ABSTRACT

The present study envisaged the effects of two mutagens, gamma rays and EMS on the phenotypes of two sesame varieties viz., TMV7 and SVPR1. A known quantity of dry, uniform, and healthy seeds of TMV7 and SVPR1 were irradiated using Co60 (Cobalt 60) with different doses (250, 300, 350, 400, 450 Gy) of gamma rays. For chemical mutagenesis, different concentrations of EMS @ 0.20%, 0.40% and 0.60% was used and treated for 8 h. The dose-response curve of the probit analysis showed that the optimal lethal dose for SVPR1 was lower than TMV7. The expected LD50 values of gamma radiation for TMV7 and SVPR1 were 403.91Gy and 343.84Gy, respectively. For EMS, the expected LD50 values are 0.525 % and 0.276% for TMV7 and SVPR1 respectively. Germination and pollen fertility declined linearly with an increase in dose or concentration of the mutagens. Three classes of chlorophyll mutants viz., xantha, chlorine, and viridis in M2 generation reveals a dose dependent relationship between mutagens and frequency of chlorophyll mutants. Mutagenic effectiveness was higher at lower doses whereas mutagenic efficiency was observed higher at extremity doses in both the varieties. The overall considerations on M1 generation effects showed that SVPR1 was highly sensitive to gamma rays and TMV7 produced more viable mutations than SVPR1. The current studies suggest gamma rays as an efficient mutagen to induce essential mutations in TMV7 for the further crop improvement program.

1 Introduction

Sesame (Sesamum indicum L.) the Indian olive oil is one of the world’s important ancient oilseed crops known as “Queen of Oil seeds”. Seeds are highly protein-rich and the essential amino acids particularly methionine are considered as rejuvenating and anti-aging factors (Namiki, 2007). Oil and protein content of sesame ranges from 48 to 55 % and 20 to 28 % respectively (Pathak et al., 2014). Fats in sesame oil are relatively stable and resist oxidative rancidity as compared to other oils. Sesame contains a high percentage of antioxidants such as sesamol, sesamin, sesamolin, and sesaminol; fatty acids like palmitic, stearic, oleic, and linoleic, and rich in minerals like vitamin E, calcium, magnesium, and phosphorus (Pusadkar et al., 2015; Myint et al., 2020). The sesame oil aids in reducing blood cholesterol, high blood pressure and prevents atherosclerosis, heart diseases, and cancers (Kumar & Singh, 2015).

It is a self-pollinated annual shrub widely grown in tropical, subtropical, and temperate areas of the world, exceptionally in India, China, South America, and Africa (Tufail et al., 2020). The architecture of sesame is poorly adapted to modern farming owing to its indeterminate growth habit, non-uniform ripening of capsules, sensitivity to wilting under intensive management, and absence of non-shattering cultivars suited for mechanical harvest (Cagirgan, 2001). Lack of elite cultivars, with inherent resistance to biotic and abiotic stresses, leads to low productivity of sesame (0.33 tonnes ha$^{-1}$) (Rao et al., 2017). Introggression of genes from wild relatives to cultivated varieties is largely unsuccessful due to the operation of high crossability barriers (Rajeswari et al., 2010; Chaudhary et al., 2019). To generate variability, attempts have been made by crossing to some extent, but desirable success could not have been attained.

Mutation breeding serves as an inevitable tool to rectify specific defects by creating desirable genetic variation with the help of physical or chemical mutagens (Chaudhary et al., 2019). Ionizing radiations include X-rays, gamma rays, protons, neutrons, alpha, and beta particles. Gamma rays are widely employed for mutation studies due to their shorter wavelength and more penetration ability (Khin, 2006). Furthermore, chemical mutagens such as sodium azide, ethyl methane sulphonate (EMS), and N-ethyl-N-nitrosooure (ENU), shows distinct negative and positive impacts on the mutated populations (Mohd-Yusoff et al., 2015). EMS is a common mutagen for mutation breeding, that pairs with T instead of C. The mispairing results in G/C to A/T transitions, apart from causing deletions and rearrangements (Rafi et al., 2016). Induced mutations with ionizing radiations and chemical mutagens offer desired phenotypic as well as genotypic effects, which can be further harnessed through recombination breeding or as such (Filibotte et al., 2010). Limited mutant population is advantageous in achieving genome-wide saturation mutagenesis (Henikoff & Comai, 2003).

Mutagenic effectiveness and efficiency are two distinct properties of mutagens in plant breeding (Shah et al., 2008; Girija & Dhanavel, 2009). The product of maximum desirable changes associated with the least possible undesirable changes is termed efficient mutagenesis. These two criterions, viz., mutagenic efficiency and effectiveness of any mutagen, determines the success of a breeding scheme. Mutagenic efficiency is the rate of mutation produced to biological damage or injury by any mutagen. However, the efficacy of a mutagen is the rate of mutation produced relative to the dose of the mutagen (Anbarasan et al., 2015). Thus the choice of effective mutagen and dose to be used (preferably one that induces enormous variability in any crop) is highly crucial for untargeted induced mutagenesis. In general, the frequency of chlorophyll mutants is used for assessing the potency of any mutagen such as Albina, Striata, Chlorina, Xantha and Viridis.

Cultivated species of sesame is under the major threat of phyllody, caused by mycoplasma like organism. Recent studies highlighted that the area and production of sesame crop is declining in the traditional areas. Lack of resistant cultivars is one of the major constraints in sesame growing regions of India (Gupta et al., 2018). With an attempt to develop an improved sesame variety via induced mutagenesis, the present study deals with the mutagenic effectiveness and efficiency of two mutagens gamma ray (Physical mutagen) and ethyl methane sulphonate (chemical mutagen) in M$_2$ generations of two commercial sesame varieties of Tamil Nadu, TMV7 and SVPR1.

2 Materials and Methods

The investigation was carried out at the experimental farm of plant breeding and Genetics, Agricultural College and Research Institute, Killikulam, Vellanad Tuticorin Dt, Tamil Nadu (8° 46’ N latitude and 77° 42’ E longitude) in two seasons Kharif (June – Sept) and Rabi season (October – March) of 2019-20. The elevation of the site is 40 m above the mean sea level with relative humidity of 60 to 80%. sub-tropical monsoon climate, and red lateritic soil (pH : 6.8; EC: 0.05 dSm$^{-1}$).

2.1. Plant materials

Seeds of two popular sesame cultivars TMV7 and SVPR1 were obtained from Oil seeds Research Station, Tindivanam, and Cotton Research Station, Siviviliputtur, Tamil Nadu Agricultural University (Table 1).

2.2 Gamma irradiation

A known quantity (2 g per dosage) of dry, uniform, and healthy seeds of two genotypes of sesame (TMV7 and SVPR1) were irradiated using Co$^{60}$ (Cobalt 60) gamma source with different doses (250, 300, 350, 400, 450 Gy) of gamma rays at Indira Gandhi Centre for Atomic Research (IGCAR), Kalpakkam, Chennai, Tamil Nadu. The irradiation
seeds were carefully transferred to sterile containers and sown in the
experimental plot within 24 h.

2.3. Chemical Mutagenesis

For EMS treatment, 2 g of dry, uniform, healthy, matured and
viable seeds of the two varieties viz., TMV7 and SVPR1 were pre-
soaked in distilled water for 12 h to enhance imbibing capacity.
Pre-soaked seeds were treated in different concentrations of EMS,
an alkylating chemical mutagen solution @ 0.20%, 0.40%, and
0.60% for 8 h under controlled conditions at room temperature
with intermittent shaking (Kim et al., 2006). After soaking, the
treated seeds were washed in running water for an hour to remove
the chemical residues. Sodium thiosulphate (100mM) was used to
clean beakers and tips that can inactivate residual EMS and enables
safe disposal.

2.4. Lethal dose of gamma and EMS

The LD₅₀ values for gamma rays and EMS for both the genotypes
were calculated according to the probit analysis (Finney, 1978).
The probit function represents the inverse cumulative distribution
function or quantile function associated with the standard normal
distribution. The steps for probit analysis are (i) transformation of
the dose concentration of mutagens into log₁₀ values (ii)
determination of the mortality % due to treatment doses. The
proportions were corrected for control mortality if it is more than
10% using Abbot Formula (Ramchander et al., 2015).

Corrected mortality (p)= \frac{\% \text{ responded} - \% \text{ responded in control}}{100 - \% \text{ responded in control}} \times 100

\text{(1)}

The corrected proportions (p) were converted to empirical probits
(y) and a dose-response regression curve drawn using log₁₀ doses
(x) and empirical probits (y). Empirical probits (y) values< 1 and
>7 are ignored (Hayes & Kruger, 2014).

Empirical probits (y) = 5 + (x - \mu)/s \text{ (2)}

From equation (2) the expected probits (Yi) were derived. Chi-
square values were obtained from the original mortality (Observed)
and derived mortality (Expected). The non-significant Chi-square
test indicates good curve fitting. The LD or LC values are derived
from the curve drawn using probits and log doses. Antilog to the
Log₁₀ value corresponds to respective probit value and 95%
fiducial confidence limits are calculated using the formula

Fiducial Limits \text{= Antilog (Log₁₀ Dose} ± 1.96 \text{ (SE))}

2.5. Field Experiment

Irradiated seeds (M₀) along with the controls (non-irradiated) were
sown in the field in a randomized block design with three
replications keeping plant to plant and row to row distance of 10
and 30 cm, respectively during Kharif 2019. Four to five capsules
of each M₁ plants against all the treatments were collected separately
to raise the M₂ generation. Individual plant to progeny
rows was maintained in M₂ generation (Rabi2019-20) keeping
row to row and plant to plant distance at 30 cm and 10 cm,
respectively. Immediately after germination, various types of
chlorophyll mutants (albina, chlorina, xantha) were recorded to
study the mutagenic effect of different doses. In every generation,
other agronomic package, practices, and plant protection measures
were taken throughout the experiment.

2.6. Crop phenotyping

Biological damage was measured in M₁ generation in terms of total
number of seeds germinated on 15 DAS, lethality (% survival)
reduction in seedling height (injury) of seedling in each treated
population on 30 DAS and pollen sterility. In M₂ generation,
seedlings were screened from 10 to 20 DAS, to record various
types of chlorophyll mutants periodically.

2.6.1. Growth analysis

For growth studies, percent germination of seeds observed on 15
DAS in each treated population. Seedling survival was recorded
based on the total number of seedlings survived on 30 DAS and the
survival percentage calculated as the ratio between numbers of
plants survived to that of the number of seeds sown.

2.6.2. Pollen sterility

Randomly selected flowers from 10 plants were collected, and with
the help of a needle and forceps, flowers dissected and anthers
were taken out. Pollen grains were smeared in the glass slide of a
compound microscope using 0.5 % potassium iodide (KI) solution
(Baker & Baker, 1979) and counted for five microscopic fields.
Regularly shaped and stained pollen grains were considered as
fertile, whereas the unstained and empty ones as sterile.

Table 1 Collection sites and typical characteristics of selected sesame cultivas

| Name of Cultivar | Selected from | Seed coat color and surface | Days to maturity | 1000 Seed weight (g) |
|------------------|---------------|----------------------------|-----------------|----------------------|
| TMV7             | Oilseeds Research Station, TindivanamTNAU | Brown, partially radially rough | 80-85 | 3.15 |
| SVPR1            | Cotton Research Station, Srivilliputtur TNAU | White, partially rough | 75-80 | 3.05 |
2.6.3. Chlorophyll mutants

Chlorophyll mutants were recorded in the M₃ generation. The spectrum of chlorophyll mutants were characterized according to Gustafsson (1940) and Blixt (1961) as follows: Xantha - yellow to whitish yellow coloured leaves and it also has minimum survival up to 15 to 20 DAS. Chlorina - the presence of light green coloured seedlings and did not survive 15 days after sowing. Viridis – light green colour in the early stages of growth which gradually changed to the normal green colour during the subsequent period of growth and plants are viable.

2.7. Efficiency and effectiveness of mutagens

Mutagenic efficiency and effectiveness were recorded for each treatment according to the formula proposed by Anbarasan et al. (2013). The frequency of chlorophyll mutants were calculated as a percentage of segregating progenies and that of mutant seedlings in the M₂ generation (Anbarasan et al., 2015).

\[
\text{Mutagenic effectiveness} = \frac{\text{Mutation Frequency} \times \text{Dose of Mutagens}}{(\text{Concentration} \times \text{Biological damage})}
\]

\[
\text{Mutagenic efficiency} = \frac{\text{Mutation Frequency}}{\text{Biological damage}}
\]

Where,

- \(M\) = Mutation frequency
- \(L\) = Percentage of lethality or survival reduction
- \(I\) = Percentage of injury or reduction in seedling size
- \(S\) = Percentage of pollen sterility

\[
\text{Mutation rate} = \frac{\text{Sum of values of efficiency or effectiveness of particular mutagen}}{\text{Number of treatments of a particular mutagen}}
\]

3 Results

3.1. Effect of mutagens on seed germination

The percentage of seed germination decreased progressively as the doses/ concentrations of mutagens increased as compared with their respective controls. The germination response for gamma rays treated seeds ranged from 80.0% (250 Gy) to 40.0% (450 Gy) for TMV7 and from 72.5% (250 Gy) to 37.5% (450 Gy) for SVPR 1, whereas EMS treated seeds registered, 72.5% to 47.5% and 57.25% to 32.5% for TMV7 and SVPR1 respectively. Significant reduction in germination percent was exhibited by both gamma (86.49 to 43.24%) and EMS (78.38 to 51.35%) treated TMV7 seeds over their corresponding controls. Furthermore, the percent reduction in the germination of gamma treated SVPR 1 was almost at par with TMV7 whereas the EMS treated SVPR 1 showed deviation from 69.39 to 39.39% over control. However, the highest percentage of reduction in seed germination was observed at 450 Gy(48.65%) followed by EMS treatment at 0.60 % (56.76%) in TMV7 and SVPR1 (54.55% and 60.61% respectively (Table 2 and Figure 1).

Furthermore, the seedling survival of both genotypes reduced significantly upon exposure to gamma rays and EMS as compared to respective controls (Table 2). On 30 DAS, SVPR1 displayed more sensitivity than TMV7 at 450 Gy. The survival percent over control for EMS treated seedlings ranged between 7.03 to 22.46 % for TMV7 and 7.8 to 10.9% for SVPR at various EMS concentrations.

The results of the seedling height indicates that TMV7 (43.33) was less affected by 450 Gy while the attribute was markedly affected in SVPR1 (32.10) as compared to control. On the contrary, TMV 7 showed more sensitivity to EMS than SVPR1. The seedling height progressively decreased in both genotypes with increasing EMS concentration. Among the genotypes, SVPR showed maximum reduction in seedling height (67.90 %) followed by TMV7 (56.67 %) at 450 Gy (Table 2 and Table S1).

3.2. Lethal Dose (LD₅₀) of mutagens

Probit analysis was carried out using seed mortality rates in both the varieties for gamma rays and EMS to determine the Lethal Dose (LD₅₀). The optimal lethal dose was recorded at 0.276% and 0.525% for SVPR1 and TMV7 to EMS respectively. In case of gamma irradiation, 343.843 Gy for SVPR1 and TMV7 fixed at 403.910 Gy (Table S2). The best fit dose-response curve of the probit analysis was shown in Figure 2. The results indicated that the optimal lethal dose for S. indicum var. SVPR1was lower than S. indicum var. TMV 7 in both the mutagens studied.

3.3. Effect of mutagens on pollen sterility

Percent increase in pollen sterility of TMV ranged from 15.5% (250 Gy) to 55.67% (450 Gy) while in SVPR1 it ranged between 34.23% (250 Gy) to 64.03% (450 Gy). Similarly in EMS treatment, pollen sterility followed a linear increase from 6.98 (0.20%) to 35.89 (0.60%) for TMV7 while in SVPR1, an uptrend from 11.42 (0.20%) to 37.96 (0.605%). The effect of mutagens on pollen fertility was presented in Figures 3 and 4.

3.4. Effect of induced mutagenesis on the spectrum of chlorophyll mutants

Results of the current investigation showed a considerable increase in the spectrum of chlorophyll mutants such as xantha, chlorina, and viridis (Figure 5 and 6). Mutagenic frequency in inducing chlorophyll mutations by gamma rays ranged from 1.71(250 Gy) to 2.81(450 Gy) for TMV7, while in SVPR1, the parameter ranged from 1.80 (250 Gy) to 3.03(450 Gy). For EMS, chlorophyll mutants were observed in the range of 1.36 (0.20%) to 3.45 (0.60%) and 1.33 (0.20%) to 1.59 (0.60%) for TMV7 and SVPR1 respectively.
Table 2 Effect of mutagens on seed germination, seedling survival and seedling height of sesame varieties

| Doses / Concentrations of mutagens | Seed germination (15 DAS) | Seedling survival (30 DAS) | Seedling height (30 DAS) |
|-----------------------------------|---------------------------|---------------------------|--------------------------|
|                                   | Mean ± SE                  | Per cent over control     | Mean ± SE                | Per cent over control |

Figure 6 Chlorophyll mutants observed in M2 generation, A: control, B: xantha, C and D: chlorina, E: viridis
Figure 7 Line Diagram showing the mutagenic effectiveness of gamma ray (a) and EMS (b) in two sesame varieties (Values are mean of three replications)

Figure 8 Line Diagram showing the mutagenic efficiencies of gamma ray (a) and EMS (b) in two sesame varieties (Values are mean of three replications)
For gamma rays, the variety, TMV7 exhibited chlorophyll mutant frequency of \textit{xantha} (6.42), \textit{chlorina} (1.91), and \textit{viridis} (2.64) while in SVPR1 5.74\%, 5.41\%, and 0.76\% of \textit{xantha}, \textit{chlorina}, and \textit{viridis} were recorded respectively (Table 3). Likewise EMS treated seeds of TMV7 and SVPR1 showed 1.53\%, 1.07\%, 1.61\% and 2.79\%, 1.79\%, 2.65\% of \textit{xantha}, \textit{chlorina}, and \textit{viridis} respectively (Tables 3 and 4).

### 3.5 Mutagenic effectiveness and efficiency

Mutagenic effectiveness for gamma rays augmented between 0.68 (250 Gy) to 0.62 (450 Gy) for TMV7, while SVPR1 showed 0.72 (250 Gy) to 0.67 (250 Gy). On the contrary, EMS treatment registered mutagenic effectiveness of 0.85 to 0.54 and 0.83 to 0.25 for TMV7 and SVPR1 respectively (Figure 7 and 8).

#### Table 3: Frequency and spectrum of gamma ray induced chlorophyll mutants in M\textsubscript{2} Generation

| Mutagen Gamma Rays (Dosage) | Classes of chlorophyll mutants | Number of chlorophyll mutants | Number of plants observed | Relative percentage (frequency) of chlorophyll mutants | Mutagenic Frequency |
|-----------------------------|--------------------------------|-------------------------------|--------------------------|-------------------------------------------------------|---------------------|

Mutagenic efficiency in terms of injury registered a considerable variation among the mutants studied. The results implied that gamma rays displayed 87.52% (TMV7) to 133.76% (SVPR1) whereas, EMS showed 28.39% (TMV7) to 23.51% (SVPR1) efficiency. In terms of lethality, TMV7 and SVPR1 exhibited 13.68 and 9.82% for EMS and 44.57 (TMV7) and 44.74 (SVPR1) for gamma rays. Significant sterility was observed in TMV (40.38) and SVPR1 (19.28) exposed to EMS followed by gamma rays (34.16 and 22.48 respectively).

4 Discussion

Induced mutagenesis is one of the tools to create genetic and phenotypic variability in plants with a higher frequency than spontaneous mutations (Chopra, 2005). Artificially induced mutations are employed using physical or chemical mutagens in which LD50 values have been considered as a critical factor for efficient mutations (Anbarasan et al., 2013). The lethal dose indicates the lethal toxicity of a given substance or type of radiation. Besides, the resistance varies from one individual to another, the "lethal dose" represents a dose at which a given percentage of plants will die. In the present investigation, the LD50 was calculated based on seed germination at different doses of gamma rays and EMS. Mean germination percentage of S. indicum (Var. TMV 7 & SVPR1) genotypes at 5 different doses of gamma rays and 3 different doses of EMS was recorded. The LD50 was calculated based on percent germination on 15 DAS. The seedlings having normal roots and shoots were considered for calculating the LD50 as most of the seedlings from delayed germinated seeds were abnormal. The LD50 for the S. indicum var. SVPR1 was found nearly 14.87% lower than the LD50 of the genotypes of S. indicum var. TMV 7 in gamma rays treatment. Similarly for EMS LD50 for the S. indicum var. SVPR1 was found nearly 47.43% lower than the LD50 of the genotypes of S. indicum var. TMV 7. More specifically, the optimal lethal dose for S. indicum var. SVPR1 was much lower than S. indicum var. TMV 7 in both the mutagens studied. The variation in the LD50 of the two varieties for both physical and EMS of the same species was found different, suggesting that it may vary from one genotype to another. It might be due to the differences in their genetic constitution and their parentage. The differential response of genotypes among the same species was reported by Sandhiya et al. (2020) on sesame varieties SVPR1 and VR13 to EMS treatment and in the rice varieties white ponni and BPT 5204 to gamma radiation by Ramchander et al. (2015).

The biological damage caused by gamma rays and EMS in M1 generation can be estimated based on plant survival (Ramchander et al., 2015). Likewise, the results indicated that the germination percentage decreased progressively as the doses/ concentrations of mutagens increased. The percent germination of gamma treated TMV 7 was reduced from 86.49 to 43.24 and EMS was treated from 78.38 to 51.35 respectively. The highest percentage of reduction in seed germination was observed at EMS treatment at higher doses (0.60%) in TMV7 (47.5%) followed by 450 Gy in TMV 7 (40%) and SVPR1 (37.5%). Among the genotypes, SVPR1 was found to be more sensitive than TMV7. Besides, the results revealed that the doses of EMS higher than 1% are highly lethal irrespective of genotype and species. The seedling survival on 30 days after treatment (DAT) was found to have a similar trend as of germination percentage. Most of the seedlings that emerged from delayed germinated seeds were abnormal which could not develop into normal seedlings. The results illustrated the effect of mutagenic treatment on the germination of seeds and their lethality. In all the mutagenic treatments, a significant reduction in seedling survival (lethality) and seedling height (injury) were observed. Similar works were done by various researchers (Anbarasan et al., 2013; Anbarasan et al., 2015; Kumari et al., 2016a; Anbarasutharsan et al., 2019; Sandhiya et al., 2020) on various sesame genotypes and observed a dose dependent reduction in germination percentage. The results are in agreement with Akilan et al. (2020) and Ramchander et al. (2015) in rice, Vasko & Kryuchenko (2019) in sunflower and Olorumuaye et al. (2019) in groundnut.

Induced mutagenesis affects mitotic index or increases micronuclei number and pollen abnormalities (Savaskan & Atila, 1991). The present investigation envisaged a significant impact of dose response on pollen fertility. In general, SVPR1 was sensitive to both the mutagens for pollen fertility. However, a gradual reduction in pollen fertility percentage was observed with an increase in the dose of mutagens. The above results are in agreement with earlier works of Pradhan & Paul (2019b) in sesame and Manjunath et al. (2020) in groundnut. Reciprocally percentage of sterile pollen grains increased significantly and observed high at extreme dose ranges. In gamma rays, pollen sterility percentage increased from 34.23% to 64.03% and 15.5% to 55.67% for SVPR1 and TMV7 respectively. But in the case of EMS mutagenesis, a gradual increase in pollen sterility was observed than that of gamma rays in both the varieties. Pollen sterility of mutagens is the result of chromosomal aberrations, damage in the synthesis of genetic material (DNA or RNA) that leads to meiotic abnormalities (Ramchander et al., 2015). EMS owes its biological activity via the transfer of ethyl group by SNI (substitution, nucleophilic, unimolecular) or SN2 (substitution, nucleophilic, and bimolecular) (Rafi et al., 2016).

Chlorophyll mutation helps in assessing the effectiveness and efficiency of a mutagen to produce a desirable genetic variation with the least undesirable effects. Accordingly, the spectrum of chlorophyll mutants like chlorina, viridis, albino, and xantha were observed in individual treatments. Chlorophyll mutant displayed a deficit of chlorophyll in primary leaves which occurs up to 15 DAS (Stummann & Henningsen, 1980). Due to recessive nature, chlorophyll mutant appears in M1 generation and not in M0 generation. In the present study, Albino and Striata type of chlorophyll mutations were absent in both Gamma-ray and EMS treated seeds of TMV7 and SVPR1. The current study recorded the highest frequency of Xantha (6.42 & 5.74) in gamma rays treated seeds irrespective of varieties, TMV7 and SVPR1 respectively. Similarly, EMS treatment also exhibited the highest frequency of Xantha.

Lethal dose and sensitivity of sesame varieties to gamma and EMS (2.79) in TMV7 and Viridis (1.61) in SVPR1. At 0.60% concentration maximum frequency of Xantha (1.48 & 0.80) found in TMV7 and SVPR1 respectively. The maximum frequency of Xantha mutants was scored in gamma ray than EMS treatment which supports the work of Tamilzharasi et al. (2019). Among the three classes of mutants, frequency of Chlorina (1.79 & 1.07) was found least in EMS treatment of TMV7 and SVPR1 respectively. According to Ramadoss et al. (2014), the frequency of chlorophyll mutants was low in oil seed crops owing to their resistance to induced chlorophyll mutations. The total mutagenic frequency was found to be higher at 0.60% concentration of EMS (3.45 & 1.59) treatment of TMV7 and SVPR1 respectively. However, the present study advocates that the mutagenic frequency of chlorophyll mutant of gamma ray treatments was higher than EMS treatments of both the varieties. The results are in agreement with earlier reports by (Boureima et al., 2012; Anbarasan et al., 2015; Kumari et al., 2016b; Pradhan & Paul, 2019a). Gene mutations in terms of dose and efficiency are represented as an estimate of induced biological effects viz., lethality, injury, and sterility. It is measured in terms of mutagenic effectiveness. According to Gaul (1972), to achieve high mutagenic efficiency, the mutagenic effect must surpass the cell damage. The current study indicated that mutagenic effectiveness (ME) was maximum (0.68 & 0.72) at 250 Gy in both the varieties viz., TMV7 and SVPR1 respectively, while in EMS treatment, significant ME (0.85 & 0.83) was observed at 0.20% concentration in both the varieties viz., TMV7 and SVPR1 respectively. Among the mutants, Gamma rays exhibited higher mutagenic effectiveness compared to EMS. However, the mutagenic effectiveness decreases with an increase in gamma rays strength irrespective of genotypes. Similar findings on the decrease in mutagenic effectiveness with increasing doses of gamma rays and EMS were reported in cowpea (Priyadharshini et al., 2020), and EMS in pigeonpea (Etther et al., 2019).

Likewise, the present study remarked that the mutagenic efficiency of gamma rays was higher in two different doses viz., 450 Gy for injury and 250 Gy for lethality and sterility in both the varieties. However, the EMS treated TMV7 expressed higher mutagenic efficiency in all the three concentrations viz., 0.40% for injury (13.58) and 0.60% for lethality (7.26), and 0.20% for sterility (19.45). More interestingly it was noted that the mutagenic efficiency is proportional to the dose or strength of mutagens in two varieties of sesame studied. Contrastingly, a dose dependent decline in the efficiency was reported by Vinithashri et al. (2019). At higher doses of both the mutagens higher efficiency in terms of lethality was expressed which was not supporting the work of Majhi & Mogali (2020). However, higher efficiency to sterility was observed at the highest concentration of EMS and the lowest dose in gamma rays.

Furthermore, the present study provided insights into the mutagenic efficiencies of two mutagens in two sesame varieties (Figure 9). The response of SVPR to gamma rays in terms of higher injury and lethality rate and TMV by inducing sterility was noted. More precisely, EMS induced TMV7 mutants exhibited more injury and lethality than SVPR1. Overall, SVPR1 is highly sensitive to both the mutagens. Furthermore, the present study also demonstrated that the degree of sensitivity differs with genotypes on subjecting to mutation (Pérez-Jiménez et al., 2020).

Conclusions

The present study concludes that lower doses or concentrations of mutagens are more effective and efficient than higher doses. SVPR1 was highly sensitive to gamma rays whereas, TMV7 produced more viable mutations. Gamma induced mutagenesis created diverse chlorophyll mutants xantha, chlorine, and viridis. The pollen fertility and plant growth showed a linear fashion of reduction with an increase in dosage of mutagens, in both the varieties. Gamma rays have proven to be a possible and more efficient mutagen to induce essential economic mutations in TMV 7.

Figure 9 Mutation rate in terms of effectiveness (a) and efficiency (b) in M2 generation of two sesame varieties.
