Can sub-GeV dark matter coherently scatter on the electrons in the atom?

Ji-Heng Guo, Yu-Xuan Sun, Wenyu Wang, Ke-Yun Wu*

Faculty of Science, Beijing University of Technology, Beijing, China

A novel detection of sub-GeV dark matter is proposed in the paper. The electron cloud is boosted by the dark matter and emits an electron when it is dragged back by the heavy nucleus, namely the coherent scattering of the electron cloud of the atom. The survey in the X-ray diffraction shows that the atomic form factors are much more complex than the naive consideration. The results of the relativistic Hartee-Fock (RHF) method give non-trivial shapes of the atoms. The detailed calculation of the recoil of the electron cloud, the kinetics, the fiducial cross section and the corresponding calculation of detection rate are given analytically. The numerical results show that the limits of the RHF form factors are much stringent than the recoil of a single electron, almost 4 orders stronger, and also gives tight limitations comparing to the Migdal effect below about several hundred MeV. The physical picture and the corresponding results are promising and need further explorations.

I. INTRODUCTION

Observations in cosmology and astrophysics clearly support the presence of dark matter (DM) [1]. Its features, such as mass and interactions are however still unknown. One of the most promising experimental avenues is to search for small energy depositions from the dark matter elastically scattering in sensitive detectors on Earth. An attractive dark matter candidate is Weakly Interacting Massive Particles (WIMPs), which have been explored in various direct detection, indirect detection and collider experiments. The null results have produced very stringent limits on the WIMP-nucleus scattering cross section heavier than 1 GeV. Thus the hunt for sub-GeV dark matter is a hot topic at the cutting edge of physics research. Nevertheless, the sub-GeV dark matter can emerge in some fundamental theory such as the Next-to-Minimal supersymmetry standard model (NMSSM) [2–4]. The self-interaction can be realized between the light dark matter to solve the small structure problems etc [5]. However, as the sensitivity is lost for the light dark matter detection, the traditional strategies for detecting WIMP-type dark matter are no longer feasible. Physicists are striving to create techniques for detecting light dark matter.

Among all the new ways searching for the sub-GeV dark matter, the ionization signal on the detectors could be the most promising one. In the dual-phase Xenon Time Projection Chamber, the Xenon atoms in the Liquid Xenon phase can be ionized due to a collision. Then the ionized electrons drift into the Gaseous Xenon layer at the top of the detector in presence of an external electric field, which produces a proportional scintillation light, namely the S2 signal. In the theoretical studies, such ionization signals can come from the DM-electron scattering [6–17] or the DM-nucleus scattering through the Migdal effect that originates from non-instantaneous movement of electron cloud during a nuclear recoil event [18–35].

In addition to those DM-electron scattering and the Migdal effect on the ionization detection, there is another way which seems to be promising for the search of the light dark matter. As it is well known that the electrons are bounded by the nucleus in an atom form the electron cloud. If the dark matter can collide with the single electron in the atom, it can also collide the whole cloud of the atom too. In fact, this is just the coherent scattering in the dark matter detection. For example, there can be $Z^2$ (charge number) or $A^2$ (atom number) enhancements in the spin-independent detection of the DM-nucleus scattering. As for the detection of the ionization, the question is that does similar coherent enhancement exist in the recoils of the electron. This is not a trivial question since it can be seen in the X-ray diffraction (XRD) on the atom, there do have the coherent scattering of electron cloud from which the atom scattering form factor can be derived. As for the sub-GeV dark matter, the de Broglie wavelength of the dark matter can be sufficiently small to inject into the target atom, the same as the diffraction of the incident X-ray too. The collision can boost the electron cloud to a sizable velocity. After that it can also be dragged back by the static heavy nucleus and throw away an electron to give similar ionization S2 signal. Such a mechanism seems reasonable, or at least should be checked that whether this effect can exist or can be significant for the detection.

In this paper, we will check this novel detection of scattering on the electron cloud to see whether a coherent enhancement exists in the recoils of the electron. As the process is similar to the diffraction of X-ray scattering on
the atom, we will show our understanding in the coherent scattering from the point of the X-ray diffraction at first. Then we will show how to calculate the coherent scattering between dark matter and the electron cloud. After that, the constraints from the current dark matter detection are calculated numerically for the comparison with the results of the DM-electron scattering and the Migdal effect. The paper is organized in the following: the coherent scattering of the electron in an atom are discussed in the sec. II; the calculation methodology for the coherent scattering is given in the sec. III; the numerical results and the comparison with the other strategies are shown in the sec. IV and our conclusion is given in the sec. V.

II. COHERENT SCATTERING OF THE ELECTRON IN AN ATOM

FIG. 1: The three processes which can induce ionization which are the collision between dark matter and single electron, the Migdal effect and the collision between dark matter and the electron cloud of an atom, respectively.

Fig. 1 shows the scattering processes of the electrons when the dark matter collide on the atom in which Fig. 1 (a) shows sketch map of that the dark matter scattering on the single electron and Fig. 1 (b) shows the sketch map of the Migdal effect. Detailed calculation of the first two processes and the comparison between them can be found in Ref. [26]. Here we just list essential points of these two processes:

1. In the recoil of the electron, the dark matter transfers momentum \( q \) directly to the single electron bounded in the atom, giving the ionization electron with recoil energy \( E_e \) and momentum \( k_e \). The impulse approximation\[36\] can be adopted in the theoretical calculation of the rate.

2. For the Migdal effect, the dark matter transfer momentum \( q \) to the nucleus. The momentum transfer happens much faster than the light-crossing time of the electron cloud, thus the nucleus get a sudden "movement" with velocity \( v_A \) which can drag the electron cloud to same velocity and throw away an electron with energy \( E_e \) and momentum \( k_e \). The inner product of the containing phase between the eigenstate wave function at rest and the Galilean transformation of the energy eigenstates of the moving atom gives the amplitude of the throwing rate of electron.

3. The numerical results show that the Migdal effect is always subdominant to the electron scattering when the mediator is light. But it can dominate the ionization for heavy mediator and mass of the dark matter in hundreds of MeV range.

In addition to these two processes, we propose another novel collision between the dark matter and the electron cloud which is formed by the bounded electrons in an atom. The corresponding sketch map of the process is shown in the Fig. 1 (c). The electron cloud is taken as a “ball” composed of the distributed electric charge, of which the amount is the charge number of the corresponding target element. As the mass of the dark matter is at the MeV order, one can simply figure out the de Broglie wavelength of the dark matter is much smaller than the radius of the target atom which is at the order of Bohr radius. Thus the collision between dark matter and the electron cloud can be considered as a collision between a “point” and a “puffy ball” [37, 38]. The corresponding scattering rate is always conveniently calculated in the momentum space, and the Fourier transformation of the charge distribution \( \rho(r) \) gives the form factor \( F(q) \) to account for the coherence of the charge distribution. The whole picture is similar to the diffraction of X-ray scattering on the crystal, thus before going to further exploration the detection of the dark matter, we discuss some essentials of X-ray diffraction.
A. Atomic form factor in XRD

The X-ray diffraction (XRD) is a powerful tool widely used in researches and the industry. While XRD is usually well known for qualitative and quantitative analyses of crystalline phases in materials, far more information can be obtained from a careful analysis of the diffraction patterns or by using specific XRD settings: i.e. characterization of solid solutions, crystallite size and shape, crystal orientation, etc. In XRD analyses, the diffraction of a wave of the characteristic length $\lambda$ is required to be of the same size as the interatomic separation of the crystal. However, XRD are in fact can also detect the inter-structure of a specific atom which is called the small-angle techniques. The sketch map is shown in the Fig. 2. Such small-angle technique, which is also known as the forward scattering in the scattering theory \cite{39}, is a method of the investigation of the non-periodic systems. The physics principles of the scattering are the same for both wide-angle diffraction and the small-angle diffraction, in which the angle-dependent scattering amplitude is related to the electron-density distribution of the scattering by a Fourier transformation. The main difference between wide- and small-angle diffraction in XRD is that we have a periodic arrangement of identical scattering centers (particles) in wide-angle diffraction, while the scattering center are limited in size, non-oriented, and non-periodic, but the number of the particles is high and this can be assumed to be identical of the small-angle diffraction. Thus the small-angle diffraction can give a detailed investigation a single target. There are both coherent and incoherent scattering in the X-ray diffraction. For the scattering on a single electron they are called Rayleigh scattering and Compton scattering, respectively. As shown in the Fig. 2, the momentum transfer $q$ to the electron can be easily derived from the small-angle deviation from the incident X-ray, thus the parameter $\sin \theta/\lambda$ are always adopted for the description of the form factor in the momentum space with the relation

$$\frac{\sin \theta}{\lambda} = \frac{q}{4\pi}.$$  \hspace{1cm} (1)

The summation of all the electrons gives the atomic scattering form factor

$$F(q) = \sum_{j}^{Z} f_{j} = \sum_{j}^{Z} \int \rho(r_{j}) \exp{(q \cdot r_{j})} dr_{j}.$$ \hspace{1cm} (2)

For the scattering by the atomic electrons, the phase of coherent scattering is by convention related to that of the a free electron at the nucleus. There is a phase shift of $\pi$ for scattering from a free electron. And the coherent scattering in the XRD is \cite{40}

$$I_{coh} = I_{e} (F(q))^{2}.$$ \hspace{1cm} (3)

In above equation, $I_{e}$ is the intensity of the scattering per unit solid angle, it is calculated from the Thomson formula

$$I_{e} = I_{0} r_{e}^{2} \left[ \frac{1 + 2 \cos^{2} \theta}{2} \right],$$ \hspace{1cm} (4)

in which $I_{0}$ is the intensity of the unpolarized incident beam and $r_{e}$ is the classical radius of the electron ($2.818 \times 10^{-15}$m). Note that $I_{e}$ and $I_{0}$ have different dimensions. Another issue should be mentioned is that the momentum...
of the incident X-ray $Q$ is much greater than the momentum transfer $q$. This means that the wavelength of incident X-ray are much smaller than the inverse momentum transfer, $\lambda_X \ll 1/q$. Thus above calculations are reliable in case of the wavelength of the X-ray larger than the classical radius of the electron, no matter how large the atom is. This is the key point of the understanding of the XRD which can be simply applied to the scattering of the dark matter. The details are talked in the next section.

It is usually considered as a common sense that the atomic form factor $F(q)$ could be described by a function equals the charge number $Z$ at zero momentum transfer and roughly decrease with the multiplicative inverse of the atom radius quickly. However, things are contrary to the usual expectation. For the Hydrogen atom, $F(q)$ can be got analytically by solving the Schrödinger equation, it is effectively zero for $\sin \theta/\lambda > 1.5 \text{Å}^{-1}$. Those for heavier atoms are for relativistic wavefunctions which can be calculated by Relativistic Hartree-Fock (RHF) method of which the details can be found in Refs. [41, 42] and all the results are summarized and listed in Ref. [40]. Note that the RHF form factor is used for searching for Axion dark matter in inverse Primakoff scattering [43] and in [44] trying to find observing atomic effects in coherent neutrino scattering. Usually, the form factor can be effectively described by “Gaussian” fits in the range $0 \text{Å}^{-1} < (\sin \theta)/\lambda < 2.0 \text{Å}^{-1}$

$$f(\sin \theta/\lambda) = \sum_{i=1}^{4} a_i \exp \left( -b_i \sin^2 \theta/\lambda^2 \right) + c.$$  

Take Xenon atom as an example, the fit parameters in above equation are $a_1 = 20.2933$, $b_1 = 3.9282$; $a_2 = 19.0298$, $b_2 = 0.344$; $a_3 = 8.9767$, $b_3 = 26.4659$; $a_4 = 1.99$, $b_4 = 64.2658$; $c = 3.7118$. But as the angle increases to $2.0 \text{Å}^{-1} < (\sin \theta)/\lambda < 6.0 \text{Å}^{-1}$, Ref. [45] shows that the fitting formula above is highly inaccurate, as the scattering angle increasing, and they produced a “logarithmic polynomial” curve-fitting routine based on the equation

$$\ln\{f(\sin \theta/\lambda)\} = \sum_{i=0}^{3} c_i s^i,$$  

for these high angles. Also take Xenon atom as an example, the $c_i$ values are $c_0 = 4.24610$, $c_1 = -1.56330$, $c_2 = 3.04200$, $c_3 = -2.34290$ give a close fit to the atomic scattering factor curves over the range and the correlation coefficient is 0.999.
In order to show the differences, we show the form factor $F(q)$ for Hydrogen, Germanium and Xenon atoms in Fig. 3, in which the Hydrogen form factor is calculated analytically from Schrödinger Equation, and the other two are calculated by RHF. The corresponding momentum of inverse Bohr radius $1/a_0$ is shown in dash vertical line in the panel. Note that all the form factors are normalized to 1 at zero momentum transfer $q = 0$ for the comparison. The form factor of Hydrogen is a “Dipole” form, and it decreases with the momentum transfer $q$ outside $1/a_0$ very quickly. As for the Germanium (125pm) [46] and Xenon (108pm) of which the radii are at the order of Bohr radius, contrary to the common sense, the $F(q)$ does not decrease at the border of inverse radius. They can maintain a sufficiently large value to the much larger $q \gg 1/a_0$. This is very important point of this work, the large $F(q)$ at the large momentum transfer can significantly enhance the rate of the recoils of the electron cloud. Before going to the detail, we show other atomic form factor in the literature.

B. Other Atomic Form factors

In addition to RHF atomic form factor in XRD, there are several other form factors applied in different physical circumstances. The first one is the screened Coulomb form factor which is usually used for the detection of the Axion dark matter [43]. This form factor is defined for the atom of which the positive charge of the nucleus in the atom center is screened by the electron cloud [47–49], forming a Yukawa potential

$$\phi(r) = \frac{Q}{4\pi r} e^{-r/r_0},$$

(6)

where $Q$ is the atomic charge, $r_0$ is the screening length. In fact, Eq. (6) is the electrostatic potential of the atom. Using Poisson’s equation $\nabla^2 \phi = -\rho$, we can get the charge density distributions outside the nucleus. Note that the potential (6) is formed by the positive charge of the nucleus in the atom center ($\delta(r)$ function density) and the negative charge of the electrons outside. Thus remove the delta function charge distribution and do the Fourier transformation, we can obtain electron density distribution in the momentum space, namely the form factor

$$F(q) = \frac{1}{1 + q^2 r_0^2}.$$  

(7)

For the Xenon atom, there are two results of the screening length used in the literature: $r_0 = 0.49\text{Å}$ is calculated in Ref. [50], $r_0 = 2.45\text{Å}$ is taken as the Wigner-Seitz radius in liquid Xenon [51].

As the inner structure of the electron cloud are rather compound, there are three kinds of simple shapes, which are called “Tophat”, “Dipole” and “Gaussian”, respectively. Those shapes are always used for the first exploration of the sized atom. The corresponding charge distribution $\rho(r)$, root-mean-square radius $r_{\text{Atom}}$ and the form factor $F(q)$ are shown in following table

| Shape   | $\rho(r)$                     | $r_{\text{Atom}}$ | $F(q)$       |
|---------|--------------------------------|-------------------|--------------|
| Tophat  | $\frac{3}{4\pi r_0^3} \theta(r_0 - r)$ | $\sqrt{3/5} r_0$ | $\frac{3\sin(\pi q r_0) - \pi q r_0 \cos(\pi q r_0)}{r_0 q^2}$ |
| Dipole  | $\frac{e^{-r/r_0}}{8\pi r_0}$ | $2\sqrt{3} r_0$ | $1 / (1 + r_0^2 q^2)$ |
| Gaussian| $\frac{1}{8\pi^3 r_0^3} e^{-r^2/(4r_0^2)}$ | $\sqrt{6} r_0$ | $e^{-r_0^2 q^2}$ |

$r_0$ in the table is always chosen as the radius of the atom. As talked above, the form factor of the ground state of the Hydrogen atom is a Dipole form. The Helm form factor, which is always used to describe the nucleon shape [52], is in fact a Tophat form. These three kinds of form factors are also used in the puffy dark matter scenario to realize the required velocity dependence in the small cosmological scale [37, 38].

The RHF form factor used in XRD differs from the form factors shown in this subsection greatly. We show the corresponding form factor $F(q)$ from RHF result together with the screened Coulomb (SC) potential, Tophat shape etc. for Xenon atom in the Fig. 4. Note that the radius $r_0$ for the Tophat, Dipole and Gaussian shapes is chosen as $\sim 2a_0$ which is got from Ref. [46]. The two $r_0$ for the SC form factors shown in the figure are tagged with “SC0.49” and “SC2.45”, respectively. The orange shade in Fig. 4 shows the interval of momentum transfer $q$ for the detection of light dark matter which will be discussed in the next section. Another thing should be mentioned is that, the Tophat model describes a homogeneous charge distribution within a sphere of radius $r_0$. We can see from the Fig. 4 and the analytical formula that $F(q)$ oscillate around zero from an appropriate $q$. It means that the charge distribution in the momentum space can be negative. This implies that the incident particle can feel an opposite charge of electron cloud in case of a specific momentum transfer. This is a special phenomenon in the effective scattering theory.
From Fig. 4, we can see that the factors of the ordinary shapes quickly decrease to zero when $q$ is greater than the inverse Bohr radius $\sim 4\text{KeV}$. Only the RHF form factor can maintain a large value to a much larger momentum. As discussed in Ref. [43], the electrostatic potential cannot be expressed in a simple form Eq. (6), SC form factor Eq. (7) is not the suitable factor either. RHF form factor are more reliable for the realistic applications. This implies that the atoms like Xenon have non-trivial shapes for the electron outside the nuclei. $F(q)$ plays a very important role in the scattering on the electrons in an atom. The slowly decreasing behavior of the RHF form factor can make the electrons recoils coherently, thus the cloud can receive a large momentum transfer $q$ from the incident particles. This is contrary to the common sense that the cloud only receive the momentum transfer $q$ at the order of the inverse radius of the atom. Thus the coherent scattering and incoherent scattering are discussed in the following subsection.

C. Coherent and incoherent scattering

In order to figure out whether coherently scattering can happen for the electron cloud, here we briefly review on the differences between coherent scattering and incoherent scattering [52, 53]. When an incoming plane wave incident on a radially symmetric potential, the outgoing wave state can be written as

$$ S|p\rangle = |p\rangle + \int \! d^3p' \delta(E_p - E_p') M(p, p') |p'\rangle. $$

Here $M(p, p')$ is the scattering matrix elements and $S$ is the usual S-matrix. If the target is composed of $N$ identical potentials, and each potential is displaced away from the origin to some location $x_i \neq 0$, S-matrix for each potential will be transformed by a unitary matrix $U = \exp(-i x_i \cdot p)$. Then the plane wave scatters to

$$ |p\rangle \rightarrow U S U^\dagger |p\rangle = |p\rangle + \int \! d^3p' \delta(E_p - E_p') e^{-i x_i \cdot q} M(p, p') |p'\rangle, $$

where the momentum transfer is $q = p' - p$. To the lowest order in the perturbation theory, the final state of the scattering is given by summing over all the amplitudes

$$ |p\rangle \rightarrow |p\rangle + \sum_{i=1}^N \int \! d^3p' \delta(E_p - E_p') e^{-i x_i \cdot q} M(p, p') |p'\rangle, $$

where $\delta(E_p - E_p')$ is the Dirac delta function.
Therefore the probability of the momentum state $|p'\rangle$ in the final state is proportional to

$$P(p') \propto |\langle p' |\psi \rangle|^2 \propto \sum_{ij} \langle e^{-i\Delta x_{ij} \cdot q} \rangle |M(p,p')|^2,$$

where $\Delta x_{ij} = x_i - x_j$. The expectation value is taken over the N-body internal state of the target. The circumstance is similar to the light diffraction which occurs only when the slit is physically the approximate size of, or even smaller than that light’s wavelength. For the N-body target, only when the momentum transfer is smaller than the inverse spacing between the potentials, i.e. $\Delta x_{ij} \cdot q < 1$ for all $i,j$, that every phase in the sum is approximately the same, the scattering will be enhanced coherently. If the spacing are too large, that only $\sum_i$ in Eq. (11) can survive. Then the incident particle scattering on the each target separately, which is incoherent scattering.

$$\text{FIG. 5: Charge distribution of } \rho(r) \text{ of Xenon, calculated by the Fourier transformation of RHF } f(q) \text{ (red solid line) and a "Tophat" model (blue dot line) in momentum space that } F(q) = \theta(q_0 - q) \text{ with } q_0 = 25\text{KeV. The dash line shows the position of Bohr radius.}$$

From the argument above, we can see that the coherence depends on the space scale. As for the electrons in an atom, whether they can behave as a compact ball at a specific momentum transfer $q$ depends on the space scale where the electron cloud locates. Naively thinking, the scale would be the radius of the atom. However, as shown in last subsection, real electron clouds outside the nuclei have non-trivial shapes. The RHF form factor $F(q)$ does not vanish outside the inverse radius of the atom, but decreases slowly with the momentum transfer $q$. In order to show the subtlety, we choose a simple form factor $F(q)$

$$F(q) = \theta(q_0 - q),$$

which is a homogeneous charge distribution in the momentum space. $q_0$ is the border of the distribution, and it is also the typical decreasing point of $F(q)$. In fact this is just a “Tophat” shape in the momentum space. Obviously the $F(q)$ decreases to zero at $q = q_0$ in this kind of distribution. However, the root-mean-square radius is not at the order of $1/q_0$. This can be derived from the shape of the charge distribution in coordinate space which is similar

$$\rho(r) = \frac{\sin(q_0 r) - q_0 r \cos(q_0 r)}{2\pi^2 r^3}.$$
quickly outside the typical inverse momentum $1/q_0$ in the Tophat model, while the distribution of the RHF is similar. However, this does not conflict with the measured radius of the atom. We can see that the charge density can maintain the oscillating behavior to the large radius. One can easily check that the root-mean-square radii in both cases are oscillating divergent functions. The results imply that the charge is dominantly located in a very small region near the center of the atom. The requirement of the coherent scattering $\Delta x_{ij} \cdot q < 1$ can be satisfied. Thus the electrons form a compact ball which can receive large momentum transfer $q$ and behave like a single particle. Then the non-trivial shape can make the form factor much different from the ordinary consideration.

From the Fig. 4, we can see that Xenon RHF form factor $F(q) \sim 0.2$ at $q = 50$KeV. The physics picture for the X-ray diffraction on this momentum transfer is that the momentum transfer $q$ is much larger than inverse atom radius $1/r_0$. Since it is a small angle (forward) scattering $Q \gg q$, the wavelength of X-ray is much smaller than the radius of the atom. This means that a much smaller X-ray photon which can inject into the interior of the atom, can still transfer a much larger momentum to the whole atom and strongly interact with it. Whether such physics picture can happen in case of an incident dark matter? This will be discussed in the next section.

III. RECOIL OF THE ELECTRON CLOUD AND ITS IONIZATION

Compare to the XRd, the key difference in the scattering between the dark matter and the atom may be that the incident particle is massive and slowly moving. However, our focus is the sub-GeV dark matter with a velocity as several hundred kilometers per second $\mathcal{O}(10^{-3}c)$. Then the de Broglie wave length for the dark matter lighter than $100$ MeV can be much larger than the classical radius of the electron. If the interaction between the dark matter and electron is compact, the time scale of the momentum transfer will also be much quicker than the light-crossing time of the electron cloud. The only problem is that the light-crossing time of the slowly moving dark matter is much longer than the X-ray, then non-trivial collision may happen. However, the whole picture is that whether the electron cloud can react as a compact ball in the collision process. Fig. 4 shows that such compactness can only maintain at a much smaller momentum transfer regime $q < 1/r_0$ for the ordinary Tophat, Dipole, Gaussian or the SC shapes. But the RHF results show that the compactness could be reliable to a much larger $q$. If the compactness maintains, the longer collision time implies the collision can be considered as to have higher order contributions from the loop diagram, thus the amplitude must be at sub-leading order. In all, the collision between the dark matter and the electron electron cloud is analogous to the XRd scattering. The collision between dark matter and the electron can transfer a much larger momentum to the whole electron cloud. The RHF form factor $F(q)$ could be used for the estimation of the momentum transfer and the cross section. In the following, we will give a detailed study on this recoil of electron cloud (REC) to see whether such estimation is suitable for the exploration of the dark matter.

In order to compare the Electron ionization via of both the Migdal effect and recoil of a single electron, Ref. [26] proposed the simple $U(1)$ extension model of the dark matter which is consist of a dark matter candidate $\chi$ and dark photon $A'$. The $A'$ kinetically mixes with the visible photon. In the work, electron ionization from REC is calculated and compared with the other two processes. Thus the corresponding calculation schemes, such as the Lagrangian, kinetics and dynamics, are similar. We just give some essential points and differences between Ref. [26]. Detailed calculation can be from Ref. [26] and the references within. First, the physical quantity for the comparison is denoted as

$$\bar{\sigma}_e = \frac{16\pi^2 \alpha_D \mu_{\chi e}^2}{(m_{A'}^2 + |q_0|^2)^2}. \quad (14)$$

It is the fiducial DM-free electron scattering cross section at fixed momentum transfer $q_0 = \alpha m_e$, from which $\mu_{\chi e}$ is the reduced mass of the $\chi - e$ system. Next, we show the kinetics of the REC and compare it with the Migdal effect and recoil of a single electron. In all these three processes, the incoming and outgoing states are the same: a dark matter particle plus a bound atom and a dark matter particle plus an ionized atom plus an unbound electron, respectively. The incoming dark matter is assumed to be a plane wave, which is both an energy eigenstate and a momentum eigenstate. The incoming atom (at rest in the lab frame) is an energy eigenstate and a momentum eigenstate too. The outgoing dark matter is also a plane wave, and the outgoing atom is in an excited state where the ionized electron belongs to the continuum spectrum of the atomic Hamiltonian. Consider the scattering process of a dark matter particle hitting electron clouds of Z electrons outside the entire nucleus, for the dark matter particle with mass $m_{\chi}$, incoming velocity $v$, and outgoing momentum $p'_{\chi}$, momentum conservation requires

$$q \equiv m_{\chi} v - p'_{\chi} \simeq Z m_e v_c. \quad (15)$$

Note that the recoil energy of the ionized electron is always negligible compared with the momentum transfer. The
energy conservation requires the ionized electron get

\[ E_{c,f} - E_{c,i} = \Delta E_c = \frac{1}{2} m_v v^2 - \frac{|m_v v - q|}{2 m_v} - \frac{q^2}{2 Z m_e} = q \cdot v - \frac{q^2}{2 \mu_{\chi_C}}, \]  

(16)

where \( \mu_{\chi_C} = Z m_e m_\chi / (Z m_e + m_\chi) \) is the DM-Cloud reduced mass.

The kinematics of the Migdal effect, single electron and REC scattering are similar, however, the dynamics differ from each other. They depend on the interacting objects, in other words, on which target the momentum are transferred to, the nucleus, electron or the electron cloud. The interaction term in the perturbation Hamiltonian of the collision between the dark matter and electron cloud with \( Ze \) is

\[ H_{\text{int, } C} = - \int \frac{d^3 q e^{i q \cdot (-x_\chi + x_e)} M_{\chi C}(q)}{4 m_\chi Ze}, \]  

(17)

where \( x_\chi \) is the charge distribution position of the electron cloud and \( M_{\chi C} \) is the Lorentz-invariant matrix element for dark matter scattering off electron clouds through 4-momentum transfer \( q \approx (0, q) \). Note that the phase of the charge distribution position \( e^{i q \cdot (-x_\chi + x_e)} \) is similar to the phase in Eq. (11) discussed in above section. Comparing with the recoil of a single electron, what we only need to do is replacing the corresponding reduced mass and interaction, etc. As the total charge of the electron cloud is \( Z \), it is obvious that the \( M_{\chi C} \) can be reduced to a similar interaction as the recoil of a single electron

\[ |M_{\chi C}|^2 = Z^2 |F_C(q)|^2 |M_{\chi e}|^2, \]  

(18)
in which \( F_C(q) \) is the normalized form factor talked in above section. Thus the same reduced cross section \( \bar{\sigma}_e \) can be defined to evaluate both recoils of the single electron and the cloud. In fact this is the usual way to do the comparison between detection strategies and the target, i.e. \( \sigma_{\text{SI}} \) spin-independent cross section for different target nuclei. Note that RHF electron cloud form factor for DM-electron-cloud scattering is used here. The reason for this is that the kinetic mixing between the dark and visible \( U(1) \) gauge field implies that the interactions between the massive dark photon \( A' \) and standard model fermion are proportional to visible \( U(1) \) charge. Thus same form factor can be used as shown in Ref. [43].

After the cloud are suddenly boosted to specific velocity \( v_C \), it will be dragged by the static nucleus and throw away an ionized electron. As talked in above section, it is in fact a similar Migdal effect but happens in different Galilean frame. Thus the Rate of dragging back can be written in similar formula

\[ R_C \propto |\langle \Psi_f | \Psi_{v_C} \rangle|^2 \sim |\langle \psi_f | e^{i q e \cdot x} | \psi_i \rangle|^2, \]  

(19)

where \( \Psi_{v_C} \) and \( \Psi_f \) are the initial and final states of the wave function of an electron cloud, and they are the single-electron states wave functions. However, being different with the Migdal effect, \( \Psi_{v_C} \) is the cloud with a velocity \( v_C \), and the \( \Psi_f \) is the final state of the almost static atom.

\[ q_c = m_e v_C = \frac{q}{Z}. \]  

(20)
The reason of this estimation is that a compact ball for the electron cloud are adopted in the whole picture, all the electrons in the cloud will move at the same velocity. Note that, though a similar \( q_c \) is using in both Migdal effect and REC, the \( q_c \) in Migdal effect is \( q_c \simeq m_e \frac{m}{m + m_e} q \), which is much smaller than \( q_c \) in Eq. (20), and this will make the phenomenology much different between the two processes. The detail will be discussed in the next section.

The calculation of the ionization rate in REC is also similar to Migdal effect and recoil of single electron. We need to integrate over the momentum transfer \( q \) and the dark matter velocity \( v \), sum over the final electronic states \( \Psi_f \) weighted by a delta function enforcing energy conservation. The specific normalization method of summation of final states can be found in Ref. [26].

As talked above, the reduced cross section \( \bar{\sigma}_e \) is adopted of the calculation of the scattering rate. In fact, the cross section is proposed under the impulse approximation which is related to the free-particle scattering matrix element as the electron recoil spectrum per unit detector mass. The scattering of the dark matter with a single electron can treat the target recoil as single-particle states of an isolated atom, described by numerical RHF bound wave functions. The velocity-averaged differential ionization cross section for electrons in the \((n,l)\) shell.

\[ \frac{d \langle \sigma_{\text{ion}}^{n,l} \rangle}{d \ln E_c} = \frac{\bar{\sigma}_e}{8 \mu_{\chi_C}^2} \times \int q dq |f_{\text{ion}}^{n,l}(k_e, q)|^2 |F_{DM}(q)|^2 \eta(v_{\text{min}}), \]  

(21)
where $\eta(v_{\text{min}}) = \langle \frac{1}{\theta(v - v_{\text{min}})} \rangle$ is the inverse mean speed for a given velocity distribution as a function of the minimum velocity. $v_{\text{min}}$ is the minimum velocity required for scattering. It can be solved by the delta function for energy conservation, going straight forward to get

$$v_{\text{min}} = \frac{|E_{nl}| + E_e}{|q|} + \frac{|q|}{2\mu_C}.$$  

(22)

We assume a standard Maxwell-Boltzmann velocity distribution with circular velocity $v_0 = 220\text{km/s}$ and a hard cutoff $v_{\text{esc}} = 544\text{km/s}$. The $q$-dependence of the matrix element is encoded in the dark matter form-factor $F_{DM}(q)$. The differential ionization rate is written as

$$\frac{dR_{\text{ion}}}{d \ln E_e} = N_T \rho_\chi \sum_{n,l} \langle \sigma_{nl}^{\text{ion}} v \rangle \frac{d}{d \ln E_e},$$  

(23)

where $N_T$ is the number of target atoms and $\rho_\chi = 0.4\text{GeV/cm}^3$ is the local dark matter density.

The key differences between the REC and the other two processes entirely hide in the ionization form factors, which are independent of all dark matter properties and depend only on the electronic and nuclear structure of the target. For coherent electron clouds scattering, the analogous ionization form factor is

$$|f_{\text{ion}, e}(E_e, q)|^2 = \frac{k^3}{4\pi^3} Z^2 |F_C(q)|^2 \times 2 \sum_{n,l,l',n'} \left| \langle \psi_{E_{nl}}^f | e^{iq_e \cdot x} | \psi_{E_{nl'}}^i \rangle \right|^2.$$  

(24)

The other two ionization form factor can be found in Ref. [26]. First there is an additional $Z^2$ factor compared with the factor of the recoil of a single electron. This is similar to the coherent enhancement in spin-independent scattering of the nucleus. Another point is that $q_e$ in REC will be much larger than the $q_e$ in Migdal effect.

The numerical calculation of the ionization factor for the Xenon atom can be found in Ref. [26]. Here we chose $m_\chi = 300\text{MeV}$, $E_e = 10\text{eV}$ and $F_{DM} = 1$ and show the differences between the three processes in the Fig. 6. In order to show the importance of the RHF electron cloud form factor, the results of the Tophat shape and SC0.49 are also shown in the figure. The interval of $q$ is just the shaded region in the Fig. 4. From Fig. 6, we can see that, the RHF form factor gives a much larger ionization form factor than the Migdal effect and the recoil of a single electron.
However, the ionization factor of the Tophat shape and the screened Coulomb potential are much smaller than the recoil of the electron. These two factors can be at the same level with the Migdal effect. As we concern, these two models coarsely depict the electron coherent scattering, which are used only as references. The key point is that REC could dominate the ionization if we take the RHF form factor seriously. Another three points should be addressed:

1. As shown in the Fig. 6, $|f_{\text{ion}, e}|^2$ decreases quickly with the $q$, thus the rate of recoil of a single electron is dominated by small $q$ region.

2. $|f_{\text{ion}, M}|^2$ increases with the growing of $q$, thus the rate is dominated by large $q$ region. Nevertheless, as the $m_\chi$ we considered is much lighter than the mass of the nucleus, the reduced mass of the collision mainly proportional to $m_\chi$. Since $q_e$ in this effect are much smaller than $q$, the ionization factor does not feel any suppression factor in the region of the integration.

3. The above two items are already addressed in Ref. [26], the RHF $|f_{\text{ion}, C}|^2$ is larger than the other two ionization factors. However, the upper limit of $q$ is

$$q_{\text{max}} = 2\mu_\chi c v_{\text{max}} \simeq 127.43 \text{KeV},$$

for a dark matter much heavier than the mass of the Xenon cloud. Note that $v_{\text{max}}$ is taken as usual 770km/s in above equation.

With these ionization form factors, we can calculate the scattering rate and get the limits on the scattering cross section which will be discussed in the next section.

IV. NUMERICAL LIMITS FROM THE EXPERIMENTAL DETECTION

Following the procedure in Ref. [7], we numerically calculate the limits on the spin-independent scattering cross section from the experimental XENON100 data [54, 55] (30 kg-years) and XENON1T data [56] (1.5 tones-years). The recoil energy $E_e$ can induce both of the observed electrons $n_e$ and scintillation photons $n_\gamma$. The numbers of quanta $n(1)$ that are produced by the step energy $W = 13.8 \text{ eV}$ which is $n(1) = \text{Floor}(E_R/W)$. The probability of the initial electron recombing with an ion is assumed as $f_R = 0$. The fraction of the primary quanta observed as the electrons is taken as $f_e = 0.83$. The corresponding uncertainties are chosen as $0 < f_R < 0.2$, $12.4 < W < 16 \text{ eV}$, and $0.62 < f_e < 0.91$. The photons are assumed from the deexcitation of the next-to-outer shells (5s, 4d, 4p, 4s), whose energies correspond to (13.3, 63.2, 87.9, 201.4) eV. Due to the photoionization effect, these photons can respectively create an additional quanta numbers $n(2) = (n_{5s}, n_{4d}, n_{4p}, n_{4s}) = (0, 4, 6 - 10, 3 - 15)$ as shown in the Table I [10]. The electron event $n_e$ can be obtained by binomial distribution. The ionized electrons will convert into the photoelectron (PE). The PE number is produced by an event of $n_e$ which obey “Gaussian” distribution with mean $n_e\mu$ and width $\sqrt{n_e\sigma^2}$, where $\mu = 19.7(11.4)$ and $\sigma = 6.2(2.8)$ for XENON100 (XENON1T). Note that the data in the range of [165, 275] of the XENON1T data are adopted for our numerical evaluation.

| shell          | 5p $^6$ | 5s $^2$ | 4d $^{10}$ | 4p $^6$ | 4 s $*$ |
|----------------|---------|---------|------------|---------|---------|
| Binding Energy eV | 12.0    | 25.7    | 75.5       | 163.9   | 213.8   |
| Additional Quanta | 0       | 0       | 4          | 6-10    | 5-15    |

TABLE I: Additional quanta of the ionization of Xenon.

Fig. 7 shows the numerical results of the limits from Xenon100 (left panel) and Xenon1T (right panel) data. The results of limits on the recoil of a single electron and Migdal effect are also shown for the comparison. We can see that, in the range of $m_\chi \gtrsim 100 \text{ MeV}$, the limits of the RHF form factor are much stringent than the recoil of a single electron, almost 4 orders stronger. This can be easily understood that the coherent enhancement of $Z^2(54^2)$ factor and a sufficiently large RHF $F(q)$ in the interval of the rate integral Eq. (21). The limits on the Tophat model and screened Coulomb potential model are at the same order of the results from the recoil of single electron under Xenon100 experiment data. However, they are negligible to the recoil of single electron under the constraints of Xenon1T experiment data. The limits on RHF form factor in both cases are much stringent than the limits of recoil of single electron, Tophat and screened Coulomb potential, due to the RHF $F(q)$. Note that, we can’t distinguish all these three processes (REC, single electron and Migdal effect) in experiments now, because the number of PE generated is observed in the experimental results, and these three processes cause the electron to ionize out and generate corresponding numbers of photoelectrons as S2 signals. It is unable to tell which physical process produces these photoelectrons. Since recoil of a single electron and REC originate from the same dark $U(1)$
FIG. 7: The limits of the cross sections and dark matter mass from Xenon100 (left panel) and Xenon1T (right panel). The blue dash (dot dash) lines show limits on the recoil of single electron and the Migdal effect. The dot line shows the result of Tophat model of the electron cloud, while the long green dash line gives the exclusion area from the screened Coulomb potential model with the screening length \( r_0 = 0.49 \) Å. The shaded regions show results of RHF form factor.

interaction, thus we just added together the both recoils, so that the summation gives a more comprehensive limits on the cross sections. The constraints of the Xenon1T data released below the 100MeV, however, the Xenon100 data can maintain the constraints to about 10MeV. The reason for this can be shown in Fig. 8 which shows the observed events versus photonelectrons (PE) from the Xenon100 and Xenon1T experimental data. The left panel shows the \( \bar{\sigma}_e = 1 \times 10^{-39} \) cm\(^2\) and \( m_\chi = 100 \) MeV result for Xenon100, and the right panel shows the \( \bar{\sigma}_e = 1 \times 10^{-40} \) cm\(^2\) and \( m_\chi = 200 \) MeV results for Xenon1T. One can check that, the lighter dark matter \( (< 100 \) MeV) in the recoil of a single electron and REC mainly cause different distribution in small PE number regions. In the numerical calculation we choose \([80, 190]\) PE bins of the Xenon100 for the constraints, while we only choose 165 PE as the bin of the Xenon1T for the constraints. Thus the Xenon100 give a better performance when the dark matter mass lighter than 100 MeV.

As for the comparison with Migdal effect, the limits on the RHF form factor are more stringent than the Migdal effect below about 400MeV (200MeV) from Xenon100 (Xenon1T) data. The reason has been addressed above that the upper limit of the rate integral Eq. (21) \( q_{\text{max}} \) in the Migdal effect can extend to a much larger value when dark matter mass is much lighter than the target nucleus. The ionization form factor can grow up to a sufficiently large value. Thus, the Migdal effect give a better performance in heavy dark matter region.

V. CONCLUSION

The searching for sub-GeV dark matter is a hot topic at the cutting edge of physics research. However, as the sensitivity lost for the light dark matter detection, the traditional strategies for detecting WIMP-type dark matter are no longer feasible. A novel detection are proposed that the electron cloud is boosted by the dark matter and throws away an electron when it is dragged back by the heavy nucleus, namely the coherent scattering of the electron cloud of the atom. The processes can be considered as an similar Migdal effect but in different Galilean frame. Though the form factor \( F(q) \) decrease quickly with the multiplicative inverse of the radius of the atom, as shown in the simple Tophat, Dipole, Gaussian shape and the SC model, this effect is still not negligible compared with the recoil of a single electron and the Migdal effect. What’s more, the survey in the X-ray diffraction show that the atomic form factor are much complicate than the naive consideration. The results of the relativistic Hartree-Fock method gives non-trivial shapes of the atom. We show that the corresponding form factors do not conflict with measured radii in the coordinate space. We also show that the collision between the sub-GeV dark matter and the electron cloud is similar to the X-ray diffraction. At least, the RHF form factor should be tried to be applied in the estimation of the scattering rate of the dark matter detection. Having equipped with the RHF form factor and impulse approximation,
we proceed to show the detailed calculation of recoil of the electron cloud. the kinetics, the fiducial cross section and the corresponding calculation of detection rate are given analytically. After that, we show the constraints on the cross section from the current experimental measurements. The Xenon100 and Xenon1T data are adopted for the constraints. The comparison between the other two processes are also discussed. We found that the limits of the RHF form factor are much stringent than the recoil of a single electron, almost 4 orders stronger. The constraints of the Xenon1T data released below the 100MeV, however, the Xenon100 data can maintain the constraints to about 10MeV. The limits on the RHF form factor are more stringent than the Migdal effect below about 400MeV (130MeV) from Xenon100 (Xenon1T) data, due to the extended interval of the rate integration. Another thing should be emphasized is that, the recoil of a single electron and recoil of the electron cloud originate from the same fundamental interaction, thus in principle both recoils should be added together and the summation gives a more comprehensive limits on the cross section.

The process we proposed and the corresponding results seem promising and novel. However, the key point of our work is that whether the RHF form factor can be used in the detection of the dark matter, which we only have neutral attitude on it.

VI. ACKNOWLEDGEMENTS

We thank Nick Houston, Lei Wu and Bin Zhu for their helpful discussions. This work was supported by the Natural Science Foundation of China under grant number 11775012.
