.

**Definition 2.3 (Quadruplet Oracle).** An oracle is a function \( O : V \times V \times V \times V \rightarrow \{\text{Yes}, \text{No}\} \). Each oracle query considers two pairs of records as input and outputs \( O(v_1, v_2, v_3, v_4) = \text{Yes} \) if \( d(v_1, v_2) \leq d(v_3, v_4) \) and \( \text{No} \) otherwise.

The quadruplet oracle is similar to the comparison oracle discussed before with a difference that the two values being compared are associated with pair of records as opposed to individual records. Given this oracle setting, we define the problem of identifying the farthest record over \( V \) with respect to a query point \( q \) as follows.

**Problem 2.4 (Farthest Point).** Given a collection of \( n \) records \( V = \{v_1, \ldots, v_n\} \), a query record \( q \) and access to a quadruplet oracle \( O \), identify \( \arg \max_{v_i \in V \setminus \{q\}} d(q, v_i) \).

Similarly, the nearest neighbor query returns a point that satisfies \( \min_{v_i \in V \setminus \{q\}} d(q, v_i) \). Now, we formally define the \( k \)-center clustering problem.

**Problem 2.5 (\( k \)-center Clustering).** Given a collection of \( n \) records \( V = \{v_1, \ldots, v_n\} \) and access to a comparison oracle \( O \), identify \( k \) centers (say \( S \subseteq V \)) and a mapping of records to corresponding centers, \( \pi : V \rightarrow S \), such that the maximum distance of any record from its center, i.e., \( \max_{v_i \in V} d(v_i, \pi(v_i)) \), is minimized.

We assume that the points \( v_i \in V \) exist in a metric space and the distance between any pair of points is not known. We denote the unknown distance between any pair of points \( (v_i, v_j) \) where \( v_i, v_j \in V \) as \( d(v_i, v_j) \) and use \( k \) to denote the number of clusters. Optimal clusters are denoted as \( C^* \) with \( C^*(v_i) \subseteq V \) denoting the set of points belonging to the optimal cluster containing \( v_i \). Similarly, \( C(v_i) \subseteq V \) refers to the nodes belonging to the cluster containing \( v_i \) for any clustering given by \( C(\cdot) \).

In addition to the \( k \)-center clustering, we study single linkage and complete linkage–agglomerative clustering techniques where the distance metric over the records is not known apriori. These techniques initialize each record \( v_i \) in a separate singleton cluster and sequentially merge the pair of clusters having the least distance between them. In case of single linkage, the distance between two clusters \( C_1 \) and \( C_2 \) is characterized by the closest pair of records defined as:

\[
\text{d}_{\text{SL}}(C_1, C_2) = \min_{v_i \in C_1, v_j \in C_2} d(v_i, v_j)
\]

In complete linkage, the distance between a pair of clusters \( C_1 \) and \( C_2 \) is calculated by identifying the farthest pair of records,

\[
\text{d}_{\text{CL}}(C_1, C_2) = \max_{v_i \in C_1, v_j \in C_2} d(v_i, v_j).
\]

### 2.2 Noise Models

The oracle models discussed in Problem 2.2, 2.4 and 2.5 assume that the oracle answers every comparison query correctly. In real world applications, however, the answers can be wrong which can lead to noisy results. To formalize the notion of noise, we consider two different models. First, adversarial noise model considers a setting where a comparison query can be adversarially wrong if the two values being compared are within a multiplicative factor of \((1 + \mu)\) for some constant \( \mu > 0 \).

\[
O(v_1, v_2) = \begin{cases} 
\text{Yes, if } v_1 < \frac{1}{(1+\mu)} v_2 \\
\text{No, if } v_1 > (1+\mu) v_2 \\
\text{adversarially incorrect if } \frac{1}{(1+\mu)} \leq \frac{v_1}{v_2} \leq (1+\mu) 
\end{cases}
\]

The parameter \( \mu \) corresponds to the degree of error. For example, \( \mu = 0 \) implies a perfect oracle. The model extends to quadruplet oracle as follows.

\[
O(v_1, v_2, v_3, v_4) = \begin{cases} 
\text{Yes, if } d(v_1, v_2) < \frac{1}{(1+\mu)} d(v_3, v_4) \\
\text{No, if } d(v_1, v_2) > (1+\mu) d(v_3, v_4) \\
\text{adversarially incorrect if } \frac{1}{(1+\mu)} \leq \frac{d(v_1, v_2)}{d(v_3, v_4)} \leq (1+\mu) 
\end{cases}
\]

The second model considers a probabilistic noise model where each comparison query is incorrect independently with a probability \( p < \frac{1}{2} \) and asking the same query multiple times yields the same response. We discuss ways to estimate \( \mu \) and \( p \) from real data in Section 6.

### 3 FINDING MAXIMUM

In this section, we present robust algorithms to identify the record corresponding to the maximum value in \( V \) under the adversarial noise model and the probabilistic noise model. Later we extend the algorithms to find the farthest and the nearest neighbor. We note that our algorithms for the adversarial model are parameter free (do not depend on \( \mu \)) and the algorithms for the probabilistic model can use \( p = 0.5 \) as a worst case estimate of the noise.

#### 3.1 Adversarial Noise

Consider a trivial approach that maintains a running maximum value while sequentially processing the records, i.e., if a larger value is encountered, the current maximum value is updated to the larger value. This approach requires \( n - 1 \) comparisons. However, in the presence of adversarial noise, our output can have a significantly lower value compared to the correct maximum. In general, if \( v_{\text{max}} \) is the true maximum of \( V \), then the above approach can return an approximate maximum whose value could be as low as \( v_{\text{max}}/(1 + \mu) \). To see this, assume \( v_1 = 1 \), and \( v_i = (1 + \mu - \epsilon) \) where \( \epsilon > 0 \) is very close to 0. It is possible that while comparing \( v_i \) and \( v_{i+1} \), the oracle returns \( v_i \) as the larger element. If this mistake is repeated for every \( i \), then, \( v_1 \) will be declared as the maximum element whereas the correct answer is \( v_{\text{max}} \approx v_1(1 + \mu)^{n-1} \).

To improve upon this naive strategy, we introduce a natural keeping score based idea where given a set \( S \subseteq V \) of records, we maintain \( \text{Count}(v, S) \) that is equal to the number of values smaller than \( v \) in \( S \).

\[
\text{Count}(v, S) = \sum_{x \in S \setminus \{v\}} 1\{O(v, x) == \text{No}\}
\]

It is easy to observe that when the oracle makes no mistakes, \( \text{Count}(v_{\text{max}}, S) = |S| - 1 \) and obtains the highest score, where \( v_{\text{max}} \) is the maximum value in \( S \). Using this observation, in Algorithm 1, we output the value with the highest \( \text{Count} \) score.
Given a set of records $V$, we show in Lemma 3.1 that Count-Max$(V)$ obtained using Algorithm 1 always returns a good approximation of the maximum value in $V$.

**Lemma 3.1.** Given a set of values $V$ with maximum value $v_{max}$, Count-Max$(V)$ returns a value $u_{max}$ where $u_{max} \geq v_{max}/(1 + \mu)^2$ using $O(|V|^2)$ oracle queries.

Using Example 3.2, when $\mu = 1$, we demonstrate that $(1 + \mu)^2 = 4$ approximation ratio is achieved by Algorithm 1.

**Example 3.2.** Let $S$ denote a set of four records $u, v, w$ and $t$ with ground truth values $51, 101, 102$ and $202$, respectively. While identifying the maximum value under adversarial noise with $\mu = 1$, the oracle must return a correct answer to $\text{O}(u, t)$ and all other oracle query answers can be incorrect adversarially. If the oracle answers all other queries incorrectly, we have, Count values of $t, w, u, v$ are $1, 1, 2, 2$ respectively. Therefore, $u$ and $v$ are equally likely, and when Algorithm 1 returns $u$, we have a $202/51 \approx 3.96$ approximation.

From Lemma 3.1, we have that $O(n^2)$ oracle queries where $|V| = n$, are required to get $(1 + \mu)^2$ approximation. In order to improve the query complexity, we use a tournament to obtain the maximum value. The idea of using a tournament for finding maximum has been studied in the past [15, 18].

Algorithm 2 presents pseudo code of the approach that takes values $V$ as input and outputs an approximate maximum value. It constructs a balanced $\lambda$-ary tree $T$ containing $n$ leaf nodes such that a random permutation of the values $V$ is assigned to the leaves of $T$. In a tournament, the internal nodes of $T$ are processed bottom-up such that at every internal node $w$, we assign the value that is largest among the children of $w$. To identify the largest value, we calculate $\text{arg max}_{v \in \text{children}(w)} \text{Count}(v, \text{children}(w))$ at the internal node $w$, where Count$(v, X)$ refers to the number of elements in $X$ that are considered smaller than $v$. Finally, we return the value at the root of $T$ as our output. In Lemma 3.3, we show that Algorithm 2 returns a value that is a $(1 + \mu)^2 \log \log n$ multiplicative approximation of the maximum value.

**Algorithm 1 Count-Max($S$): finds the max. value by counting**

1. **Input:** A set of values $S$
2. **Output:** An approximate maximum value of $S$
3. for $v \in S$ do
4. Calculate Count$(v, S)$
5. $u_{max} \leftarrow \text{arg max}_{v \in S} \text{Count}(v, S)$
6. **return** $u_{max}$

**Lemma 3.3.** Suppose $u_{max}$ is the maximum value among the set of records $V$. Algorithm 2 outputs a value $u_{max}$ such that $u_{max} \geq u_{max}/(1 + \mu)^2\log \log n$ using $O(n^2)$ oracle queries.

According to Lemma 3.3, Algorithm 2 identifies a constant approximation when $\lambda = \Theta(n)$, $\mu$ is a fixed constant and has a query complexity of $\Theta(w^2)$. By reducing the degree of the tournament tree from $\lambda$ to 2, we can achieve $\Theta(n)$ query complexity, but with a worse approximation ratio of $(1 + \mu)\log n$.

Now, we describe our main algorithm (Algorithm 4) that uses the following observation to improve the overall query complexity.

**Observation 3.4.** At an internal node $w \in T$, the identified maximum is incorrect only if there exists $x \in \text{children}(w)$ that is very close to the true maximum (say $w_{max}$), i.e., $w_{max}/(1 + \mu) \leq x \leq (1 + \mu)w_{max}$.

Based on the above observation, our Algorithm Max-Adv uses two steps to identify a good approximation of $v_{max}$. Consider the case where there are a lot of values that are close to $v_{max}$. In Algorithm Max-Adv, we use a subset $\hat{V} \subseteq V$ of size $\sqrt{n}$ (for a suitable choice of parameter $t$) obtained using uniform sampling with replacement. We show that using a sufficiently large subset $\hat{V}$, obtained by sampling, we ensure that at least one value that is closer to $v_{max}$ is in $\hat{V}$, thereby giving a good approximation of $v_{max}$.

**Algorithm 2 Tournament : finds the maximum value using a tournament tree**

1. **Input:** Set of values $V$, Degree $\lambda$
2. **Output:** An approximate maximum value $u_{max}$
3. Construct a balanced $\lambda$-ary tree $T$ with $|V|$ nodes as leaves.
4. Let $p_V$ be a random permutation of $V$ assigned to leaves of $T$
5. for $i = 1$ to $\log \lambda |V|$ do
6. for internal node $w$ at level $\log \lambda |V| - i$ do
7. Let $U$ denote the children of $w$.
8. Set the internal node $w$ to Count-Max$(U)$
9. $u_{max} \leftarrow$ value at root of $T$
10. **return** $u_{max}$

In order to handle the case when there are only a few values closer to $v_{max}$, we divide the entire data set into $l$ disjoint parts (for a suitable choice of $l$) and run the Tournament algorithm with degree $\lambda = 2$ on each of these parts separately (Algorithm 3). As there are very few points close to $v_{max}$, the probability of comparing any such value with $v_{max}$ is small, and this ensures that in the partition containing $v_{max}$, Tournament returns $v_{max}$. We collect the maximum values returned by Algorithm 2 from all the partitions and include these values in $T$ in Algorithm Max-Adv. We repeat this procedure $t$ times and set $l = \sqrt{n}$, $t = 2\log(2/\delta)$ to achieve the desired success probability $1 - \delta$. We combine the outputs of both the steps, i.e., $\hat{V}$ and $T$ and output the maximum among them using Count-Max. This ensures that we get a good approximation as we use the best of both the approaches.

**Algorithm 3 Tournament-Partition**

1. **Input:** Set of values $V$, number of partitions $l$
2. **Output:** A set of maximum values from each partition
3. Randomly partition $V$ into $l$ equal parts $V_1, V_2, \ldots, V_l$
4. for $i = 1$ to $l$ do
5. $p_{V_i} \leftarrow$ Tournament$(V_i, 2)$
6. $T \leftarrow T \cup \{p_{V_i}\}$
7. **return** $T$

**Theoretical Guarantees.** In order to prove approximation guarantee of Algorithm 4, we first argue that the sample $\hat{V}$ contains a good approximation of the maximum value $v_{max}$ with a high probability. Let $C$ denote the set of values that are very close to $v_{max}$. Suppose $C = \{u : u_{max}/(1 + \mu) \leq u \leq v_{max}\}$. In Lemma 3.5, we first
Algorithm 4 MAX-ADV : Maximum with Adversarial Noise

1: Input : Set of values \( V \), number of iterations \( t \), partitions \( l \)
2: Output : An approximate maximum value \( u_{\text{max}} \)
3: \( i \leftarrow 1 \), \( T \leftarrow \phi \)
4: Let \( \overline{V} \) denote a sample of size \( \sqrt{n}t \) selected uniformly at random (with replacement) from \( V \).
5: for \( i \leq t \) do
6: \( T_i \leftarrow \text{Tournament-Partition}(V, l) \)
7: \( T \leftarrow T \cup T_i \)
8: \( u_{\text{max}} \leftarrow \text{Count-Max}(\overline{V} \cup T) \)
9: return \( u_{\text{max}} \)

show that \( \overline{V} \) contains a value \( v_j \in \overline{V} \) such that \( v_j \geq u_{\text{max}}/(1+\mu) \), whenever the size of \( C \) is large, i.e., \(|C| > \sqrt{n}/2 \). Otherwise, we show that we can recover \( u_{\text{max}} \) correctly with probability \( 1 - \delta/2 \) whenever \(|C| \leq \sqrt{n}/2 \).

**Lemma 3.5.** (1) If \(|C| > \sqrt{n}/2 \), then there exists a value \( v_j \in \overline{V} \) satisfying \( v_j \geq u_{\text{max}}/(1+\mu) \) with probability of at least \( 1 - \delta/2 \).

(2) Suppose \(|C| \leq \sqrt{n}/2 \). Then, \( T \) contains \( u_{\text{max}} \) with probability at least \( 1 - \delta/2 \).

Now, we briefly provide a sketch of the proof of Lemma 3.5. Consider the first step, where we use a uniformly random sample \( \overline{V} \) of \( \sqrt{n}t \) points from \( V \) (obtained with replacement). When \(|C| \geq \sqrt{n}/2 \), probability that \( \overline{V} \) contains a value from \( C \) is given by

\[
1 - \left(1 - \frac{|C|}{\sqrt{n}}\right)^{\sqrt{n}t} = 1 - \left(1 - \frac{1}{2\sqrt{n}}\right)^{2\sqrt{n}t \log(2/\delta)} \approx 1 - \delta/2.
\]

In the second step, Algorithm 4 uses a modified tournament tree that partitions the set \( V \) into \( l = \sqrt{n} \) parts of size \( n/l = \sqrt{n} \) each and identifies a maximum \( p_i \) from each partition \( V_i \) using Algorithm 2. We have that the expected number of elements from \( C \) in a partition \( V_i \) containing \( u_{\text{max}} \) is \(|C|/l = \sqrt{n}/(2\sqrt{n}) = 1/2 \). Thus by the Markov’s inequality, the probability that \( V_i \) contains a value from \( C \) is \( \leq 1/2 \). With \( 1/2 \) probability, \( u_{\text{max}} \) will never be compared with any point from \( C \) in the partition \( V_i \). To increase the success probability, we run this procedure \( t \) times and obtain all the outputs. Among the \( t \) runs of Algorithm 2, we argue that \( u_{\text{max}} \) is never compared with any value of \( C \) in at least one of the iterations with a probability at least \( 1 - \left(1 - 1/2\right)^2 \geq 1 - \delta/2 \).

In Lemma 3.1, we show that using Count-Max we get a \((1+\mu)^2\) multiplicative approximation. Combining it with Lemma 3.5, we have that \( u_{\text{max}} \) returned by Algorithm 4 satisfies \( u_{\text{max}} \geq u_{\text{max}}/(1+\mu)^2 \) with probability \( 1 - \delta \). For query complexity, Algorithm 3 identifies \( \sqrt{n}t \) samples denoted by \( \overline{V} \). These identified values, along with \( T \) are then processed by Count-Max to identify the maximum \( u_{\text{max}} \). This step requires \( O(|\overline{V} \cup T|^2) = O(n \log^2(1/\delta)) \) oracle queries.

**Theorem 3.6.** Given a set of values \( V \), Algorithm 4 returns a \((1+\mu)^3\) approximation of maximum value with probability \( 1 - \delta \) using \( O(n \log^3(1/\delta)) \) oracle queries.

### 3.2 Probabilistic Noise

We can directly extend the algorithms for the adversarial noise model to probabilistic noise. Specifically, the theoretical guarantees of Lemma 3.3 do not apply when the noise is probabilistic. In this section, we develop several new ideas to handle probabilistic noise.

---

**Figure 2:** Example for Lemma 3.1 with \( \mu = 1 \).

Let \( \text{rank}(u, V) \) denote the index of \( u \) in the non-increasing sorted order of values in \( V \). So, \( u_{\text{max}} \) will have rank 1 and so on. Our main idea is to use an early stopping approach that uses a sample \( S \subseteq V \) of \( O(\log n/\delta) \) values selected randomly and for every value \( u \) that is not in \( S \), we calculate \( \text{Count}(u, S) \) and discard \( u \) using a chosen threshold for the Count scores. We argue that by doing so, it helps us eliminate the values that are far away from the maximum in the sorted ranking. This process is continued \( \Theta(\log n) \) times to identify the maximum value. We present the pseudo code in the Appendix and prove the following approximation guarantee.

**Theorem 3.7.** There is an algorithm that returns \( u_{\text{max}} \in V \) such that \( \text{rank}(u_{\text{max}}, V) = O(\log^2(n/\delta)) \) with probability \( 1 - \delta \) and requires \( O(n \log^2(n/\delta)) \) oracle queries.

The algorithm to identify the minimum value is same as that of maximum with a modification where Count scores consider the case of Yes (instead of No): \( \text{Count}(s, V) = \sum_{x \in S \setminus \{u\}} 1 \cdot O(v, x) \Rightarrow \text{Yes} \)

### 3.3 Extension to Farthest and Nearest Neighbor

Given a set of records \( V \), the farthest record from a query \( u \) corresponds to the record \( u' \in V \) such that \( d(u, u') \) is maximum. This query is equivalent to finding maximum in the set of distance values given by \( D(u) = \{d(u, u') : \forall u' \in V \} \) containing \( n \) values for which we already developed algorithms in Section 3. Since the ground truth distance between any pair of records is not known, we require quadruplet oracle (instead of comparison oracle) to identify the maximum element in \( D(u) \). Similarly, the nearest neighbor of query record \( u \) corresponds to finding the record with minimum distance value in \( D(u) \). Algorithms for finding maximum from previous sections, extend for these settings with similar guarantees.

**Example 3.8.** Figure 2 shows a worst-case example for the approximation guarantee to identify the farthest point from \( s \) (with \( \mu = 1 \)). Similar to Example 3.2, we have, Count values of \( t, w, u, v \) are 1, 2, 2 respectively. Therefore, \( u \) and \( v \) are equally likely, and when Algorithm 1 outputs \( u \), we have \( a \approx 3.96 \) approximation.

For probabilistic noise, the farthest identified in Section 3.2 is guaranteed to rank within the top-\( O(\log^2 n) \) values of set \( V \) (Theorem 3.7). In this section, we show that it is possible to compute the farthest point within a small additive error under the probabilistic model, if the data set satisfies an additional property discussed below. For the simplicity of exposition, we assume \( p \leq 0.4 \), though our algorithms work for any value of \( p \leq 0.5 \) (with different constants).

One of the challenges in developing robust algorithms for farthest identification is that every relative distance comparison of records from \( u \) \( (O(u, v_j, u, v_j) \) for some \( u_j, v_j \in V) \) may be answered incorrectly with constant error probability \( p \) and the success probability cannot be boosted by repetition. We overcome this challenge by performing pairwise comparisons in a robust manner. Suppose the desired failure probability is \( \delta \), we observe that if \( \Theta(\log(1/\delta)) \) records closest to the query \( u \) are known (say...
we show that, if $S$ or $\max_k$ prove constant approximation guarantees of our algorithm. Our
In this section, we present algorithms for $k$-center clustering and prove constant approximation guarantees of our algorithm. Our
algorithm is an adaptation of the classical greedy algorithm for $k$-center [27]. The greedy algorithm [27] is initialized with an arbitrary point as the first cluster center and then iteratively identifies the next centers. In each iteration, it assigns all the points to the current set of clusters, by identifying the closest center for each point. Then, it finds the farthest point among the clusters and uses it as the new center. This technique requires $O(nk)$ distance comparisons in the absence of noise and guarantees $2$-approximation of the optimal clustering objective. We provide the pseudocode for this approach in Algorithm 6. Using an argument similar to the one presented for the worst case example in Section 3, we can show that if we use Algorithm 6 where we replace every comparison with an oracle query, the generated clusters can be arbitrarily worse even for small error. In order to improve its robustness, we devise new algorithms to perform assignment of points to respective clusters and farthest point identification. Missing Details from this section are discussed in Appendix 10 and 11.

Algorithm 6 Greedy Algorithm

1. $\textbf{Input} : \text{Set of points } V$
2. $\textbf{Output} : \text{Clusters } C$
3. $s_1 \leftarrow \text{arbitrary point from } V, S = \{s_1\}, C = \{\emptyset\}$
4. for $i = 2$ to $k$ do
5. $s_i \leftarrow \text{APPROX-Farthest}(S, C)$
6. $S \leftarrow S \cup \{s_i\}$
7. $C \leftarrow \text{Assign}(S)$
8. return $C$

4.1 Adversarial Noise

Now, we describe the two steps (APPROX-Farthest and Assign) of the Greedy Algorithm that will complete the description of Algorithm 6. To do so, we build upon the results from previous section that give algorithms for obtaining maximum/farthest point.

**APPROX-Farthest.** Given a clustering $C$, and a set of centers $S$, we construct the pairs $(v_i, s_j)$ where $v_i$ is assigned to cluster $C(s_j)$ centered at $s_j \in S$. Using Algorithm 4, we identify the point, center pair that have the maximum distance i.e. arg $\max_{v_i \in V} d(v_i, s_j)$, which corresponds to the farthest point. For the parameters, we use $l = \sqrt{n} \cdot t = \log(2k/\delta)$ and number of samples $V = \sqrt{n}t$. Assign. After identifying the farthest point, we reassign all the points to the centers (now including the farthest point as the new center) closest to them. We calculate a movement score called $MCount$ for every point with respect to each center. $MCount(u, s_j) = \sum_{s_k \in S \setminus \{s_j\}} I(O((s_j, u), (s_k, u)) == Yes)$, for any record $u \in V$ and $s_j \in S$. This step is similar to COUNT-Max Algorithm. We assign the point $u$ to the center with the highest $MCount$ value.

**Example 4.1.** Suppose we run $k$-center algorithm with $k = 2$ and $\mu = 1$ on the points in Example 3.8. The optimal centers are $u$ and $t$ with radius $51$. On running our algorithm, suppose $w$ is chosen as the first center and APPROX-Farthest calculates Count values similar to Example 3.2. We have, Count values of $s, t, u, o$ are $1, 2, 3, 0$ respectively. Therefore, our algorithm identifies $u$ as the second center, achieving $3$-approximation.
Theoretical Guarantees. We now prove the approximation guarantee obtained by Algorithm 6.

In each iteration, we show that ASSIGN reassigns each point to a center with distance approximately similar to the distance from the closest center. This is surprising given that we only use \( \text{MCount} \) scores for assignment. Similarly, we show that APPROX-FARDEST (Algorithm 4) identifies a close approximation to the true farthest point. Concretely, we show that every point is assigned to a center which is a \((1 + \mu)^2\) approximation. Algorithm 4 identifies farthest point \( w \) which is a \((1 + \mu)^3\) approximation.

In every iteration of the Greedy algorithm, if we identify an \( \alpha \)-approximation of the farthest point, and a \( \beta \)-approximation when reassigning the points, then, we show that the clusters output are a \( 2\alpha\beta^2 \)-approximation to the \( k \)-center objective. For complete details, please refer Appendix 10. Combining all the claims, for a given error parameter \( \mu \), we obtain:

\[ \text{Algorithm 7 Greedy Clustering} \]

1: \( \textbf{Input} \) : Set of points \( V \), smallest cluster size \( m \).
2: \( \textbf{Output} \) : Clusters \( C \)
3: For every \( u \in V \), include \( u \) in \( \tilde{V} \) with probability \( \frac{y \log(n/\delta)}{m} \)
4: \( s_1 \leftarrow \) select an arbitrary point from \( \tilde{V} \), \( S \leftarrow \{s_1\} \)
5: \( C(s_1) \leftarrow \tilde{V} \)
6: \( R(s_1) \leftarrow \text{IDENTIFY-CORE}(C(s_1), s_1) \)
7: for \( i = 2 \) to \( k \) do
8: \( s_i \leftarrow \text{APPROX-FARDEST}(S, C) \)
9: \( C, R \leftarrow \text{ASSIGN}(S, s_i, R) \)
10: \( S \leftarrow S \cup \{s_i\} \)
11: \( C \leftarrow \text{ASSIGN-FINAL}(S, R, V \setminus \tilde{V}) \)
12: return \( C \)

the main challenge in extending APPROX-FARDEST and ASSIGN ideas of Algorithm 6. Given a cluster \( C \) containing the center \( s_i \), when we find the APPROX-FARDEST, the ideas from Section 3.2 give a \( O(\log^2 n) \) rank approximation. As shown in section 3.3, we can improve the approximation guarantee by considering a set of \( \Theta(n/\delta) \) points close to \( s_j \), denoted by \( R(s_j) \) and call them core of \( s_j \). We argue that such an assumption of set \( R \) is justified. For example, consider the case when clusters are of size \( \Theta(n) \) and sampling \( k \log(n/\delta) \) points gives us \( \log(n/\delta) \) points from each optimum cluster; which means that there are \( \log(n/\delta) \) points within a distance of \( 2 \text{OPT} \) from every sampled point where OPT refers to the optimum \( k \)-center objective.

\[ \text{Algorithm 8 ASSIGN(S, S_1, R)} \]

1: \( C(s_1) \leftarrow \{s_1\} \)
2: for \( s_j \in S \) do
3: for \( u \in C(s_j) \) \( \setminus R(s_j) \) do
4: \( \text{MCount}(u, s_i, s_j) = \sum_{v \in R(s_j)} 1\{O(u, s_i, u, v) == \text{Yes}\} \)
5: if \( \text{MCount}(u, s_i, s_j) > 0.3|R(s_j)| \) then
6: \( C(s_j) \leftarrow C(s_j) \cup \{u\}; C(s_j) \leftarrow C(s_j) \setminus \{u\} \)
7: return \( C \)

\[ \text{Algorithm 9 IDENTIFY-CORE}(C(s_j), s_j) \]

1: for \( u \in C(s_j) \) do
2: \( \text{MCount}(u) = \sum_{v \in C(s_j)} 1\{O(s_j, u, s_i, u) == \text{Yes}\} \)
3: \( R(s_j) \) denote set of \( 8y \log(n/\delta)/9 \) points with the highest Count values.
4: return \( R(s_j) \)

IDENTIFY-CORE. After forming cluster \( C(s_j) \), we identify the core of \( s_j \). For this, we calculate a score, denoted by Count and captures number of times it is closer to \( s_j \) compared to other points in \( C(s_j) \). Intuitively, we expect points with high values of Count to belong to \( C^*(s_j) \) i.e., optimum cluster containing \( s_j \). Therefore we sort these Count scores and return the highest scored points.

\[ \text{Algorithm 10 APPROX-FARDEST} \]

1: for \( u \in C(s_j) \) do
2: \( \text{MCount}(u) = \sum_{v \in C(s_j)} 1\{O(s_j, u, s_i, u) == \text{Yes}\} \)
3: \( R(s_j) \) denote set of \( 8y \log(n/\delta)/9 \) points with the highest Count values.
4: return \( R(s_j) \)

APPROX-FARDEST. For a set of clusters \( C \), and a set of centers \( S \), we construct the pairs \( (u_i, s_j) \) where \( u_i \) is assigned to cluster \( C(s_j) \) centered at \( s_j \in S \) and each center \( s_j \in S \) has a corresponding core \( R(s_j) \). The farthest point can be found by finding the maximum distance (point, center) pair among all the points considered. To do so, we use the ideas developed in section 3.3.

We leverage ClusterComp (Algorithm 10) to compare the distance of two points, say \( v_i, v_j \) from their respective centers \( s_i, s_j \). ClusterComp gives a robust answer to a pairwise comparison query to the oracle \( O(v_i, s_i, v_j, s_j) \) using the cores \( R(s_i) \) and \( R(s_j) \). ClusterComp can be used as a pairwise comparison subroutine in place of PairwiseComp for the algorithm in Section 3 to calculate the farthest point. For every \( s_j \in S \), let \( R(s_j) \) denote an arbitrary set of \( \sqrt{R(s_j)} \) points from \( R(s_j) \). For a ClusterComp comparison
query between the pairs \((u_i, s_i)\) and \((v_j, s_j)\), we use these subsets in Algorithm 10 to ensure that we only make \(\Theta(\log(n/\delta))\) oracle queries for every comparison. However, when the query is between points of the same cluster, say \(C(s_j)\), we use all the \(\Theta(\log(n/\delta))\) points from \(R(s_i)\). For the parameters used to find maximum using Algorithm 4, we use \(l = \sqrt{n}, t = \log(n/\delta)\).

Example 4.3. Suppose we run \(k\)-center Algorithm 7 with \(k = 2\) and \(m = 2\) on the points in Example 3.8. Let \(w\) denote the first center chosen and Algorithm 7 identifies the core \(R(w)\) by calculating Count Values. If \(O(u, w, s, w)\) and \(O(s, w, t, w)\) are answered incorrectly (with probability \(p\)), we obtain \(\text{Count}(s, u, t, v) = O(\log(n/\delta))\) robust pairwise comparison queries (similar to Section 3.3), in our \(\text{Count}\) closest points using \(e\) core that good approximation of the \(e\) scores, we identify the clusters \(C\) not sampled, we first assign it to \(\text{Assign}(s)\), similar to the one described in Example 4.3. After assigning (using \(\text{Assign}\)), the clusters identified are \(\{w, v\}, \{u, s, t\}\), achieving \(3\)-approximation.

Algorithm 10 ClusterComp \((u_i, s_i, u_j, s_j)\)

1: comparisons ← 0, \(\text{Count}(u_i, u_j) ← 0\)
2: if \(s_i \neq s_j\) then
3: \(\text{Let } \text{Count}(u_i, u_j) = \sum_{s \in \mathcal{R}(s_i)} 1\{O(u_i, x, u_j, x) == \text{Yes}\}\)
4: comparisons ← \(|\mathcal{R}(s_i)|\)
5: else Let \(\text{Count}(u_i, u_j) = \sum_{s \in \mathcal{R}(s_i), s \in \mathcal{R}(s_j)} 1\{O(u_i, x, u_j, y) == \text{Yes}\}\)
6: comparisons ← \(|\mathcal{R}(s_i)| \cdot |\mathcal{R}(s_j)|\)
7: if \(\text{Count}(u_i, u_j) < 0.3 \cdot \text{comparisons}\) then
8: return No
9: else return Yes

Assign-Final. After obtaining \(k\) clusters on the set of sampled points \(V\), we assign the remaining points using \(\text{Count}\) scores, similar to the one described in Assign. For every point that is not sampled, we first assign it to \(s_1 \in S\), and if \(\text{Count}(u, s_2, s_1) \geq 0.3|\mathcal{R}(s_1)|\), we re-assign it to \(s_2\), and continue this process iteratively. After assigning all the points, the clusters are returned as output.

Theoretical Guarantees

Our algorithm first constructs a sample \(\bar{V} \subseteq V\) and runs the greedy algorithm on this sampled set of points. Our main idea to ensure that good approximation of the \(k\)-center objective lies in identifying a good core around each center. Using a sampling probability of \(y \log(n/\delta)/m\) ensures that we have at least \(\Theta(\log(n/\delta))\) points from each of the optimal clusters in our sampled set \(\bar{V}\). By finding the closest points using Count scores, we identify \(O(\log(n/\delta))\) points around every center that are in the optimal cluster. Essentially, this forms the core of each cluster. These cores are then used for robust pairwise comparison queries (similar to Section 3.3), in our \(\text{Approx-Farthest}\) and \(\text{Assign}\) subroutines. We give the following theorem, which guarantees a constant, i.e., \(O(1)\) approximation with high probability.

Theorem 4.4. Given \(p \leq 0.4\), a failure probability \(\delta\), and \(m = \Omega(\log^2(n/\delta))/\delta\). Then, Algorithm 7 achieves a \(O(1)\)-approximation for the \(k\)-center objective using \(O(kn \log(n/\delta) + \frac{m^2}{p^2} k \log^2(n/\delta))\) oracle queries with probability \(1 - O(\delta)\).

5 HIERARCHICAL CLUSTERING

In this section, we present robust algorithms for agglomerative hierarchical clustering using single linkage and complete linkage objectives. The naive algorithms initialize every record as a singleton cluster and merge the closest pair of clusters iteratively. For a set of clusters \(C = \{C_1, \ldots, C_t\}\), the distance between any pair of clusters \(C_i\) and \(C_j\), for single linkage clustering, is defined as the minimum distance between any pair of records in the clusters, \(d_{ij}(C_i, C_j) = \min_{v_i \in C_i, v_j \in C_j} d(v_i, v_j)\). For complete linkage, cluster distance is defined as the maximum distance between any pair of records. All algorithms discussed in this section can be easily extended for complete linkage, and therefore we study single linkage clustering. The main challenge in implementing single linkage clustering in the presence of adversarial noise is identification of minimum value in a list of at most \(\binom{m}{2}\) distance values. In each iteration, the closest pair of clusters can be identified by using Algorithm 4 with \(t = 2\log(n/\delta)\) to calculate the minimum over the set containing pairwise distances. For this algorithm, Lemma 5.1 shows that the pair of clusters merged in any iteration are a constant approximation of the optimal merge operation at that iteration. The proof of this lemma follows from Theorem 3.6.

Lemma 5.1. Given a collection of clusters \(C = \{C_1, \ldots, C_t\}\), our algorithm to calculate the closest pair (using Algorithm 4) identifies \(C_i\) and \(C_j\) to merge according to single linkage objective if \(d_{ij}(C_i, C_j) \leq (1 + \mu)^3 \min_{C_i, C_j \in C} d(C_i, C_j)\) with \(1 - \delta n\) probability and requires \(O(n^2 \log^2(n/\delta))\) queries.

Algorithm 11 Greedy Algorithm

1: Input : Set of points \(V\)
2: Output : Hierarchy \(H\)
3: \(H \leftarrow \{(v) \mid v \in V\}\), \(C \leftarrow \{(v) \mid v \in V\}\)
4: for \(C_i \in C\) do
5: \(\tilde{C}_i \leftarrow \text{NearestNeighbor of } C_i \text{ among } C \setminus \{C_i\} \text{ using Sec 3.3}\)
6: while \(|C| > 1\) do
7: Let \((C_i, \tilde{C}_j)\) be the closest pair among \((C_i, \tilde{C}_j), \forall C_i \in C\)
8: \(C' \leftarrow C_i \cup C_j\)
9: Update Adjacency list of \(C'\) with respect to \(C\)
10: Add \(C'\) as parent of \(\tilde{C}_i\) and \(\tilde{C}_j\) in \(H\).
11: \(C \leftarrow (C \setminus \{C_i, \tilde{C}_j\}) \cup (C')\)
12: \(C' \leftarrow \text{NearestNeighbor of } C' \text{ from its adjacency list}\)
13: return \(H\)

Overview. Agglomerative clustering techniques are known to be inefficient. Each iteration of merge operation compares at most \(\binom{m}{2}\) pairs of distance values and the algorithm operates \(n\) times to construct the hierarchy. This yields an overall query complexity of \(O(n^3)\). To improve their query complexity, SLINK algorithm [47] was proposed to construct the hierarchy in \(O(n^2)\) comparisons. To implement this algorithm with a comparison oracle, for every cluster \(C_i \in C\), we maintain an adjacency list containing every cluster \(C_j\) in \(C\) along with a pair of records with the distance equal to the distance between the clusters. For example, the entry for \(C_j\) in the adjacency list of \(C_i\) contains the pair of records \((u_i, u_j)\) such that \(d(u_i, u_j) = \min_{v_i \in C_i, v_j \in C_j} d(v_i, v_j)\). Algorithm 11 presents the pseudo code for single linkage clustering under the adversarial noise model. The algorithm is initialized with singleton clusters where every record is a separate cluster. Then, we identify the closest cluster for every \(C_i \in C\), and denote it by \(\tilde{C}_i\). This step takes
After merging these clusters, the data structure is updated as follows. To update the adjacency list, we need the pair of records with minimum distance between the merged cluster $C' \equiv C_j \cup C_k$ and every other cluster $C_k$. In the previous iteration of the algorithm, we already have the minimum distance record pair for $(C_j, C_k)$ and $(C_j, C_k)$ and $(C_k, C_k)$. Therefore a single query between these two pairs of records is sufficient to identify the minimum distance edge between $C'$ and $C_k$ (formally: $d_{SL}(C_j \cup C_k, C_k) = \min\{d_{SL}(C_j, C_k), d_{SL}(C_k, C_k)\}$). The nearest neighbor of the merged cluster is identified by running minimum calculation over its adjacency list. In Algorithm 11, as we identify closest pair of clusters, each iteration requires $O(n \log^2(n/\delta))$ queries. As our algorithm terminates in at most $n$ iterations, it has an overall query complexity of $O(n^2 \log^2(n/\delta))$. In Theorem 5.2, we given an approximation guarantee for every merge operation of Algorithm 11.

Theorem 5.2. In any iteration, suppose the distance between a cluster $C_j \in C$ and its identified nearest neighbor $C_j'$ is $\alpha$-approximation of its distance from the optimal nearest neighbor, then the distance between pair of clusters merged by Algorithm 11 is $\alpha(1 + \mu)^3$ approximation of the optimal distance between the closest pair of clusters in $C$ with a probability of $1 - \delta$ using $O(n \log^2(n/\delta))$ oracle queries.

Probabilistic Noise model. The above discussed algorithms do not extend to the probabilistic noise due to constant probability of error for each query. However, when we are given a priori, a partitioning of $V$ into clusters of size $\lambda \approx n$ such that the maximum distance between any pair of records in every cluster is smaller than $\alpha$ (a constant), Algorithm 11 can be used to construct the hierarchy correctly. For this case, the algorithm to identify the closest and farthest pair of clusters is same as the one discussed in Section 3.3. Note that agglomerative clustering algorithms are known to require $\Omega(n^2)$ queries, which can be infeasible for million scale datasets. However, blocking based techniques present efficient heuristics to prune out low similarity pairs [44]. Devising provable algorithms with better time complexity is outside the scope of this work.

6 EXPERIMENTS

In this section, we evaluate the effectiveness of our techniques on various real world datasets and answer the following questions. 

Q1: Is quadruplet oracle practically feasible? How do the different types of queries compare in terms of quality and time taken by annotators? 
Q2: Are proposed techniques robust to different levels of noise in oracle answers? 
Q3: How does the query complexity and solution quality of proposed techniques compare with optimum for varied levels of noise?

6.1 Experimental Setup

Datasets. We consider the following real-world datasets.

(1) cities dataset [2] comprises of 36k cities of the United States. The different features of the cities include state, county, zip code, population, time zone, latitude and longitude.

(2) caltech dataset comprises 11.4K images from 20 categories. The ground truth distance between records is calculated using the hierarchical categorization as described in [29].

(3) amazon dataset contains 7K images and textual descriptions collected from amazon.com [31]. For obtaining the ground truth distances we use Amazon’s hierarchical catalog.

(4) monuments dataset comprises of 100 images belonging to 10 tourist locations around the world.

(5) dblp contains 1.8M titles of computer science papers from different areas [60]. From these titles, noun phrases were extracted and a dictionary of all the phrases was constructed. Euclidean distance in word2vec embedding space is considered as the ground truth distance between concepts.

Baselines. We compare our techniques with the optimal solution (whenever possible) and the following baselines. (a) Tour 2 constructs a binary tournament tree over the entire dataset to compare the values and the root node corresponds to the identified maximum/minimum value (Algorithm 2 with $\lambda = 2$). This approach is an adaptation of the finding maximum algorithm in [15] with a difference that each query is not repeated multiple times to increase success probability. We also use them to identify the farthest and nearest point in the greedy k-center Algorithm 6 and closest pair of clusters in hierarchical clustering.

(b) Samp considers a sample of $\sqrt{N}$ records and identifies the farthest/nearest by performing quadratic number of comparisons over the sampled points using COUNT-MAX. For k-center, Samp considers a sample of $k \log n$ points to identify k centers over these samples using the greedy algorithm. It then assigns all the remaining points to the identified centers by querying each record with every pair of centers.

Calculating optimal clustering objective for k-center is NP-hard even in the presence of accurate pairwise distance [59]. So, we compare the solution quality with respect to the greedy algorithm on the ground truth distances, denoted by TDist. For farthest, nearest neighbor and hierarchical clustering, TD1st denotes the optimal technique that has access to ground truth distance between records.

Our algorithm is labelled Far for farthest identification, NN for nearest neighbor, KC for k-center and HC for hierarchical clustering with subscript a denoting the adversarial model and p denoting the probabilistic noise model. All algorithms are implemented in C++ and run on a server with 64GB RAM. The reported results are averaged over 100 randomly chosen iterations. Unless specified, we set $t = 1$ in Algorithm 4 and $y = 2$ in Algorithm 7.

Evaluation Metric. For finding maximum and nearest neighbors, we compare different techniques by evaluating the true distance of the returned solution from the queried points. For k-center, we use the objective value, i.e., maximum radius of the returned clusters as the evaluation metric and compare against the true greedy algorithm (TDist) and other baselines. For datasets where ground truth clusters are known (amazon, caltech and monuments), we use F-score over intra-cluster pairs for comparing it with the baselines [20]. For hierarchical clustering, we compute the pairs of clusters merged in every iteration and compare the average true distance between these clusters. In addition to the quality of returned solution, we compare the query complexity and running time of the proposed techniques with the baselines described above.

Noise Estimation. For cities, amazon, caltech and monuments datasets, we ran a user study on Amazon Mechanical Turk to estimate the noise in oracle answers over a small sample of the dataset,
Figure 4: Accuracy values (denoted by the color of a cell) for different distance ranges observed during our user study. The diagonal entries refer to the quadruplets with similar distance between the corresponding pairs and the distance increases as we go further away from the diagonal.

6.2 User study

In this section, we evaluate the users ability to answer quadruplet queries and compare it with other types of queries.

Setup. We ran a user study on Amazon Mechanical Turk platform for four datasets, cities, amazon, caltech and monuments. We consider the ground truth distance between record pairs and discretize them into buckets, and assign a pair of records to a bucket if the distance falls within its range. For every pair of buckets, we query a random subset of log \( n \) quadruplet oracle queries (where \( n \) is size of dataset). Each query is answered by three different crowd workers and a majority vote is taken as the answer to the query.

6.2.1 Qualitative Analysis of Oracle. In Figure 4, for every pair of buckets, using a heat map, we plot the accuracy of answers obtained from the crowd workers for quadruplet queries. For all datasets, average accuracy of quadruplet queries is more than 0.83 and the accuracy is minimum whenever both pairs of records belong to the same bucket (as low as 0.5). However, we observe varied behavior across datasets as the distance between considered pairs increases.

For the caltech dataset, we observe that when the ratio of the distances is more than 1.45 (indicated by a black line in the Figure 4(a)), there is no noise (or close to zero noise) observed in the query responses. As we observe a sharp decline in noise as the distance between the pairs increases, it suggests that adversarial noise is satisfied for this dataset. We observe a similar pattern for the cities and monuments datasets. For the amazon dataset, we observe that there is substantial noise across all distance ranges (See Figure 4(b)) rather than a sharp decline, suggesting that the probabilistic model is satisfied.

6.2.2 Comparison with pairwise querying mechanisms. To evaluate the benefit of quadruplet queries, we compare the quality of quadruplet comparison oracle answers with the following pairwise oracle query models. (a) Optimal cluster query: This query asks questions of type ‘do \( u \) and \( v \) refer to same/similar type?’ (b) Distance query: How similar are the records \( x \) and \( y \)? In this query, the annotator scores the similarity of the pair within 1 to 10.

We make the following observations. (i) Optimal cluster queries are answered correctly only if the ground truth clusters refer to different entities (each cluster referring to a distinct entity). Crowd workers tend to answer ‘No’ if the pair of records refer to different entities. Therefore, we observe high precision (more than 0.90) but low recall (0.50 on amazon and 0.30 on caltech for \( k = 10 \)) of the returned labels. (ii) We observed very high variance in the distance estimation query responses. For all record pairs with identical entities, the users returned distance estimates that were within 20% of the correct distances. In all other cases, we observe the estimates to have errors of upto 50%. We provide more detailed comparison on the quality of clusters identified by pairwise query responses along with quadruplet queries in the next section.

6.3 Crowd Oracle: Solution Quality & Query Complexity

In this section, we compare the quality of our proposed techniques for the datasets on which we performed the user study. Following the findings of Section 6.2, we use probabilistic model based algorithm for amazon (with \( p = 0.50 \)) and adversarial noise model based algorithm for caltech, monuments and cities.

Finding Max and Farthest/Nearest Neighbor. Figure 5 compares the quality of farthest and nearest neighbor (NN) identified by proposed techniques along with other baselines. The values are normalized according to the maximum value to present all datasets on the same scale. Across all datasets, the point identified by Far and NN is closest to the optimal value, TDist. In contrast, the farthest returned by Tour2 is better than that of Samp for cities dataset but not for caltech, monuments and amazon. We found that this difference in quality across datasets is due to varied distance distribution between pairs. The cities dataset has a skewed distribution of distance between record pairs, leading to a unique optimal solution to the farthest/NN problem. Due to this reason, the set of records sampled by Samp does not contain any record that is a good approximation of the optimal farthest. However, ground truth distances between record pairs in amazon, monuments and caltech are less skewed with more than log \( n \) records satisfying the optimal farthest point for all queries. Therefore, Samp performs better than Tour2.
6.4 Simulated Oracle: Solution Quality & Query Complexity

In this section, we compare the robustness of the techniques where the query response is simulated synthetically for given $\mu$ and $p$.

---

Table 1: F-score comparison of $k$-center clustering. $Oq$ is marked with * as it was computed on a sample of 150 pairwise queries to the crowd. All other techniques were run on the complete dataset using a classifier.

| Datasets | Technique | $kC$ | Tour2 | Samp | $Oq$ |
|----------|-----------|------|-------|------|-----|
| caltech ($k = 10$) | 1 | 0.88 | 0.91 | 0.45 |
| caltech ($k = 15$) | 1 | 0.89 | 0.88 | 0.49 |
| caltech ($k = 20$) | 0.99 | 0.93 | 0.87 | 0.58 |
| monuments ($k = 10$) | 1 | 0.95 | 0.97 | 0.77 |
| amazon ($k = 7$) | 0.96 | 0.74 | 0.57 | 0.48 |
| amazon ($k = 14$) | 0.92 | 0.66 | 0.54 | 0.72 |

---

Figure 8: Comparison of farthest identification techniques for adversarial and probabilistic noise models.

Finding Max and Farthest/Nearest Neighbor. In Figure 8(a), $\mu = 0$ denotes the setting where the oracle answers all queries correctly. In this case, Far and Tour2 identify the optimal solution, but Samp does not identify the optimal solution for cities. In both datasets, Far identifies the correct farthest point for $\mu < 1$. Even with an increase in noise ($\mu$), we observe that the farthest is always within 4 times the optimal distance (See Fig 8(a)). We observe that the quality of farthest identified by Tour2 is close to that of Far for smaller $\mu$ because the optimal farthest point $v_{\text{max}}$ has only a few points in the confusion region $C$ (See Section 3) that contains the points that are close to $v_{\text{max}}$. For e.g., less than 10% are present in $C$ when $\mu = 1$ for cities dataset, i.e., less than 10% points return erroneous answer when compared with $v_{\text{max}}$.

In Figure 8(b), we compare the true distance of the identified farthest points for the case of probabilistic noise with error probability $p$. We observe that $\text{Far}_p$ identifies points with distance values very close to the farthest distance $d_{\text{max}}$, across all data sets and error values. This shows that Far performs significantly better than the theoretical approximation presented in Section 3. On the other hand, the solution returned by Samp is more than 4 times smaller than the value returned by $\text{Far}_p$ for an error probability of 0.3. Tour2 has a similar performance as that of $\text{Far}_p$ for $p \leq 0.1$, but we observe a decline in solution quality for higher noise ($p$) values.
In this paper, we show how algorithms for various basic tasks such as finding maximum, nearest neighbor, k-center clustering, and agglomerative hierarchical clustering can be designed using distance based comparison oracle in presence of noise. We believe that our techniques can be useful for other clustering tasks such as k-means and k-median, and we leave those as future work.

8 FINDING MAXIMUM

Lemma 8.1. (Hoeffding’s Inequality) If $X_1, X_2, \ldots, X_n$ are independent random variables with $a_i \leq X_i \leq b_i$ for all $i \in [n]$, then

$$
\Pr \left[ \left| \sum_i X_i - \mathbb{E}[X_i] \right| \geq ne \right] \leq 2 \exp \left( - \frac{2n^2 e^2}{\sum_i (b_i - a_i)^2} \right)
$$

8.1 Adversarial Noise

Let the maximum value among $V$ be denoted by $v_{\text{max}}$ and the set of records for which the oracle answer can be incorrect is given by

$$
C = \{ u \mid u \in V, u \geq \frac{v_{\text{max}}}{1 + \mu} \}
$$

Claim 8.2. For any partition $V_i$, Tournament($V_i$) uses at most $2|V_i|$ oracle queries.

Proof. Consider the $i$th round in Tournament. We can observe that the number of remaining values is at most $\frac{|V_i|}{2^i}$. So, we make $\frac{|V_i|}{2^i}$ many oracle queries in this round. Total number of oracle queries made is

$$
\sum_{i=0}^{\log n} \frac{|V_i|}{2^i} \leq 2|V_i|
$$

Lemma 8.3. Given a set of values $S$, COUNT-MAX$(S)$ returns a $(1 + \mu)^2$ approximation of maximum value of $S$ using $O(|S|^2)$ oracle queries.

Proof. Let $v_{\text{max}} = \max\{x \in S\}$. Consider a value $w \in S$ such that $w < \frac{v_{\text{max}}}{1 + \mu^2}$. We compare the Count values for $v_{\text{max}}$ and $w$ given by, Count($v_{\text{max}}, S$) = $\sum_{x \in S} 1\{O(v_{\text{max}}, x) = \text{No}\}$ and Count($w, S$) = $\sum_{x \in S} 1\{O(w, x) = \text{No}\}$. We argue that $w$ can never be returned by Algorithm 1, i.e., Count($w, S$) < Count($v_{\text{max}}, S$).

$$
\text{Count}(v_{\text{max}}, S) = \sum_{x \in S} 1\{O(v_{\text{max}}, x) = \text{No}\} \geq \sum_{x \in S \setminus \{v_{\text{max}}\}} 1\{x < v_{\text{max}}/(1 + \mu)\} = 1\{O(v_{\text{max}}, w) = \text{No}\} + \sum_{x \in S \setminus \{v_{\text{max}}\}} 1\{x < v_{\text{max}}/(1 + \mu)\} = 1 + \sum_{x \in S \setminus \{v_{\text{max}}\}} 1\{x < v_{\text{max}}/(1 + \mu)\}
\text{Count}(w, S) = \sum_{y \in S} 1\{O(w, y) = \text{No}\} \leq \sum_{y \in S \setminus \{w\}} 1\{y \leq (1 + \mu)w\} \leq \sum_{y \in S \setminus \{w\}} 1\{y \leq v_{\text{max}}/(1 + \mu)\}
$$

Combining the two, we have:

$$
\text{Count}(v_{\text{max}}, S) > \text{Count}(w, S)
$$

This shows that the Count of $v_{\text{max}}$ is strictly greater than the count of any point $w$ with $w < \frac{v_{\text{max}}}{1 + \mu^2}$. Therefore, our algorithm would have output $v_{\text{max}}$ instead of $w$. For calculating the Count for all values in $S$, we make at most $|S|^2$ oracle queries as we compare every value with every other value. Finally, we output the maximum value as the value with highest Count. Hence, the claim.

Lemma 8.4 (Lemma 3.3 restated). Suppose $v_{\text{max}}$ is the maximum value among the set of records $V$. Algorithm 2 outputs a value $u_{\text{max}}$ such that $u_{\text{max}} \geq \frac{\max_{\text{val}}}{{(1+\mu)^2}}$ using $O(n\lambda)$ oracle queries.

Proof. From Lemma 8.3, we have that we lose a factor of $(1 + \mu)^2$ in each level of the tournament tree, we have that after $\log\lambda n$ levels, the final output will have an approximation guarantee of $(1 + \mu)^2 \log\lambda n$. The total number of queries used is given by $\sum_{i=0}^{\log\lambda n} \frac{|V_i|}{\lambda^2} = O(n\lambda)$ where $V_i$ is the number of records at level $i$.

Lemma 8.5. Suppose $|C| > \sqrt{n}/2$. Let $\tilde{V}$ denote a set of $2\sqrt{n}\log(2/\delta)$ samples obtained by uniform sampling with replacement from $V$. Then, $\tilde{V}$ contains a $(1 + \mu)$ approximation of the maximum value $v_{\text{max}}$ with probability $1 - \delta/2$. 

□
Proof. Consider the first step where we use a uniformly random sample \( \tilde{V} \) of \( \sqrt{n}t = 2\sqrt{n}\log(2/\delta) \) values from \( V \) (obtained by sampling with replacement). Given \( |C| \geq \sqrt{\frac{n}{t}} \), probability that \( \tilde{V} \) contains a value from \( C \) is given by

\[
\Pr[\tilde{V} \cap C \neq \phi] = 1 - \left(1 - \frac{|C|}{n}\right)\frac{|\tilde{V}|}{n} = 1 - \left(1 - \frac{1}{2\sqrt{n}}\right)^{2\sqrt{n}\log(2/\delta)} > 1 - \frac{\delta}{2}
\]

So, with probability \( 1 - \delta/2 \), there exists a value \( u \in C \cap \tilde{V} \). Hence, the claim. \( \square \)

Lemma 8.6. Suppose the partition \( V_i \) contains the maximum value \( u_{\max} \) of \( V \). If \( |C| \leq \sqrt{n}/2 \), then, \( \text{Tournament}(V_i) \) returns \( u_{\max} \) with probability \( 1/2 \).

Proof. Algorithm 4 uses a modified tournament tree that partitions the set \( V \) into \( l = \sqrt{n} \) parts of size \( \frac{n}{l} = \sqrt{n} \) each and identifies a maximum \( \mu_i \) from each partition \( V_i \) using Algorithm 2. If \( u_{\max} \in V_i \), then,

\[
E[|C \cap V_i|] = \frac{|C|}{l} = \frac{\sqrt{n}}{2\sqrt{n}} = \frac{1}{2}
\]

Using Markov’s inequality, the probability that \( V_i \) contains a value from \( C \) is given by :

\[
\Pr[|C \cap V_i| \geq 1] \leq E[|C \cap V_i|] \leq \frac{1}{2}
\]

Therefore, with at least a probability of \( \frac{1}{2} \), \( u_{\max} \) will never be compared with any point from \( C \) in the partition \( V_i \) containing \( u_{\max} \). Hence, \( u_{\max} \) is returned by \( \text{Tournament}(V_i) \) with probability \( 1/2 \).

\( \square \)

Lemma 8.7 (Lemma 3.5 restated). (1) If \( |C| > \sqrt{n}/2 \), then there exists a value \( v_j \in \tilde{V} \) satisfying \( v_j \geq u_{\max}/(1 + \mu) \) with a probability of \( 1 - \delta/2 \).

(2) Suppose \( |C| \leq \sqrt{n}/2 \). Then, \( T \) contains \( u_{\max} \) with a probability at least \( 1 - \delta/2 \).

Proof. Claim (1) follows from Lemma 8.5.

In every iteration \( i \leq t \) of Algorithm 4, we have that \( u_{\max} \in T_i \) with probability \( \frac{1}{2} \) (Using Lemma 8.6). To increase the success probability, we run this procedure \( t \) times and obtain all the outputs. Among the \( t = 2\log(2/\delta) \) runs of Algorithm 2, we have that \( u_{\max} \) is never compared with any value of \( C \) in atleast one of the iterations with a probability at least

\[
1 - (1 - 1/2)^{2\log(2/\delta)} \geq 1 - \frac{\delta}{2}
\]

Hence, \( T = \cup_i T_i \) contains \( u_{\max} \) with a probability \( 1 - \delta/2 \). \( \square \)

Theorem 8.8 (Theorem 3.6 restated). Given a set of values \( V \), Algorithm 4 returns a \( (1 + \mu)^3 \) approximation of maximum value with probability \( 1 - \delta \) using \( O(n\log^2(1/\delta)) \) oracle queries.

Proof. In Algorithm 4, we first identify an approximate maximum value using Sampling. If \( |C| \geq \frac{\sqrt{n}}{2} \), then, from Lemma 8.5, we have that the value returned is a \( (1 + \mu) \) approximation of the maximum value of \( V \). Otherwise, from Lemma 8.7, \( T \) contains \( u_{\max} \) with a probability \( 1 - \delta/2 \). As we use \( \text{Count-Max} \) on the set \( \tilde{V} \cup T \), we know that the value returned, i.e., \( u_{\max} \) is a \( (1 + \mu)^2 \) of the maximum among values from \( \tilde{V} \cup T \). Therefore, \( u_{\max} \geq \frac{u_{\max}}{(1 + \mu)^2} \). Using union bound, the total probability of failure is \( \delta \).

For query complexity, Algorithm 3 obtains a set \( \tilde{V} \) of \( \sqrt{nt} \) sample values. Along with the set \( T \) obtained (where \( |T| = \frac{nt}{l} \)), we use \( \text{Count-Max} \) on \( \tilde{V} \cup T \) to output the maximum \( u_{\max} \). This step requires \( O(|\tilde{V} \cup T|^2) = O((\sqrt{nt} + \frac{nt}{l})^2) \) oracle queries. In an iteration \( i \), for obtaining \( T_i \), we make \( O(\sum_j |V_j|) = O(n) \) oracle queries (Claim 8.2), and for \( t \) iterations, we make \( O(nt) \) queries. Using \( t = 2\log(2/\delta), l = \sqrt{n} \), in total, we make \( O(nt + (\sqrt{nt} + \frac{nt}{l})^2) = O(n\log^2(1/\delta)) \) oracle queries. Hence, the theorem. \( \square \)

### 8.2 Probabilistic Noise

Lemma 8.9. Suppose the maximum value \( u_{\max} \) is returned by Algorithm 2 with parameters \((V, n)\). Then, \( \text{rank}(u_{\max}; V) = O(\sqrt{n\log(1/\delta)}) \) with a probability of \( 1 - \delta \).

Proof. We have for the maximum value \( u_{\max} \), expected count value :

\[
\mathbb{E}[\text{Count}(u_{\max}, V)] = \sum_{w \in V} 1\{O(w, u_{\max}) = w\} = (n - 1)(1 - p)
\]
Using Hoeffding’s inequality, with probability $1 - \delta/2$:

$$\text{Count}(v_{\text{max}}, V) \geq (n - 1)(1 - p) - \sqrt{((n - 1)\log(2/\delta))/2}$$

Consider a record $u \in V$ with rank at most $5\sqrt{2n \log(2/\delta)}$. Then,

$$\mathbb{E}[\text{Count}(u, V)] = \sum_{v \in V} 1\{O(u, v_{\text{max}}) == w\} = (n - \text{rank}(u))(1 - p) + (\text{rank}(u) - 1)p$$

Using Hoeffding’s inequality, with probability $1 - \delta/2$:

$$\text{Count}(u, V) < (n - 1)(1 - p) - (\text{rank}(u) - 1)(1 - 2p) + \sqrt{0.5(n - 1)\log(2/\delta)}$$

$$< (n - 1)(1 - p) - (5\sqrt{2n \log(2/\delta)} - 1)(1 - 2p) + \sqrt{0.5(n - 1)\log(2/\delta)}$$

$$< \text{Count}(v_{\text{max}}, V)$$

The last inequality is true for a value of $p \leq 0.4$. As Algorithm 2 returns the record $v_{\text{max}}$ with maximum $\text{Count}$ value, we have that rank($v_{\text{max}}, V$) = $O(\sqrt{n \log(1/\delta)})$. Using union bound, for the above conditions to be met, we have the claim.

To improve the query complexity, we use an early stopping criteria that discards a value $x$ using the Count$(x, V)$ when it determines that $x$ has no chance of being the maximum. Algorithm 12 presents the pseudocode for this modified count calculation. We sample $100 \log(n/\delta)$ values randomly, denoted by $S_t$ and compare every non-sampled point with $S_t$. We argue that by doing so, it helps us eliminate the values that are far away from the maximum in the sorted ranking. Using Algorithm 12, we compare the Count scores with respect to $S_t$ of a value $u \in V \setminus S_t$ and if Count$(u, S_t) \geq 50 \log(n/\delta)$, we make it available for the subsequent iterations.

**Algorithm 12**

**COUNT-MAX-PROB : Maximum with Probabilistic Noise**

1. **Input**: A set $V$ of $n$ values, failure probability $\delta$.
2. **Output**: An approximate maximum value of $V$
3. $t \leftarrow 1$
4. **while** $t < \log(n)$ or $|V| > 100 \log(n/\delta)$ **do**
5. $S_t$ denote a set of $100 \log(n/\delta)$ values obtained by sampling uniformly at random from $V$ with replacement.
6. Set $X \leftarrow \phi$
7. **for** $u \in V \setminus S_t$ **do**
8. **if** $\text{Count}(u, S_t) \geq 50 \log(n/\delta)$ **then**
9. $X \leftarrow X \cup \{u\}$
10. $V \leftarrow X, t \leftarrow t + 1$
11. $v_{\text{max}} \leftarrow \text{COUNT-MAX}(V)$
12. **return** $v_{\text{max}}$

As Algorithm 12 considers each value $u \in V \setminus S_t$ by iteratively comparing it with each value $x \in S_t$ and the error probability is less than $p$, the expected count of $v_{\text{max}}$ (if it is available) at any iteration $t$ is $(1 - p)|S_t|$. Accounting for the deviation around the expected value, we have that the Count$(v_{\text{max}}, S_t)$ is at least $50 \log(n/\delta)$ when $p \leq 0.4$.

If a particular value $u$ has Count$(u, S_t) < 50 \log(n/\delta)$ in any iteration, i.e., then it can not be the largest value in $V$ and therefore, we remove it from the set of possible candidates for maximum. Therefore, any value that remains in $V$ after an iteration $t$, must have rank closer to that of $v_{\text{max}}$. We argue that after every iteration, the number of candidates remaining is at most $1/60t$ of the possible candidates.

**Lemma 8.10.** In an iteration $t$ containing $n_t$ remaining records, using Algorithm 5, with probability $1 - \delta/n$, we discard at least $50/60 \cdot n_t$ records.

**Proof.** Consider an iteration $t$ which has $n_t$ remaining records. Algorithm 5 and a record $u$ with rank $\alpha \cdot n_t$. Now, we have:

$$\mathbb{E}[\text{Count}(u, S_t)] = ((1 - \alpha)(1 - p) + \alpha p)100 \log(n/\delta)$$

For $\alpha = 0$, i.e., we have for maximum value $v_{\text{max}}$

$$\mathbb{E}[\text{Count}(v_{\text{max}}, S_t)] = (1 - p)100 \log(n/\delta)$$

Using $p \leq 0.4$ and Hoeffding’s inequality, with probability $1 - \delta/n^2$, we have:

$$\text{Count}(v_{\text{max}}, S_t) \geq (1 - p)100 \log(n/\delta) - \sqrt{100 \log(n/\delta)} \geq 50 \log(n/\delta)$$

The constants 50, 100 etc. are not optimized and set just to satisfy certain concentration bounds.
For $u$, we calculate the Count value. Using $p \leq 0.4$ and Hoeffding’s inequality, with probability $1 - \delta/n^2$, we have:

\[
\text{Count}(u, S_t) < ((1 - \alpha)(1 - p) + ap)100 \log(n/\delta) + \sqrt{100((1 - \alpha)(1 - p) + ap)\log(n/\delta)}
\]

\[
< ((1 - 0.6\alpha)100 + \sqrt{100(1 - 0.6\alpha)}\log(n/\delta)) < 50\log(n/\delta)
\]

Upon calculation, for $\alpha > \frac{59}{n^2}$, we have the above expression. Therefore, using union bound, with probability $1 - O(\delta/n)$, all records $u$ with rank at least $\frac{59n}{\delta^2}$ satisfy:

\[
\text{Count}(u, S_t) < \text{Count}(u_{\max}, S_t)
\]

So, all such values can be removed. Hence, the claim.

In the previous lemma, we argued that in every iteration, at least $1/60$th fraction is removed and therefore in $\Theta(\log n)$ iterations, the algorithm will terminate. In each iteration, we discard the sampled values $S_t$ to ensure that there is no dependency between the Count scores, and our guarantees hold. As we remove at most $O(t \cdot \log(n/\delta)) = O(\log^2(n/\delta))$ sampled points, our final statement of the result is:

**Lemma 8.11.** Query complexity of Algorithm 5 is $O(n \cdot \log^2(n/\delta))$ and $u_{\max}$ satisfies $\text{rank}(u_{\max}, V) \leq O(\log^2(n/\delta))$ with probability $1 - \delta$.

**Proof.** From Lemma 8.10, we have with probability $1 - \delta/n$, after iteration $t$, at least $\frac{59n}{\delta^2}$ records removed along with the $100 \log(n/\delta)$ records that are sampled. Therefore, we have:

\[
n_{t+1} \leq n_t - 100 \log(n/\delta)
\]

After $\log(n/\delta)$ iterations, we have $n_{t+1} \leq 1$. As we have removed $\log(n) \cdot \log(n/\delta)$ records that were sampled in total, these could records with rank $\leq 100 \log^2(n/\delta)$. So, the rank of $u_{\max}$ output is at most $100 \log^2(n/\delta)$. In an iteration $t$, the number of oracle queries calculating Count values is $O(n_t \cdot \log(n/\delta))$. In total, Algorithm 5 makes $O(n \log^2(n/\delta))$ oracle queries. Using union bound over $\log(n/\delta)$ iterations, we get a total failure probability of $\delta$. □

**Theorem 8.12 (Theorem 3.7 restated).** There is an algorithm that returns $u_{\max} \in V$ such that $\text{rank}(u_{\max}, V) = O(\log^2(n/\delta))$ with probability $1 - \delta$ and requires $O(n \log^2(n/\delta))$ oracle queries.

**Proof.** The proof follows from Lemma 8.11. □

9 FARthest AND Nearest Neighbor

**Lemma 9.1 (Lemma 3.9 restated).** Suppose $\max_{i \in S} d(u, v_i) \leq \alpha$ and $|S| \geq 6 \log(1/\delta)$. Consider two records $v_i$ and $v_j$ such that $d(u, v_i) < d(u, v_j) - 2\alpha$ then $F\text{Count}(v_i, v_j) \geq 0.3|S|$ with a probability of $1 - \delta$

**Proof.** Since $d(u, v_i) < d(u, v_j) - 2\alpha$, for a point $x \in S$,

\[
d(v_j, x) \geq d(u, v_j) - d(u, x)
\]

\[
> d(u, v_i) + 2\alpha - d(u, x)
\]

\[
\geq d(v_i, x) + 2\alpha - 2d(u, x)
\]

\[
\geq d(v_i, x)
\]

So, $O(v_i, x, v_j, x)$ is $\alpha$ with a probability $p$. As $p \leq 0.4$, we have:

\[
E[F\text{Count}(v_i, v_j)] = (1 - p)|S|
\]

\[
\Pr[F\text{Count}(v_i, v_j) \leq 0.3|S|] \leq \Pr[F\text{Count}(v_i, v_j) \leq (1 - p)|S|/2]
\]

From Hoeffding’s inequality (with binary random variables), we have with a probability $\exp(-\frac{|S|(1-p)^2}{2}) \leq \delta$ (using $|S| \geq 6 \log(1/\delta)$, $p < 0.4$) : $F\text{Count}(v_i, v_j) \leq (1 - p)|S|/2$. Therefore, with probability at most $\delta$, we have, $F\text{Count}(v_i, v_j) \leq 0.3|S|$. □

For the sake of completeness, we restate the Count definition that is used in Algorithm Count-Max. For every oracle comparison, we replace it with the pairwise comparison query described in Section 3.3. Let $u$ be a query point and $S$ denote a set of $\Theta(\log(n/\delta))$ points within a distance of $\alpha$ from $u$. We maintain a Count score for a given point $v_i \in V$ as:

\[
\text{Count}(u, v_i, S, V) = \sum_{v_j \in V \setminus \{v_i\}} 1\{\text{PAIRWISE-COMP}(u, v_i, v_j, S) == \text{No}\}
\]

**Lemma 9.2.** Given a query vertex $u$ and a set $S$ with $|S| = \Omega(\log(n/\delta))$ such that $\max_{v \in S} d(u, v) \leq \alpha$. Then the farthest identified using Algorithm 13 (with $\text{PAIRWISE-COMP}$), denoted by $u_{\max}$ is within $4\alpha$ distance from the optimal farthest point, i.e., $d(u, u_{\max}) \geq \max_{v \in V} d(u, v) - 4\alpha$ with a probability of $1 - \delta$. Further the query complexity is $O(n^2 \log(n/\delta))$. 

Raghavendra Addanki, Sainyam Galhotra, and Barna Saha
Algorithm 13 Count-Max(V): finds the farthest point by counting in V

1: Input: A set of points V, and query point u and a set S.
2: Output: An approximate farthest point from u
3: for v ∈ V do
4:   Calculate Count(u, v, S, V)
5:   \( u_{\text{max}} \leftarrow \arg \max_{v \in S} \text{Count}(u, v, S, V) \)
6: return \( u_{\text{max}} \)

Proof. Let \( u_{\text{max}} = \max_{v \in V} d(u, v) \). Consider a value \( w \in V \) such that \( d(u, w) < d(u, u_{\text{max}}) - 4\alpha \). We compare the Count values for \( u_{\text{max}} \) and \( w \) given by, \( \text{Count}(u, u_{\text{max}}, S, V) = \sum_{v_j \in V \setminus \{u_{\text{max}}\}} 1\{\text{Pairwise-Comp}(u, u_{\text{max}}, v_j, S) == \text{No}\} \) and \( \text{Count}(u, w, S, V) = \sum_{v_j \in V \setminus \{w\}} 1\{\text{Pairwise-Comp}(u, w, v_j, S) == \text{No}\} \). We argue that \( w \) can never be returned by Algorithm 13, i.e., \( \text{Count}(u, w, S, V) < \text{Count}(u, u_{\text{max}}, S, V) \). Using Lemma 9.1 we have:

\[
\text{Count}(u, u_{\text{max}}, S, V) = \sum_{v_j \in V \setminus \{u_{\text{max}}\}} 1\{\text{Pairwise-Comp}(u, u_{\text{max}}, v_j, S) == \text{No}\} \\
\geq \sum_{v_j \in V \setminus \{u_{\text{max}}\}} 1\{d(u, v_j) < d(u, u_{\text{max}}) - 2\alpha\} \\
= 1\{d(u, w) < d(u, u_{\text{max}}) - 2\alpha\} + \sum_{v_j \in V \setminus \{u_{\text{max}}, w\}} 1\{d(u, v_j) < d(u, u_{\text{max}}) - 2\alpha\} \\
= 1 + \sum_{v_j \in V \setminus \{u_{\text{max}}, w\}} 1\{d(u, v_j) < d(u, u_{\text{max}}) - 2\alpha\}
\]

Combining the two, we have:

\[
\text{Count}(u, u_{\text{max}}, S, V) > \text{Count}(u, w, S, V)
\]

This shows that the Count of \( u_{\text{max}} \) is strictly greater than the count of any point \( w \) when \( d(u, w) < d(u, u_{\text{max}}) - 4\alpha \). Therefore, our algorithm would have output \( u_{\text{max}} \) instead of \( w \). For calculating the Count for all points in \( V \), we make at most \(|V|^2 \cdot |S|\) oracle queries as we compare every point with every other point using Algorithm 5. Finally, we output the point \( u_{\text{max}} \) as the value with highest Count. From Lemma 9.1, when \(|S| = \Omega(\log(n/\delta))\), the answer to any pairwise query is correct with a failure probability of \( \delta/n^2 \). As there are \( n^2 \) pairwise comparisons, and each with failure probability of \( \delta/n^2 \), from union bound, we have that that the total failure probability is \( \delta \). Hence, the claim. \( \square \)

Algorithm 14 Tournament: finds the farthest point using a tournament tree

1: Input: Set of values \( V \), Degree \( \lambda \), query point \( u \) and a set \( S \).
2: Output: An approximate farthest point from \( u \)
3: Construct a balanced \( \lambda \)-ary tree \( T \) with \(|V| \) nodes as leaves.
4: Let \( \pi_T \) be a random permutation of \( V \) assigned to leaves of \( T \)
5: for \( i = 1 \) to \( \log_\lambda |V| \) do
6:   for internal node \( w \) at level \( \log_\lambda |V| = i \) do
7:     Let \( U \) denote the children of \( w \).
8:     Set the internal node \( w \) to \( \text{COUNT-MAX}(u, S, U) \)
9:   \( u_{\text{max}} \leftarrow \text{point at root of } T \)
10: return \( u_{\text{max}} \)

Let the farthest point from query point \( u \) among \( V \) be denoted by \( u_{\text{max}} \) and the set of records for which the oracle answer can be incorrect is given by

\[
C = \{v \mid v \in V, d(u, v) \geq d(u, u_{\text{max}}) - 2\alpha\}.
\]
Algorithm 15 Tournament-Partition

1: **Input**: Set of values $V$, number of partitions $l$, query point $u$ and a set $S$.
2: **Output**: A set of farthest points from each partition $V_j$, $V_2, \ldots, V_l$.
3: Randomly partition $V$ into $l$ equal parts $V_1, V_2, \ldots, V_l$.
4: for $i = 1$ to $l$ do
5: $p_i \leftarrow$ Tournament($u, S, V_i, 2$)
6: $T \leftarrow T \cup \{p_i\}$
7: return $T$

Algorithm 16 Max-Prob: Maximum with Probabilistic Noise

1: **Input**: Set of values $V$, number of iterations $t$, query point $u$ and a set $S$.
2: **Output**: An approximate farthest point $u_{\text{max}}$
3: $i \leftarrow 1$, $T \leftarrow \emptyset$
4: Let $\tilde{V}$ denote a sample of size $\sqrt{n}t$ selected uniformly at random (with replacement) from $V$.
5: for $i \leq t$ do
6: $T_i \leftarrow$ Tournament-Partition($u, S, V, I$)
7: $T \leftarrow T \cup T_i$
8: $u_{\text{max}} \leftarrow$ Count-Max($u, S, \tilde{V} \cup T$)
9: return $u_{\text{max}}$

**Lemma 9.3**. 
1. If $|C| > \sqrt{n}/2$, then there exists a value $v_j \in V$ satisfying $d(u, v_j) \geq d(u, v_{\text{max}}) - 2\alpha$ with a probability of $1 - \delta/2$.
2. Suppose $|\tilde{C}| \leq \sqrt{n}/2$. Then, $T$ contains $v_{\text{max}}$ with a probability at least $1 - \delta/2$.

**Proof**. The proof is similar to Lemma 8.7.

**Theorem 9.4** (Theorem 3.10 restated). Given a query vertex $u$ and a set $S$ with $|S| = \Omega(\log(n/\delta))$ such that $\max_{v \in S} d(u, v) \leq \alpha$ then the farthest identified using Algorithm 4 (with PairwiseComp) denoted by $u_{\text{max}}$ is within $6\alpha$ distance from the optimal farthest point, i.e., $d(u, u_{\text{max}}) \geq \max_{v \in V} d(u, v) - 6\alpha$ with a probability of $1 - \delta$. Further the query complexity is $O(n \log^3(n/\delta))$.

**Proof**. The proof is similar to Theorem 8.8. In Algorithm 16, we first identify an approximate maximum value using Sampling. If $|C| \geq \sqrt{n}$, then, from Lemma 9.3, we have that the value returned is a $2\alpha$ additive approximation of the maximum value of $V$. Otherwise, from Lemma 9.3, $T$ contains $v_{\text{max}}$ with a probability $1 - \delta/2$. As we use Count-Max on the set $\tilde{V} \cup T$, we know that the value returned, i.e., $u_{\text{max}}$ is a $4\alpha$ of the maximum among values from $\tilde{V} \cup T$. Therefore, $d(u, u_{\text{max}}) \geq d(u, v_{\text{max}}) - 6\alpha$. Using union bound over $n \cdot t$ comparisons, the total probability of failure is $\delta$.

For query complexity, Algorithm 15 obtains a set $\tilde{V}$ of $\sqrt{n}t$ sample values. Along with the set $T$ obtained (where $|T| = n/2$), we use Count-Max on $\tilde{V} \cup T$ to output the maximum $u_{\text{max}}$. This step requires $O(|\tilde{V} \cup T|^2|S|) = O((\sqrt{n}t + n/2)^2 \log(n/\delta))$ oracle queries. In an iteration $i$, for obtaining $T_i$, we make $O(\sum_j |V_j| \log(n/\delta)) = O(n \log(n/\delta))$ oracle queries (Claim 8.2), and for $t$ iterations, we make $O(n t \log(n/\delta))$ queries. Using $t = 2 \log(2n/\delta), \delta = \sqrt{n}$, in total, we make $O(n t \log(n/\delta)) + (\sqrt{n}t + n/2)^2 \log(n/\delta)) = O(n \log^3(n/\delta))$ oracle queries. Hence, the theorem.

**10 k-CENTER: ADVERSARIAL NOISE**

**Lemma 10.1**. Suppose in an iteration $t$ of Greedy algorithm, centers are given by $S_t$ and we reassign points using Assign which is a $\beta$-approximation to the correct assignment. In iteration $t + 1$, using this assignment, if we obtain an $\alpha$-approximate farthest point using Approx-Farthest, then, after $k$ iterations, Greedy algorithm obtains a $2\beta + 2\alpha$-approximation for the $k$-center objective.

**Proof**. Consider an optimal clustering $C^*$ with centers $u_1, u_2, \ldots, u_k$ respectively: $C^*(u_1), C^*(u_2), \cdots, C^*(u_k)$. Let the centers obtained by Algorithm 6 be denoted by $S$. If $|S \cap C^*(u_j)| = 1$ for all $i$, then, for some point $x \in C^*(u_j)$ assigned to $s_j \in S$ by Algorithm Assign, we have

$$d(x, S \cap C^*(u_j)) \leq d(x, u_j) + d(u_j, S \cap C^*(u_j)) \leq 2\text{OPT}$$

Thus $d(x, s_j) \leq \beta \min_{s \in S} d(x, s) \leq \beta d(x, S \cap C^*(u_j)) \leq 2\beta \text{OPT}$

Therefore, every point in $V$ is at a distance of at most $2\beta \text{OPT}$ from a center assigned in $S$.

Suppose for some $j$ we have $|S \cap C^*(u_j)| \geq 2$. Let $s_1, s_2 \in S \cap C^*(u_j)$ and $s_2$ appeared after $s_1$ in iteration $t + 1$. As $s_1 \in S_t$, we have $\min_{w \in S_t} d(w, s_2) \leq d(s_1, s_2)$. In iteration $t$, we know that the farthest point $s_2$ is an $\alpha$-approximation of the farthest point (say $f_j$). Moreover, suppose $s_2$ assigned to cluster with center $s_h$ in iteration $t$ that is a $\beta$-approximation of it’s true center. Therefore,

$$\frac{1}{\alpha} \min_{w \in S_t} d(w, f_j) \leq d(s_h, s_2) \leq \beta \min_{w \in S_t} d(w, s_2) \leq \beta d(s_1, s_2)$$
Because \(s_1\) and \(s_2\) are in the same optimum cluster, from triangle inequality we have \(d(s_1, s_2) \leq 2OPT\). Combining all the above we get \(\min_{w \in S} d(w, f_i) \leq 2\alpha\beta OPT\) which means that farthest point of iteration \(t\) is at a distance of \(2\alpha\beta OPT\) from \(S_t\). In the subsequent iterations, the distance of any point to the final set of centers, given by \(S\) only gets smaller. Hence, 
\[
\max \min_{v \in S} d(v, w) \leq \min \max_{v \in S} d(v, w) = \min \min_{w \in S} d(f_i, w) \leq 2\alpha\beta OPT
\]
However, when we output the final clusters and centers, the farthest point after \(k\)-iterations (say \(f_k\)) could be assigned to center \(v_j \in S\) that is a \(\beta\)-approximation of the distance to true center.
\[
d(f_k, v_j) \leq \beta \min_{w \in S} d(f_k, w) \leq 2\alpha\beta^2 OPT
\]
Therefore, every point is assigned to a cluster with distance at most \(2\alpha\beta^2 OPT\). Hence the claim. 

**Lemma 10.2.** Given a set \(S\) of centers, Algorithm Assign assigns a point \(u\) to a cluster \(s_j \in S\) such that \(d(u, s_j) \leq (1 + \mu)^2 \min_{s \in S} \{d(u, s_j)\}\) using \(O(nk)\) queries.

**Proof.** The proof is essentially the same as Lemma 8.3 and uses \(\text{MCount}\) instead of \(\text{Count}\).

**Lemma 10.3.** Given a set of centers \(S\), Algorithm 4 identifies a point \(v_j\) with probability \(1 - \delta/k\), such that 
\[
\min_{s_j \in S} d(v_j, s_j) \geq \max_{v \in V} \min_{s_j \in S} \{d(v, s_j)\} \geq (1 + \mu)^3
\]

**Proof.** Suppose \(v_j\) is the farthest point assigned to center \(s_j \in S\). Let \(v_j\), assigned to \(s_j \in S\) be the point returned by Algorithm 4. From Theorem 8.8, we have:
\[
d(v_j, s_j) \geq \frac{\max_{v \in V} d(v, s_j)}{(1 + \mu)^3} \geq \frac{d(v, s_j)}{(1 + \mu)^3} \geq \min_{s_j' \in S} d(v_j, s_j')
\]
Due to error in assignment, using Lemma 10.2
\[
d(v_j, s_j) \leq (1 + \mu)^2 \min_{s_j' \in S} d(v_j, s_j')
\]
Combining the above equations we have
\[
\min_{s_j' \in S} d(v_j, s_j') \geq \frac{\min_{s_j' \in S} d(v_j, s_j')}{(1 + \mu)^3}
\]
For Approx-Farthest, we use \(l = \sqrt{n}\) and \(t = \log(2k/\delta)\) and \(\overline{V} = \sqrt{n}t\). So, following the proof in Theorem 3.6, we succeed with probability \(1 - \delta/k\). Hence, the lemma. 

**Lemma 10.4.** Given a current set of centers \(S\),
(1) Assign assigns a point \(u\) to a cluster \(C(s_j)\) such that \(d(u, s_j) \leq (1 + \mu)^2 \min_{s \in S} \{d(u, s_j)\}\) using \(O(nk)\) oracle queries additionally.
(2) Approx-Farthest identifies a point \(w\) in cluster \(C(s_j)\) such that \(\min_{s_j \in S} d(w, s_j) \geq \max_{v \in V} \min_{s_j \in S} \{d(v, s_j)\}/(1 + \mu)^3\) with probability \(1 - \frac{\delta}{k}\) using \(O(n \log^2 (k/\delta))\) oracle queries.

**Proof.** (1) From Lemma 10.2, we have the claim. We assign a point to a cluster based on the scores the cluster center received in comparison to other centers. Except for the newly created center, we have previously queried every center with every other center. Therefore, number of new oracle queries made for every iteration \(O(k)\); that gives us a total of \(O(nk)\) additional queries used by Assign.

(2) From Lemma 10.3, we have that \(\min_{s_j \in S} d(w, s_j) \geq \max_{v \in V} \min_{s_j \in S} \{d(v, s_j)\}/(1 + \mu)^3\) with probability \(1 - \frac{\delta}{k}\). As the total number of queries made by Algorithm 4 is \(O(nt + (\frac{n}{T} + \sqrt{n}t)^2)\). For Approx-Farthest, we use \(l = \sqrt{n}\) and \(t = \log(2k/\delta)\) and \(\overline{V} = \sqrt{n}t\), therefore, the query complexity is \(O(n \log^2 (k/\delta))\).

**Theorem 10.5 (Theorem 4.2 Restated).** For \(\mu < \frac{1}{\beta}\), Algorithm 6 achieves a \((2 + O(\mu))\)-approximation for the \(k\)-center objective using \(O(nk^2 + nk \cdot \log^2 (k/\delta))\) oracle queries with probability \(1 - \delta\).

**Proof.** From the above discussed claim and Lemma 10.4, we have that Algorithm 6 achieves a \(2(1 + \mu)^3\) approximation for \(k\)-center objective. When \(\mu < \frac{1}{\beta}\), we can simplify the approximation factor to \(2 + 18\mu\), i.e., \(2 + O(\mu)\). From Lemma 10.4, we have that in each iteration, we succeed with probability \(1 - \delta/k\). Using union bound, the failure probability is given by \(\delta\). For query complexity, as there are \(k\) iterations, and in each iteration we use Assign and Approx-Farthest, using Lemma 10.4, we have the theorem.
11 k-CENTER: PROBABILISTIC NOISE

11.1 Sampling

**Lemma 11.1.** Consider the sample \( \overline{V} \subseteq V \) of points obtained by selecting each point with a probability \( \frac{450 \log (n/\delta)}{m} \). Then, we have \( \frac{400 \log(n/\delta)}{m} \leq |\overline{V}| \leq \frac{500 \log (n/\delta)}{m} \) and for every \( i \in [k] \), \( |C^*(s_i) \cap \overline{V}| \geq 400 \log(n/\delta) \) with probability \( 1 - O(\delta) \) for sufficiently large \( \gamma > 0 \).

**Proof.** We include every point in \( \overline{V} \) with a probability \( \frac{450 \log (n/\delta)}{m} \) where the size of the smallest cluster is \( m \). Using Chernoff bound, with probability \( 1 - O(\delta) \), we have:

\[
\frac{400 \log(n/\delta)}{m} \leq |\overline{V}| \leq \frac{500 \log (n/\delta)}{m}
\]

Consider an optimal cluster \( C^*(u_j) \) with center \( u_j \). As every point is included with probability \( \frac{450 \log (n/\delta)}{m} \):

\[
E[|C^*(s_i) \cap \overline{V}|] = |C^*(s_i)| \cdot \frac{450 \log(n/\delta)}{m} \geq 450 \log(n/\delta)
\]

Using Chernoff bound, with probability at least \( 1 - \delta/n \), we have

\[
|C^*(s_i) \cap \overline{V}| \geq 400 \log(n/\delta)
\]

Using union bound for all the \( k \) clusters, we have the lemma. \( \square \)

11.2 Assignment

\[
\text{ACount}(u, s_i, s_j) = \sum_{x \in R(s_i)} 1\{O(u, x, u, s_j) == \text{Yes}\}
\]

**Lemma 11.2.** Consider a point \( u \) and \( s_j \neq s_i \) such that \( d(u, s_i) \leq d(u, s_j) - 2 \text{OPT} \) and \( |R(s_i)| \geq 12 \log(n/\delta) \), then, \( \text{ACount}(u, s_i, s_j) \geq 0.3|R(s_i)| \) with a probability of \( 1 - \frac{\delta}{n^2} \).

**Proof.** Using triangle inequality, for any \( x \in R(s_i) \)

\[
d(u, x) \leq d(u, s_i) + d(s_i, x) \leq d(u, s_j) - 2 \text{OPT} + d(s_i, x) \leq d(u, s_j)
\]

So, \( O(u, x, u, s_j) \) is Yes with a probability at least \( 1 - p \). We have:

\[
E[\text{ACount}(u, s_i, s_j)] = \sum_{x \in R(s_i)} E[1\{O(u, x, u, s_j) == \text{Yes}\}] \geq (1 - p)|R(s_i)|
\]

Using Hoeffding’s inequality, with a probability of \( \exp(-|R(s_i)|(1 - p)^2/2) \leq \frac{\delta}{n^2} \) (using \( p \leq 0.4 \)), we have

\[
\text{ACount}(u, s_i, s_j) \leq (1 - p)|R(s_i)|/2
\]

We have \( \text{Pr}[\text{ACount}(u, s_i, s_j) \leq 0.3|S|] \leq \text{Pr}[\text{ACount}(u, s_i, s_j) \leq (1 - p)|S|/2]. \) Therefore, with probability \( \frac{\delta}{n^2} \), we have \( \text{ACount}(u, s_i, s_j) \leq 0.3|S|. \) Hence, the lemma.

**Lemma 11.3.** Suppose \( u \in C^*(s_i) \) and for some \( s_j \in S \), if \( d(s_i, s_j) \geq 6 \text{OPT} \), then, Algorithm 8 assigns \( u \) to center \( s_i \) with probability \( 1 - \frac{\delta}{n^2} \).

**Proof.** As \( u \in C^*(s_i) \), we have \( d(u, s_i) \leq 2 \text{OPT} \). Therefore,

\[
d(s_j, u) - d(s_i, u) \geq d(s_i, s_j) - 2d(s_i, u) \geq 2 \text{OPT}
\]

\[
d(s_j, u) \geq d(s_i, u) + 2 \text{OPT}
\]

From Lemma 11.2, we have that if \( d(u, s_i) \leq d(u, s_j) - 2 \text{OPT} \), then, we will assign \( u \) to \( s_i \) with probability \( 1 - \frac{\delta}{n^2} \). \( \square \)

**Lemma 11.4.** Given a set of centers \( S \), every \( u \in V \) is assigned to a cluster \( s_i \) such that \( d(u, s_i) \leq \min_{s_j \in S} d(u, s_j) + 2 \text{OPT} \) with a probability of \( 1 - 1/n^2 \).

**Proof.** From Lemma 11.2, we have that a point \( u \) is assigned to \( s_j \) from \( s_m \) if \( d(u, s_i) \leq d(u, s_m) - 2 \text{OPT} \). If \( s_i \) is the final assigned center of \( u \), then, for every \( s_j \), it must be true that \( d(u, s_j) \geq d(u, s_i) - 2 \text{OPT} \), which implies \( d(u, s_i) \leq \min_{s_j \in S} d(u, s_j) + 2 \text{OPT} \). Using union bound over at most \( n \) points, we have with a probability of \( 1 - \frac{\delta}{n^2} \), every point \( u \) is assigned as claimed. \( \square \)
11.3 Core Calculation

Consider a cluster $C(s_i)$ with center $s_i$. Let $S^d(u)$ denote the number of points in the set $\{x : a \leq d(x, s_i) < b\}$.

$$\text{Count}(u) = \sum_{x \in C(s_i)} 1\{O(s_i, x, s_i, u) == \text{No}\}$$

**Lemma 11.5.** Consider any two points $u_1, u_2 \in C(s_i)$ such that $d(u_1, s_i) \leq d(u_2, s_i)$, then $E[\text{Count}(u_1)] - E[\text{Count}(u_2)] = (1 - 2p)S^d(u_2, s_i)$

**Proof.** For a point $u \in C(s_i)$

$$E[\text{Count}(u)] = E\left[\sum_{x \in C(s_i)} 1\{O(s_i, x, s_i, u) == \text{No}\}\right]$$

$$= S^d(u, s_i) + S^\infty\left(d(u, s_i) (1 - p)\right)$$

$$E[\text{Count}(u_1)] - E[\text{Count}(u_2)] = \left(S^d(u_1, s_i) + S^\infty\left(d(u_1, s_i) (1 - p)\right)\right) - \left(S^d(u_2, s_i) + S^\infty\left(d(u_2, s_i) (1 - p)\right)\right)$$

$$= (1 - 2p)S^d(u_2, s_i)$$

**Lemma 11.6.** Consider any two points $u_1, u_2 \in C(s_i)$ such that $d(u_1, s_i) \leq d(u_2, s_i)$ and $|S^d(u_1, s_i)| \geq \sqrt{100|C(s_i)| \log(n/\delta)}$. Then, $\text{Count}(u_1) > \text{Count}(u_2)$ with probability $1 - \delta/n^2$.

**Proof.** Suppose $u_1, u_2 \in C(s_i)$. We have that $\text{Count}(u_1)$ and $\text{Count}(u_2)$ is a sum of $|C(s_i)|$ binary random variables. Using Hoeffding’s inequality, we have with probability $\exp(-\beta^2/2|C(s_i)|)$ that

$$\text{Count}(u_1) \leq E[\text{Count}(u_1)] - \frac{\beta}{2}$$

$$\text{Count}(u_2) > E[\text{Count}(u_2)] + \frac{\beta}{2}$$

Using union bound, with probability at least $1 - 2 \exp(-\beta^2/2|C(s_i)|)$, we can conclude that

$$\text{Count}(u_1) - \text{Count}(u_2) > E[\text{Count}(u_1) - \text{Count}(u_2)] - \beta > (1 - 2p)S^d(u_2, s_i) - \beta$$

Choosing $\beta = (1 - 2p)S^d(u_2, s_i)$, we have $\text{Count}(u_1) > \text{Count}(u_2)$ with a probability (for constant $p \leq 0.4$)

$$1 - 2 \exp(-(1 - 2p)^2(S^d(u_2, s_i)^2)/|C(s_i)|) \geq 1 - 2 \exp(-0.02(S^d(u_2, s_i)^2)/|C(s_i)|)$$

Further, simplifying using $S^d(u_2, s_i) \geq \sqrt{100|C(s_i)| \log(n/\delta)}$, we get probability of failure is $2 \exp(-2 \log(n/\delta)) = O(\delta/n^2)$

**Lemma 11.7.** If $|C(s_i)| \geq 400 \log(n/\delta)$, then, $|R(s_i)| \geq 200 \log(n/\delta)$ with probability $1 - |C(s_i)|^2 \delta/n^2$.

**Proof.** From Lemma 11.6, we have that if there are points $u_1, u_2$ with $\sqrt{100|C(s_i)| \log(n/\delta)}$ many points between them, then, we can identify the cluster one correctly. When $|C(s_i)| \geq 400 \log(n/\delta)$, we have $\sqrt{100|C(s_i)| \log(n/\delta)} \geq 200 \log(n/\delta)$ points between every point and the point with the rank $200 \log(n/\delta)$. Therefore, $|R(s_i)| \geq 200 \log(n/\delta)$. Using union bound over all pairs of points in the cluster, we get the claim.

**Lemma 11.8.** If $x \in C^*(s_i)$, then, $x \in C(s_j)$ or $x$ is assigned to a cluster $s_j$ such that $d(x, s_j) \leq 8 \text{OPT}$.

**Proof.** If $x \in C^*(s_i)$, we argue that it will be assigned to $C(s_i)$. For the sake of contradiction, suppose $x$ is assigned to a cluster $C(s_j)$ for some $s_j \in S$. We have $d(x, s_j) \leq 2 \text{OPT}$ and let $d(s_i, s_j) \geq 6 \text{OPT}$

$$d(s_i, s_j) \leq d(s_j, x) + d(s_i, x)$$

$$d(s_j, x) \geq 4 \text{OPT}$$

However, we know that $d(s_j, x) \leq d(s_j, x) + 2 \text{OPT} \leq 4 \text{OPT}$ from Lemma 11.2. We have a contradiction. Therefore, $x$ is assigned to $s_i$. If $d(s_i, s_j) \leq 6 \text{OPT}$, we have $d(x, s_j) \leq d(x, s_i) + 2 \text{OPT} \leq 8 \text{OPT}$. Hence, the lemma.
11.4 Farthest point computation

Let \( R(s_i) \) represent the core of the cluster \( C(s_i) \) and contains \( \Theta(n/\delta) \) points. We define \( \text{FCount} \) for comparing two points \( v_i, v_j \) from their centers \( s_i, s_j \) respectively. If \( s_i \neq s_j \), we let:

\[
\text{FCount}(v_i, v_j) = \sum_{x \in R(s_i), y \in R(s_j)} 1\{O(v_i, x, v_j, y) = \text{Yes}\}
\]

Otherwise, we let \( \text{FCount}(v_i, v_j) = \sum_{x \in R(s_i)} 1\{O(v_i, x, v_j, x) = \text{Yes}\} \). First, we observe that each of the summation is over \(|R(s_i)|\) many terms, because \(|\mathbf{R}(s_i)| = \sqrt{|R(s_i)|}\).

**Lemma 11.9.** Consider two records \( v_i, v_j \) in different clusters \( C(s_i), C(s_j) \) respectively such that \( d(s_i, v_i) < d(s_j, v_j) - 4\OPT \). Then \( \text{FCount}(v_i, v_j) \geq 0.3|R(s_i)||\mathbf{R}(s_i)| \) with a probability of \( 1 - \frac{\delta}{n^2} \).

**Proof.** We know max \( d(u, v_i) \leq 2\OPT \) and max \( d(v_j, s_j) \leq 2\OPT \). For a point \( x \in R(s_i) \), \( y \in R(s_j) \)

\[
d(v_j, y) \geq d(s_j, v_j) - d(s_j, y) > d(v_i, s_i) + 4\OPT - d(s_j, y) > d(v_i, x) - d(x, s_i) + 4\OPT - d(s_j, y) > d(v_i, x)
\]

So, \( O(v_i, x, v_j, y) = \text{NO} \) with probability \( p \). As \( p \leq 0.4 \), we have:

\[
\Pr[\text{FCount}(v_i, v_j) \leq 0.3|R(s_i)||\mathbf{R}(s_i)|] \leq \Pr[\text{FCount}(v_i, v_j) \leq 0.6p|\mathbf{R}(s_i)|]|\mathbf{R}(s_i)|/2
\]

From Hoeffding’s inequality (with binary random variables), we have with a probability \( \exp(-\frac{|\mathbf{R}(s_i)||\mathbf{R}(s_j)|}{2^2}) \leq \frac{\delta}{n^2} \) (using \(|\mathbf{R}(s_i)||\mathbf{R}(s_j)| \geq 12\log(n/\delta) \), \( p < 0.4 \)). Therefore, with probability at most \( \delta/n^2 \), we have, \( \text{FCount}(v_i, v_j) \leq 0.3|\mathbf{R}(s_i)||\mathbf{R}(s_j)| \).

In order to calculate the farthest point, we use the ideas discussed in Section 3 to identify the point that has the maximum distance from its assigned center. As noted in Section 3.3, our approximation guarantees depend on the maximum distance of points in the core from the center. In the next lemma, we show that assuming a maximum distance of a point in the core (See Lemma 11.8), we can obtain a good approximation for the farthest point.

**Lemma 11.10.** Let max \( d(u, v_i) \leq \alpha \). In every iteration, if the farthest point is at a distance more than \((6\alpha + 3)\OPT\), then, APPROX-FARDEST outputs a \((6\alpha/\OPT + 3)\)-approximation. Otherwise, the point output is at most \((6\alpha + 3)\OPT\) away.

**Proof.** The farthest point output APPROX-FARDEST is a \(6\alpha\) additive approximation. However, the assignment of points to the cluster also introduces another additive approximation of \( 2\OPT \), resulting in a total \( 6\alpha + 2\OPT \) approximation. Suppose in the current iteration, the distance of the farthest point is \( \beta \OPT \), then the point output by APPROX-FARDEST is at least \( \beta \OPT - (6\alpha + 2)\OPT \) away. So, the approximation ratio is \( \frac{\beta \OPT}{\beta \OPT - (6\alpha + 2)\OPT} \). If \( \beta \OPT \geq 6\alpha + 3 \OPT \), we have \( \frac{\beta \OPT}{\beta \OPT - (6\alpha + 2)\OPT} \leq \beta \). As we are trying to minimize the approximation ratio, we set \( \beta \OPT = 6\alpha + 3 \OPT \) and get the claimed guarantee.

11.5 Final Guarantees

Throughout this section, we assume that \( m = \Omega\left(\frac{\log^2(n/\delta)}{\delta}\right) \) for a given failure probability \( \delta > 0 \).

**Lemma 11.11.** Given a current set of centers \( S \), and max \( d(u, v_i) \leq \alpha \), we have:

1. Every point \( u \) is assigned to a cluster \( C(s_j) \) such that \( d(u, s_j) \leq \min_{v_j \in S} d(u, v_j) + 2\OPT \) using \( O(nk \log(n/\delta)) \) oracle queries with probability \( 1 - O(\delta) \).
2. APPROX-FARDEST identifies a point \( w \) in cluster \( C(s_j) \) such that \( \min_{v_j \in S} d(w, v_j) \geq \max_{v_j \in V} \min_{v_j \in S} d(v_j, s_j) / (6\alpha/\OPT + 3) \) with probability \( 1 - O(\delta/\kappa) \) using \( O(|V| \log^2(n/\delta)) \) oracle queries.

**Proof.** (1) First, we argue that cores are calculated correctly. From Lemma 11.3, we have that a point \( u \in C^*(s_i) \) is assigned to the center correctly \( s_i \). Therefore, all the points from \( V \cap C^*(s_i) \) move to \( C(s_i) \). As the size of \( |C(s_i)| \geq |V \cap C^*(s_i)| \geq 400 \log(n/\delta) \), we have \(|R(s_i)| \geq 200 \log(n/\delta) \) with a probability \( 1 - O(C(s_j)/\delta) \) (From Lemma 11.6). Using union bound, we have that all the cores are calculated correctly.
correctly with a failure probability of $\sum_i |C(s_i)|^2 / n^2 = \delta$.

For every point, we compare the distance with every cluster center by maintaining a center that is the current closest. From Lemma 11.2, we have that the query will fail with a probability of $\delta / n^2$. Using union bound, we have that the failure probability is $O(kn\delta / n^2) = \delta$. From Lemma 11.2, we have the approximation guarantee.

(2) From Lemma 11.10, we have our claim regarding the approximation guarantees. For *Approx-Farthest*, we use the parameters $t = 2 \log(2k/\delta)$, $l = \sqrt{|V|}$. As we make $O(|V| \log^2 (k/\delta))$ cluster comparisons using Algorithm ClusterComp (for *Approx-Farthest*), we have that the total number of oracle queries is $O(|V| \log(n/\delta) \log^2(k/\delta)) = O(|V| \log^3(n/\delta))$. Using union bound, we have that the failure probability is $O(\delta/k + |V| \log^2(k/\delta)/n^2) = O(\delta/k)$.

**Theorem 11.12.** [Theorem 4.4 restated] Given $p \leq 0.4$, a failure probability $\delta$, and $m = \Omega\left(\frac{\log^3(n/\delta)}{\delta}\right)$. Then, Algorithm 7 achieves a $O(1)$-approximation for the $k$-center objective using $O(nk \log(n/\delta) + \frac{n^2}{m^2} k \log^2(n/\delta))$ oracle queries with probability $1 - O(\delta)$.

**Proof.** Using similar proof as Lemma 10.1, we have that the approximation ratio of Algorithm 7 is $4(6\alpha/OPT + 3) + 2$. Using $\alpha = 8$ OPT from Lemma 11.11, we have that for all the $k$ iterations, the number of oracle queries is $O(|V| \log^3(n/\delta))$. Using union bound over $k$ iterations, success probability is $1 - O(\delta)$. For the calculation of core, the query complexity is $O(|V| \log^2k)$. For assignment, the query complexity is $O(nk \log(n/\delta))$. Therefore, total query complexity is $O(nk \log(n/\delta) + \frac{n^2}{m^2} k \log^2(n/\delta)) = O(nk \log(n/\delta) + \frac{n^2}{m^2} k \log^2(n/\delta))$. □

12 HIERARCHICAL CLUSTERING

**Lemma 12.1 (Lemma 5.1 restated).** Given a collection of clusters $C = \{C_1, \ldots, C_r\}$, our algorithm to calculate the closest pair (using Algorithm 4) identifies $C_1$ and $C_2$ to merge according to single linkage objective if $d_{SL}(C_2, C_2) \leq (1 + \mu)^3 \min_{C_i, C_j \in C} d(C_i, C_j)$ with $1 - \delta$ probability and requires $O(r^2 \log^2(n/\delta))$ queries.

**Proof.** In each iteration, our algorithm considers a list of $\binom{r}{2}$ distance values and calculates the closest using Algorithm 4. The claim follows from the proof of Theorem 3.6 □

Using the same analysis, we get the following result for complete linkage.

**Lemma 12.2.** Given a collection of clusters $C = \{C_1, \ldots, C_r\}$, our algorithm to calculate the closest pair (using Algorithm 4) identifies $C_1$ and $C_2$ to merge according to complete linkage objective if $d_{SL}(C_2, C_2) \leq (1 + \mu)^3 \min_{C_i, C_j \in C} d(C_i, C_j)$ with $1 - \delta$ probability and requires $O(r^2 \log^2(n/\delta))$ queries.

**Theorem 12.3 (Theorem 5.2 restated).** In any iteration, suppose the distance between a cluster $C_j \in C$ and its identified nearest neighbor $\widetilde{C}_j$ is $\alpha$-approximation of its distance from the optimal nearest neighbor, then the distance between pair of clusters merged by Algorithm 11 is $\alpha(1 + \mu)^3$ approximation of the optimal distance between the closest pair of clusters in $C$ with a probability of $1 - \delta$ using $O(n \log^2(n/\delta))$ oracle queries.

**Proof.** Algorithm 11 iterates over the list of pairs $(C_i, \widetilde{C}_i), \forall C_i \in C$ and identifies the closest pair using Algorithm 4. The claim follows from the proof of Theorem 3.6 □
