Abstract

**Background:** Appendectomy for acute appendicitis is the most common procedure performed emergently by general surgeons in the United States. The current management of acute appendicitis is increasingly controversial as non-operative management gains favor as a primary therapy. Appendiceal neoplasms are found rarely and often as an incidental finding in the setting of appendectomy for acute appendicitis. Criteria and screening for appendiceal neoplasms are not standardized among surgical societies.

**Methods:** We reviewed electronic medical records for a nine-year period (2010-2018) of patients who underwent appendectomy in two municipal hospitals in The Bronx, New York City. The authors also examined patients undergoing appendectomy during the same time interval through a query of the National Surgical Quality Improvement Program (NSQIP) database.

**Results:** We found a 1.7% incidence of appendiceal neoplasms locally and a 0.53% incidence of appendiceal tumors in available national population sample. Both groups demonstrated an increased incidence of appendiceal carcinoma by age. This finding was most pronounced after the age of 40 in both local and national populations. In our study, the incidence of appendiceal tumors increased with each decade interval up to the age of 80, and peaked at 2.1% in patients between 70 and 79 years.

**Conclusions:** We submit that the management of acute appendicitis involves a consideration of appendiceal neoplasm in patients over the age of 40. This should be considered in the management of older patients with acute appendicitis before a decision to embark on non-operative therapy. If this is undertaken, interval appendectomy or further cancer screening and surveillance should be performed.

**Background**

The incidence of appendicitis in the US has been reported to be between 82 and 111 per 100,000 population per year, with a life-time risk of 1 in 15 (6.7%)(1). Appendectomy for acute appendicitis is the most common emergency intra-abdominal operation performed by general surgeons, and approximately 300,000 appendectomies are performed annually in the United States alone (2). In recent years, there has been increased interest in non-operative management of acute appendicitis as first line therapy (3–6). A meta-analysis from Europe reported that the treatment of acute appendicitis was approached with antibiotic therapy in 40–45% of the patients compared to less than 5% in the United States (7, 8). This shift in clinical practice has raised concern regarding the risk of missing an appendiceal neoplasms in patients who receive non-operative therapy (9). While the overall incidence remains low, there are neither established criteria to determine which patients are eligible for medical management nor criteria for patients who may require oncologic surveillance after non-operative treatment for appendicitis. The aims of this study were 1) to determine first the incidence of appendiceal neoplasms in two urban municipal hospitals in the Bronx, New York City and 2) to compare these findings to those reported in the literature and the National Surgical Quality Improvement Program (NSQIP) database.
Methods

In this retrospective cohort study, data were collected from the electronic medical records of all patients diagnosed with acute appendicitis in the period January, 2010 through December, 2018 in two Bronx municipal hospitals. Medical records were identified through ICD-9 codes for ‘appendicitis”: 540 (540.0, 540.1, 540.9), 541, 542; “appendectomy as an outpatient procedure”: 44950, 44955, 44960, 44870, 44979, 44900, 44901; “appendectomy as an inpatient procedure”: 45.72, 45.73, 47, 47.01, 47.09, 47.1, 47.11, 47.19, 47.2, 47.92, 47.99; “neoplasm of the appendix”: 153.9 and 152.9; and the ICD 10 codes for “appendicitis” K35, K36, “other appendicitis” K37 and K38; “neoplasm of the appendix”, “neoplasm of the intestinal tract”, “small intestine and colon unspecified” C17.9, C18.9, C26.0 and C18.1 and for “appendectomy”: 0DTJ0ZZ, 0DTJ4ZZ, 0DTJ7ZZ, 0DTJ8ZZ. Records were further confirmed with an institutional Tumor Registry and Pathology database to ensure inclusion of all malignant cases. All 2131 pathology reports were reviewed to evaluate for neoplasms in appendectomy specimens. Data acquitted included age at diagnosis, sex, prior colonoscopy records, radiographic findings, as well as final pathology and oncologic outcomes.

Continuous variables were expressed as means with 95% confidence intervals (CI) or median with interquartile range (IQR). Categorical variables were described with number counts and percentages. Continuous variables were compared using independent t-test or Mann-Whitney U test for normal and non-normal predictors, respectively. Categorical variables were compared using Chi-square tests. A p-value less than 0.05 was considered statistically significant. All analyses were performed using SPSS Version 25.0 (IBM Corp, Armonk, NY, USA). All data collection and chart review were performed with approval by the hospital's Institutional Review Board (IRB) of the Albert Einstein College of Medicine (IRB Protocol #2017–7530).

The National Surgical Quality Improvement Program (NSQIP) personal use file database was queried using the ICD-9 codes listed above in the time interval of May 1, 2010 to December 31, 2018. During this time period there were over 2.8 million patients in the database. All patients who had undergone appendectomy were then queried for appendiceal neoplasm. Cases of appendiceal neoplasm were then broken down by age, type of procedure, and pathologic diagnosis. In the database there were only three pathologies of appendiceal neoplasm specified: adenocarcinoma, malignant carcinoid, and unspecified. Cases with benign pathology after appendectomies were excluded from the analysis.

Results

A total of 2131 medical charts from patients diagnosed with acute appendicitis were reviewed in two municipal hospitals using the electronic medical records from 2010 through 2018. At these institutions, 1996 patients (93.7%) underwent operative treatment for acute appendicitis, with 1108 patients (55.5% of total surgeries) undergoing laparoscopic appendectomy, 854 for open surgery (42.8%) and 33 (1.7%) who underwent conversion from laparoscopic to open approach. From the operative cohort, 34 patients were diagnosed with appendiceal neoplasm after the pathologic study of the removed appendix which
reflected an incidence of 1.7% in this study population over nine years (Fig. 1). The mean age of the neoplasm cohort was 48.6 years (95% CI [42.1–55.2]), with approximately 2:1, female to male ratio (65.7% female). Remaining demographics and clinical factors are presented by benign (low-grade appendiceal mucinous neoplasm or LAMN, neuroendocrine), or malignant or disseminated (adenocarcinoma, metastatic) disease in Table 1. Of note, all neuroendocrine tumors were Grade 1 and categorized as benign.

### Table 1
Demographics

|                        | Benign* (n = 23) | Malignant / Disseminated (n = 11) | P-value |
|------------------------|------------------|----------------------------------|---------|
| Age, years (95% CI)    | 43.7 [35.9–51.5] | 59.1 [46.5–71.7]                | 0.035   |
| Female sex (%)         | 16 (69.6)        | 7 (63.6)                         | 1.000   |
| Previous colonoscopy (%) | 7 (30.4)       | 3 (27.3)                         | 1.000   |
| Imaging size (cm) – median (IQR) | 1.2 (1.0) | 1.3 (0.6)                        | 0.637   |
| Emergency department presentation (%) | 19 (82.6) | 10 (90.9)                        | 0.797   |
| Operative intervention (%) | 0.525          |                                  |         |
| Open                   | 9 (39.1)         | 6 (54.5)                         | —       |
| Laparoscopic           | 13 (56.5)        | 4 (36.4)                         | —       |
| Converted              | 1 (4.3)          | 1 (9.1)                          | —       |

IQR – interquartile range

*Patients with appendectomy specimen pathology consistent with low-grade appendiceal mucinous neoplasm or neuroendocrine tumors were defined as “benign.” Patients with clinical or pathological evidence of appendiceal adenocarcinoma or metastatic disease were defined as malignant/disseminated.

**Complicated cases included peritonitis, pneumoperitoneum, perforation, abscess, or phlegmon

The entire series of patients with appendiceal neoplasms are presented in Table 2 with associated age at diagnosis, appendiceal size on imaging, surgical approach, pathology, and stage. The final pathology revealed 8 cases of adenocarcinoma (0.4% of appendectomy specimens), 14 neuroendocrine tumors (0.7%), 9 low-grade appendiceal mucinous neoplasms (LAMN, 0.4%), and three cases evident of metastatic disease (0.2%). Twenty-six (74.3%) of the patients were 40 years or older at the time of diagnosis. Moreover, the diameter of the appendix was greater or equal to 1.0 cm on pre-operative imaging in 28 of 34 (82.3%) of patients with appendiceal cancer. All patients with LAMN (n = 9) had an appendiceal diameter greater than 1.0 cm. A representation of patients divided by type of neoplasm and
age is presented in Fig. 2. Adenocarcinoma only appeared in patients older than the age of 40 in the local cohort. Older age was associated with malignant or disseminated disease: 59.1 [46.5–71.7] vs. 43.7 [35.9–51.5] years (p = 0.035; Table 1).
Table 2
Summary of Appendiceal Neoplasms

| Patient ID | Age at Presentation (years) | Appendiceal Imaging Size (cm) | Pathology | Stage (TNM) | Surgical Procedure |
|------------|-----------------------------|-------------------------------|-----------|-------------|--------------------|
| 1          | 73                          | 3.1                           | Adenocarcinoma | IIA (T3, N0, M0) | Open right hemicolecotomy |
| 2          | 67                          | 3.0                           | Adenocarcinoma | IV           | Diagnostic laparoscopy with appendectomy, omental and peritoneal biopsy |
| 3          | 66                          | 0.8                           | Adenocarcinoma | I (T2, N0, M0) | Open right hemicolecotomy |
| 4          | 63                          | 1.2                           | Adenocarcinoma | IIA (T3, N0, M0) | Open right hemicolecotomy |
| 5          | 62                          | 0.5                           | Adenocarcinoma | IIA (T3, N0, M0) | Laparoscopic appendectomy converted to open right hemicolecotomy with partial omentectomy |
| 6          | 82                          | 1.4                           | Adenocarcinoma | IV (T4, N2, M1) | Open right hemicolecotomy |
| 7          | 54                          | 1.4                           | Adenocarcinoma | IIA (T3, N0, M0) | Laparoscopic appendectomy with interval open right hemicolecotomy |
| 8          | 49                          | 1.3                           | Adenocarcinoma | IV (T3, N2, M1) | Open right hemicolecotomy |

LAMN – low-grade appendiceal mucinous neoplasm
| Patient ID | Age at Presentation (years) | Appendiceal Imaging Size (cm) | Pathology | Stage (TNM) | Surgical Procedure                  |

LAMN – low-grade appendiceal mucinous neoplasm

The National Surgical Quality Improvement Program (NSQIP) database was queried between 2010 and 2018. A total of 154,596 appendectomies performed in adult (age ≥ 18 years) patients were identified, which included 812 cases of appendiceal cancer (for an incidence of 0.53%). The incidence of appendiceal tumors stratified by age are summarized in Fig. 3. The combined incidence of appendiceal neoplasms identified in these data are 0.4%, 0.8%, 1.6%, 2.1%, and 1.6% respectively for age 40–49, 50–59, 60–69, 70–79, and > 80. For patients older than 40 years, 1% of appendectomy specimens demonstrated an appendiceal neoplasm. From the 812 appendiceal neoplasms, 681 adenocarcinomas of the appendix (0.4%) were identified. For these patients, 290 underwent appendectomy and 524 underwent colectomy; 133 patients underwent both procedures.

**Discussion**

In this study we reviewed 2131 cases of acute appendicitis in two municipal hospitals. The incidence of adenocarcinoma increased with age greater than 40 at our institutions, while cases of adenocarcinoma were reported in patients under 40 years in the NSQIP analysis. These data concur with a similar NSQIP analysis performed by Lu, et al between 2016 and 2017. These results were in agreement with those
established in prior reports that support a significant association between increased risk of malignancy and increasing age in patients who have undergone surgical appendectomy for presumed appendicitis (10). The rate of appendectomy at Jacobi Medical Center and North Central Bronx Hospital for acute appendicitis was 94%, which also matched the United States NSQIP rate of 95%. The rate of appendiceal cancer at Jacobi and North Central Bronx Hospital of 1.7% was higher than the observed NSQIP rate of 0.53% for appendiceal cancer in acute appendicitis.

Although the cause of appendicitis is unknown, the incidence of appendicitis has increased in industrialized countries. In the setting of a progressively aging population, there is an observed increase in appendicitis in older adults. The management patterns of acute appendicitis are also evolving. Many patients are managed non-operatively(1). Over the last several years, numerous studies have determined safety and efficacy of non-operative treatment with specific indications (1, 2, 6, 11–20). Healthcare providers have been eager to adapt this new modality without consideration for possible long-term outcomes, and oncologic ramifications. To date, the only gold standard confirmatory test for appendiceal cancer is appendectomy that is usually performed for the presentation of acute appendicitis (21–23). In a recent prospective study of acute complex appendicitis, patients with complicated appendicitis who underwent either surveillance or interval appendectomy were found to have an exceedingly high rate of malignancy that even resulted in premature discontinuation of a prospective study (10, 24–26). Our findings corroborate recent findings in prospectively collected data, analyzed post-hoc, from the MUSTANG trial (27). Taken together we concur that age older than 40 must be considered a risk factor for malignancy when considering appendectomy at initial presentation or at a later date (27, 28).

Appendiceal neoplasms are a heterogeneous entity that escape straightforward classification or management (29–31). Further study of these tumors in the acute setting is required to adequately screen patients who may not be eligible for medical management or whose atypical presentation may highlight the need for further oncologic workup prior to surgical intervention.

Our local study was limited by its retrospective design and review of patient data from a now unmaintained, older electronic medical record. In the emergency surgery setting, patient follow-up was poor. Our municipal hospital system also serves underrepresented and an economically disadvantaged patient population with limited adherence in all surgical settings. Furthermore, the practice patterns at our institution, with inclusion of earlier data, reflected a surgical practice pattern that may be limited at other centers, especially outside the United States.

Analysis of the NSQIP data demonstrated that the incidence of appendiceal neoplasm was higher in older adults, with a marked increase after 50 years. Nonetheless, this incidence was lower than that observed in our urban, Bronx-based population (0.53% vs. 1.7%). There are several explanations for this discrepancy. NSQIP does not capture every case of appendicitis. This leaves open the possibility that cases of appendicitis were missed. This deficiency combined with the larger sample size may lead to a decrease in relative percentages of appendicitis in the NSQIP sample. Another point of possible discrepancy involved the pathologic diagnosis of appendiceal cancer. In the local group, anatomic pathology was performed
and reviewed by one group. In NSQIP the data input was entered at the time of initial diagnosis based on a pathology report. It is possible that diagnostic criteria may vary from facility to facility across a national database. Regardless, the overall trends were similar. The incidence of appendiceal neoplasm, in particular appendiceal adenocarcinoma, increased with age and highlighted the need to consider the possibility of underlying malignancy in acute appendicitis in adults over the age of 40.

Conclusions

Appendiceal neoplasms are a heterogeneous group of diseases that vary significantly in oncologic outcomes and are often diagnosed in the setting of acute appendicitis. Age greater than 40 years and female gender were more common in our patients with appendiceal neoplasms. General and acute care surgeons should remain vigilant in recognition of these diseases and ensure appropriate surgical care, oncologic management, and surveillance are maintained outside of the emergency setting.

CI: confidence interval

IQR: interquartile range

LAMN: low-grade appendiceal mucinous neoplasm

Declarations

Ethics approval

This study received ethics approval by the Albert Einstein College of Medicine Internal Review Board prior to data collection and analysis.

Consent for publication

Not applicable

Availability of supporting data

De-identified patient data are available for external review upon request. Requests for identified patient data will be submitted to the Internal Review Board of Albert Einstein College of Medicine for consideration.

Competing interests

The authors declare that they have no competing interests.
**Funding**

Not applicable.

**Author contribution**

Victor S. Alemany and John P. Skendelas are both co-first authors of this manuscript and contributed equally in the collection, categorization, organization, and analysis of the data and wrote the manuscript with assistance and supervision of Peter K. Kim. Vincent Au contributed to the writing of the manuscript and data collection. Devika Rao conceived the design and collection of the data. John McNelis obtained the National Surgery Quality Improvement Program (NSQIP) data and helped with the manuscript preparation. Peter K. Kim conceived the original idea, supervised manuscript preparation, and took the lead of the project.

**Acknowledgements**

We thank the Physician Affiliate Group of New York (PAGNY) Health and Research Foundation who supported this project and is committed to enhancing health on all of New York City’s diverse communities. We also thank Sherrie R. White, MD and Joanne Stern, who aided in data collection.

Figures
Figure 1

The total number of local cases of appendicitis and those managed surgically reviewed from two Bronx municipal hospitals for the period 2010 through 2018. The number of cases found to be appendiceal cancers are further categorized into adenocarcinoma, neuroendocrine, low grade appendiceal mucinous neoplasm (LAMN), and metastatic cancer.
Figure 2

The incidence of adenocarcinoma, neuroendocrine, low grade appendiceal mucinous neoplasm (LAMN), and metastatic cancer from two Bronx municipal hospitals for the period 2010 through 2018 categorized into ten-year age groups.
Figure 3

The incidence of adenocarcinoma, neuroendocrine, low grade appendiceal mucinous neoplasm (LAMN), and metastatic cancer obtained from the National Surgical Quality Improvement Program (NSQIP) database from 2010 to 2018 categorized into ten year age groups.
