Objective: To investigate associations between maternal rotating night shift work history before pregnancy and number of night shifts worked as nurses during pregnancy and offspring early-life through adolescence weight outcomes.

Methods: Over 4,000 children, enrolled in the Growing Up Today Study 2 between 2004 and 2013, and their mothers participating in the Nurses Health Study 2 were included in our analyses.

Results: Children of women who worked rotating night shifts before pregnancy were similar in birth weight and body size at age 5 compared to children of women without any night shift work before pregnancy. However, they had a modestly elevated risk of having overweight or obesity (relative risk (RR)=1.11, 95% confidence interval (CI): 1.02, 1.21), which was stronger for persistently having overweight or obesity during adolescence and early adulthood. Longer...
duration of rotating night shift work was not associated with any of these weight outcomes. Weight outcomes of children of women with versus without night shift work during pregnancy were similar, regardless of frequency of night shifts worked during pregnancy (all Ptrend>0.09).

**Conclusions:** Overall, nurses’ night shift work before or during pregnancy did not affect offspring weight outcomes. Future larger studies should explore these associations in more detail.

**Introduction**
Childhood and adolescent overweight and obesity have become a major public health concern in the United States and globally (1). Apart from childhood obesity’s more immediate co-morbidities, such as hyperinsulinaemia, poor glucose tolerance, and increased risk of type 2 diabetes and hypertension, it can also lead to an increased risk of heart disease and certain cancers later in life (2). Although environmental and behavioral factors, such as parental socio-economic status and children’s sedentary behavior, have been established as major determinants of childhood obesity (3), growing evidence suggests that several childhood and even adulthood health outcomes are, at least in part, programmed during pregnancy (4). Specifically, the maternal environment during pregnancy could influence fetal development and programming through alterations in the intrauterine environment (5).

Night shift work and the resulting disruption of social and biological rhythms have been linked to higher risk of several chronic diseases (6–8) as well as epigenetics alterations (9); in addition, night shift work during pregnancy has been linked to an increased risk of spontaneous abortions (10) and preterm delivery (11). Emerging evidence from animal models suggests that maternal circadian disruption can also induce long-term metabolic changes in the offspring (12–14). For example, exposing pregnant rats to reversals of the photoperiod twice every week throughout gestation and for the first week after birth showed no effect on litter size or birth weight; however, the progeny had an increased risk of adiposity, hyperleptinaemia and altered glucose metabolisms in adulthood (13).

Despite the high prevalence of shift work among US women during pregnancy (15), little is known about the potential health implications of pre-conception shift work and night shift work during pregnancy on offspring later in life. We therefore aimed to provide insights regarding the association of pre-conception night shift work history and shift work during pregnancy with offspring weight outcomes during childhood and adolescence using existing data from mother-child pairs participating in the Nurses Health Study II (NHS II) and Growing Up Today Study 2 (GUTS2).

**Methods**
**Study population**
The present study included mothers who were enrolled in the Nurses’ Health Study II (NHS II) and their children who participated in the Growing Up Today Study 2 (GUTS2). NHS II
is an ongoing prospective cohort study of US female nurses, which was established in 1989 when 116,430 female nurses aged 25–42 years responded to mailed questionnaires regarding their lifestyle, reproductive factors, and medical history. Follow-up questionnaires are mailed biennially to these nurses to update information on various risk factors and occurrence of major diseases. GUTS2 began in 2004 when NHS II participants who had previously reported to have children born between 1987 and 1995 were asked whether their children could participate in a follow-up study. After receiving maternal consent, invitation letters and questionnaires were sent to 17,280 children; 10,918 children returned their completed questionnaire. Follow-up questionnaires were sent to these children in 2006, 2008, 2011, and 2013 to update information on health, lifestyle factors, and growth indicators.

This study was approved by the Committee on the Use of Human Subject in Research at the Brigham and Women’s Hospital and the Harvard T.H. Chan School of Public Health (Boston, MA, USA). Returning the self-administered questionnaires was taken to imply informed consent in both cohorts.

**Ascertainment of night shift work among mothers**

**Mother’s history of rotating night shift before pregnancy**—The NHS II baseline questionnaire queried number of years having worked rotating night shifts (defined as “at least three nights per month in addition to working days or evenings in the respective month”). This information was updated in 1991 and 1993 to capture changes since the previous questionnaire, and again in 2001 to capture changes between 1993 and 1995 (the latest possible year of conception). Based on the return date of the respective NHS II questionnaire and birth date of the GUTS2 participant, we calculated the cumulative number of years a mother had worked rotating night shifts before conception for children born in 1989 or later.

**Mother’s night shift work exposure during pregnancy**: On the 2001 NHS II questionnaire, participants were asked whether they had experienced at least one pregnancy since 1993, had worked as a nurse during the most recent pregnancy, and would be willing to answer a supplemental questionnaire focused on occupational activities and exposures during this pregnancy. A supplemental questionnaire that queried shift work information among other occupational exposures during the most recent pregnancy since 1993 was mailed to those participants who answered ‘yes’ to all 3 questions. Women were asked to report usual working schedules and average number of night shifts per month for each trimester of pregnancy, with the following response options: none, 1–2 nights/month, 3–4 nights/month, 2–3 nights/week, or 4+ nights/week.

**Ascertainment of weight outcomes among offspring**

Information on offspring birth weight was obtained from the 2009 GUTS2 mothers’ questionnaire. Recall of offspring birth weight has been found to have excellent validity (16). On the baseline questionnaire in 2004, GUTS2 participants (age range 9–15 years) were asked to recall their body size at age 5 by selecting one of eight pictograms (“somatotypes”) that would most accurately represent their body shape at that age (ranging from 1=most lean to 8=most obese). Correlations between recalled somatotypes and BMI
measured at approximately the same ages have ranged from 0.53 to 0.75 among studies of adults (17). We created a binary outcome splitting at the median value of the distribution, and defined larger than median body sizes as cases. Information on weight and height was self reported on each GUTS2 questionnaire. To classify the offspring as having normal weight, overweight, or obesity, we used age-and sex specific cutoffs from the International Obesity Task Force (18) for participant aged 18 years or younger. Beyond age 18, overweight and obesity were defined using standard World Health Organization (WHO) cutoffs (i.e., body mass index (BMI, kg/m²) 25.0–29.9 overweight, BMI >30 obese). We defined participants as cases if they were classified as having either overweight or obesity at any given time during follow-up. Additionally, we defined participants as persistently having overweight or obesity if they were classified as having overweight or obesity at three consecutive questionnaire cycles. Figure 1 displays a timeline of exposure and outcomes assessments.

Ascertainment of covariates

Maternal age at delivery was derived calculating the difference between a mother’s birth date and that of her child. We utilized maternal dietary information assessed by the well-validated Willett food frequency questionnaire FFQ (19) using information from the 1991 NHS II questionnaire to calculate the Alternative Healthy Eating Index (AHEI) (20). Physical activity was assessed in 1989 and derived as metabolic equivalent (MET)-hours per week (21). Smoking status and BMI were queried biannually, and we selected the most recent value prior to conception of the first included child. Maternal chronotype was assessed in 2009. As a proxy for socioeconomic status, we used husband’s education, which was assessed in 1999.

Information on number of previous pregnancies, mode of delivery, pregnancy-related hypertension, pre-eclampsia, gestational diabetes, gestational age at delivery, and pregnancy multiplicity was extracted from the lifetime pregnancy assessment in 2009. We approximated pregnancy-related weight gain by taking the difference of the first BMI reported after delivery and the last recorded BMI before conception.

From the occupational supplemental questionnaire, we had trimester-specific information on smoking behavior, alcohol consumption, coffee consumption, and frequency of activities involving lifting or moving a physical load of 25 pounds or more during pregnancy.

Offspring Tanner stage of pubertal development was determined in 2004 on the GUTS2 baseline questionnaire, using a validated scale of pubic hair illustrations (22). Tanner stage ranges from 1 to 5, with stage 1 indicating prepubescence and stage 5 indicating maturity. Offspring sedentary behavior was summarized by the sum of the hours per week spent watching television, using the computer, surfing on the internet, and reading/doing homework over the past year, as reported in 2004. Detailed cutoffs used in all analyses are presented in the footnotes of Tables 2 and 3.
Statistical analysis

**Mother’s history of rotating night shift exposure before conception**—As pre-conception history of rotating night shift work could be assessed only after 1989, we excluded from the original cohort of 10,918 children the 4,721 children conceived before 1989. Among the remainder born after 1989, we further excluded twins and triplets (195 children, 87 mothers), children who were not born full term (less than 37 weeks) (1,182 children, 1,001 mothers), and mother-child pairs with missing exposure information (7 children, 6 mothers), leaving 4,813 children born to 4,044 mothers that comprised our analytic sample. Out of these 91% had at least 2 measurements of BMI at different time points.

We used generalized estimating equations (GEE) regression models specifying an exchangeable correlation structure with appropriate link functions (to account for within-sibling correlation in outcomes) to estimate mean differences (MD) and 95% confidence intervals (CIs) in offspring birth weight comparing none vs. any number of years of rotating night shift work, as well as across four data-driven categories of cumulative years of rotating night shift work before conception (none, <3 years, 3–5 years, and ≥6 years). We calculated relative risks (RR) and 95% CIs of offspring overweight/obesity and larger than median somatotype at age 5. We considered women without a history of rotating night shift work as the reference group. If the log-binomial model did not converge, we approximated RRs using Poisson models with robust variance estimators (23).

To utilize all available repeated measurements of offspring BMI, we applied linear mixed effects models with random intercepts and an unstructured covariance structure, which permit description of individual BMI trajectories across age and provide explicit tests for changes in BMI with age (24). In these analyses, we included terms for the exposure, covariates, offspring age, and the interaction of BMI and offspring age to evaluate differences in change in BMI over time across exposure groups.

In basic models, we adjusted for offspring sex, gestational age, and offspring age at baseline where appropriate (Basic model). We then considered the inclusion of several sets of potential confounding variables. First, we added maternal lifestyle characteristics (multivariate (MV) model 1), including smoking status before pregnancy, alternative healthy eating score (AHEI), physical activity, husband’s education, and parity. The addition of pregnancy-related factors including pre-eclampsia, gestational hypertension or diabetes, type of delivery, or change in maternal BMI before and after pregnancy did not markedly change effect estimates for shiftwork; therefore, these variables were not retained in the model. Lastly, we additionally adjusted for maternal BMI before pregnancy (MV model 2).

**Mother’s night shift work exposure during pregnancy**—For analyses assessing associations between night shift work during pregnancy and weight outcomes in the offspring, we identified all GUTS2 participants whose mothers had completed the supplemental pregnancy questionnaire between 2001 and 2003, resulting in 621 mother-child pairs with available information on pregnancy behaviors coupled with outcome information on the matching GUTS2 child. Of these, only full-term pregnancies were considered eligible (n=549). After further removal of mother-child pairs with missing
exposure information, 545 matching pairs were left for these analyses, whereof 89% had at least 2 repeated BMI measurements.

Using trimester-specific information on shift work frequency from the supplemental questionnaire, we calculated average number of night shifts per month throughout the entire pregnancy and created four categories (none, 2–9, and ≥10 night shifts per month); we also created the category of any number of night shifts per month.

We used standard generalized linear models with appropriate link functions (linear or log-binomial/Poisson), and added covariates following a similar approach as described above; we added history of night shift work to MV model 1. We also considered maternal pregnancy-related lifestyle factors (smoking behavior, alcohol consumption, coffee consumption, heavy lifting during first trimester), but did not retain these variables in our main models because they did not alter our estimates (data not shown).

Since previous studies found maternal BMI before pregnancy (25) to be one of the strongest predictors of offspring obesity during adolescence, in addition to adjustment for maternal BMI, we assessed effect modification for offspring weight outcomes by maternal BMI before pregnancy. Maternal chronotype was also found to potentially interact with work schedules in determining a person’s disease risk (26–28), hence we examined whether associations were different in children born to mothers with reportedly different chronotypes. In all analyses, missing indicators were created for missing covariate values. P values for interactions were obtained by testing the significance of multiplicative interaction terms in multivariable regression models. All statistical tests were two sided and were considered statistically significant at p<0.05. All analyses were conducted using SAS version 9.4 (SAS Institute, Cary, NC).

**Results**

**Mother’s history of rotating night shift work before pregnancy**

The 4,044 mothers were on average 33.4 (SD=3.6) years old when they gave birth to the children included in this analysis, and 65% of them reported ever having worked night shifts. At enrollment in GUTS2 in 2004, children were on average 11.7 (SD=1.2) years old. Overall, there were only modest differences in terms of maternal and offspring characteristics according to history of night shift work before pregnancy (Table 1a). Mothers who had worked night shifts for six years or more prior to conception of the first considered child were older, more likely to be past or current smokers, more adherent to a healthy diet (AHEI), and more physically active compared to women with no history of working night shifts. Also, offspring born to mothers with longer shift work history were more likely to be delivered by Cesarean section compared to those born to mothers without a history of shift work.

Overall, when we evaluated the associations between night shift work history before pregnancy with different weight outcomes across childhood and adolescence, we observed few differences in offspring weight comparing women with and without night shift work history (Table 2). Because differences between basic and multivariable models were small,
we describe results of fully-adjusted models only (i.e., MV models 1 including the most important confounding variables).

There were no associations of history of shiftwork with birth weight or somatotype at age 5 (Table 2). We did find a significantly higher risk of the offspring having overweight or obesity at any time during follow-up between 2004 and 2013 for mothers with any history of night shift work before pregnancy (MV RR_any 1.11, 95% CI, 1.02–1.21) when compared to mothers who never worked any night shifts (Table 2). The association was slightly more pronounced for the risk of persistently having overweight or obesity (MV RR_any 1.25, 95% CI, 1.00–1.56). However, there was no evidence of a dose-response association with increasing number of years of night shift work history (overweight/obese MV RR_extreme 1.07, 95% CI, 0.92–1.23; \( P_{\text{trend}} = 0.14 \); persistently overweight/obese MV RR_extreme 1.04, 95% CI, 0.71–1.52; \( P_{\text{trend}} = 0.17 \)). Longer duration of night shift work was not associated with changes in BMI with age (\( P_{\text{trend}} > 0.34 \)), but was associated with greater differences in mean BMI (\( P_{\text{trend}} < 0.01 \)) at baseline age (Table 2).

Since maternal diet was first assessed in 1991, we conducted a sensitivity analysis, including only children who were born after 1991, and results remained largely unchanged. In addition to adjustment for maternal BMI, we examined whether associations were different in children born to normal weight versus overweight or obese mothers. Formal tests for interactions revealed no significant effect modification (\( P_{\text{interaction}} \) for all outcomes >0.43). When examining whether associations were different in children born to mothers with reportedly different chronotypes (evening versus morning chronotypes), tests for interaction were not significant (all \( P_{\text{interaction}} > 0.44 \)).

**Maternal night shift work exposure during pregnancy**

Mothers included in the analyses exploring associations between night shift work during pregnancy and weight outcomes in their offspring were on average 34.7 (SD=3.3) years old when they gave birth to the children considered in this analysis, while these children were on average 10.0 (SD=0.6) years old at enrollment in GUTS2 (Table 1b). Of 545 women total, 110 women (20.2%) had worked night shifts during their pregnancy; they worked a mean of 6.0 (SD=4.8) night shifts per month (range 0.5 and 16 night shifts per month). Mothers reporting a higher number of night shifts were more likely to be either current or past smokers and more likely to describe themselves as definite evening chronotypes compared to women who did not work night shifts during pregnancy. They also exercised less and adhered to a less healthy diet than mothers with no night shift work during pregnancy.

Because estimates comparing results from base and multivariable-adjusted models were similar, we report results from the fully-adjusted models (MV model 1) only. We found no associations of night shiftwork during pregnancy with offspring birth weight, offspring somatotype at age 5, or relative risk of having overweight or obesity (Table 3); we were unable to examine the risk for persistently having overweight/obesity due to small numbers. We observed no differences in change in BMI at baseline age or over time across exposure groups.
When investigating potential effect modification by maternal BMI before pregnancy and mother’s chronotype using collapsed exposure categories (no night shifts, 1–5 nights/month and ≥6 nights per month), we did not find evidence for effect modification by maternal BMI ($P_{\text{interaction}}$ for all outcomes >0.13) or mother’s chronotype (all $P_{\text{interaction}}$ >0.28).

**Discussion**

In this study conducted among NHS II participants and their children enrolled in GUTS2, we found little evidence to support the hypothesis that history of night shift work before pregnancy or higher frequency of night shiftwork during pregnancy increases the risk of adverse weight outcomes in offspring during childhood and adolescence. Although we observed a modest association between a history of night shift work before pregnancy and offspring’s risk of having overweight or obesity, there was no dose-response association with longer duration of night shiftwork before pregnancy, and other weight outcomes were not related to mother’s shift work history before or during pregnancy.

Animal studies have suggested that perturbations at critical windows of development can cause life-long alterations in adiposity (29). More particularly, studies in rats have demonstrated that disruptions of the maternal photoperiod (i.e. exposing pregnant rats to chronic phase shifts, thereby mimicking shift work) negatively influences several metabolic parameters in the subsequent adult offspring, such as increased adiposity, hyperleptinaemia, hyperinsulinaemia, and reduced glucose tolerance and insulin sensitivity (12, 13, 30). A recent study modeling the impact of circadian disruption through mice with knockout clock genes did not find any of these associations. However, the authors suggested that previous findings might be explained by mediation through other pathways activated by circadian disruption that may not have been activated in the knockout gene experiment (14).

Previous meta-analyses consistently suggested no association between shift work exposure during pregnancy and pre-term birth (11, 31, 32) or low birth weight (31, 32), which is in line with our findings. We too did not observe any associations between shift work during pregnancy and birth weight even after adjusting for maternal pre-pregnancy night shift work history.

There are virtually no data regarding the potential long-term impacts of night shift work on weight outcomes after birth on children born to night shift workers. In our study, we observed no association between night shift work before or during pregnancy and offspring childhood somatotype. While a recent study has shown associations between nighttime feeding post partum and risk of overweight in early childhood (33), our study is the first to examine the relationship between circadian disruption before and during pregnancy and offspring early life weight outcomes. We did find a modestly increased risk for the offspring having overweight or obesity among offspring born to mothers who worked night shifts at any time before pregnancy, but the risk did not increase with longer duration of shiftwork. Night work during pregnancy did not further alter this association.

To the best of our knowledge, there is no inter-generational study thus far relating pre-conception shift work exposure and shift work during pregnancy to offspring outcomes.
during childhood and adolescence. Strengths of the current study include the longitudinal 
follow up of mothers and children, and detailed information on multiple potential 
confounders including shift work information during pregnancy. However, our study also 
has several limitations. We only had limited information on paternal factors. Nevertheless, in 
all our multivariable models we adjusted for husband’s education, a proxy for 
socioeconomic status and important confounding variable possibly affecting both maternal 
shift work exposure and offspring weight outcomes. Most mothers gave birth to respective 
child included in our study relatively late, i.e. in their early to mid 30ies. Hence, our results 
might not be generalizable to women giving birth at a younger age. Further, power was 
limited for some secondary analyses, including for mothers who continued to work night 
shifts throughout their pregnancies and in analyses differentiating having overweight or 
obesity. Other limitations include the retrospective assessment of body size at age 5 and the 
self-reported nature of maternal and offspring weight measures. Previous validation studies 
within the Harvard cohorts (34–38) have shown reasonable accuracy of self-reported 
maternal physical characteristics. Studies comparing measured vs. self-reported weight and 
height in US-adolescents (39–41) concluded that on average self-reports are a useful proxy. 
Self-reported history of rotating night shift work may have been misclassified, though likely 
randomly, hence biasing our results only towards the null. Further, this exposure has 
previously been linked to several chronic disease outcomes (e.g. 42).

Conclusion

In conclusion, while women’s night shiftwork before pregnancy was associated with a 
modestly increased risk of having overweight or obesity in their offspring through 
adolescence and young adulthood, there was no overall evidence that duration of night shift 
work before pregnancy or night shift work during pregnancy was associated with offspring 
adiposity in this study. Further studies with larger sample sizes and more detailed 
information on shift work exposure and outcomes into adulthood as well as more specific 
markers of metabolic alterations during adulthood are needed.

Acknowledgements

We thank the thousands of participants in the Growing Up Today Study 2, as well as their mothers.

Funding/Support: This study was supported by Center for Disease Control and Prevention/The National Institute 
for Occupational Safety and Health grant 5R01OH009803 (PI: Schernhammer E), as well as grants UM1 
CA176726 from the National Institute of Health.

Role of the Funder/Sponsor: The funding sources had no role in the design and conduct of the study; collection, 
management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; and 
decision to submit the manuscript for publication.

What is already known about this subject?

- Several childhood and/or adulthood health outcomes are probably in part programmed during pregnancy.
- Night shift work and the resulting disruption of social and biological rhythms is a risk factor for several chronic diseases and epigenetics alterations.
- Animal models suggest that maternal circadian disruption can induce long-term metabolic changes in the offspring.

What does the study add?

- First inter-generational study in humans relating pre-conception shift work exposure and shift work during pregnancy to offspring outcomes during childhood and adolescence.
- Children of women who worked rotating night shifts before pregnancy had a modestly elevated risk of having overweight in our study.
- Longer duration of rotating night shift work before pregnancy or night shift work during pregnancy were not associated with any of these weight outcomes.
Timeline of exposure and outcome assessment

**GUTS 2** (birth years 1987-1995)

| Year | 2004 | 2006 | 2008 | 2011 | 2013 |
|------|------|------|------|------|------|
| NHS 2 | 89 | 91 | 93 | 95 | 97 | 01 |

**Exposures**
- History of night shift work (total number of years in 1989, updates for the past 24 months thereafter)
- Pregnancy questionnaire, asking about night work during pregnancy for the most recent pregnancy since 1993

**Outcomes**
- Offspring self-report of height and weight used for BMI calculation
- Offspring self-report of somatotype at age 5
- GUTS2 mothers questionnaire, maternal reports of offspring birth weight

Figure 1.
Timeline of exposure and outcomes assessments in NHS2 and GUTS2 cohorts.
Table 1a. Maternal and Offspring Characteristics by Rotating Night Shift Work History Before pregnancy, for 4,044 Mothers of a Total of 4,813 Children, Born Between 1989 and 1995, Enrolled in the Growing Up Today Study 2.

| Characteristic                           | History of rotating night shift work | Never worked rotating night shifts (n=1,424) | <3 yrs (n=1,254) | 3–5 yrs (n=946) | ≥6 yrs (n=420) | Ever worked rotating night shifts (n=2,620) |
|------------------------------------------|--------------------------------------|---------------------------------------------|------------------|----------------|--------------|-------------------------------------------|

Abbreviations: CI, confidence interval; MD, mean difference; MV, multivariable model; RR, relative risk

<sup>a</sup>Adjusted for offspring gender (boy/girl) and gestational age ≥32 wks (yes/no)

<sup>b</sup>Additionally adjusted for maternal age at pregnancy, smoking status before pregnancy (never, current, past), alternative healthy eating score (quintiles), physical activity (METs hours/week; quintiles), husband’s education (less than 2yr college, 4yr college, grad school), parity (nulliparity, 1, 2, 3+ previous pregnancies)

<sup>c</sup>Additionally adjusted for BMI before pregnancy (<25, 25–29, ≥30 kg/m<sup>2</sup>)

<sup>d</sup>Overweight and obesity status defined according to the age-and sex specific cutoffs from the International Obesity Task Force.

<sup>e</sup>Persistently overweight or obese was defined as falling into that category in 3 consecutive follow-up cycles.

<sup>f</sup>All models are additionally adjusted for age at BMI measurement.
Table 3.

Adjusted Mean Differences (MD) and Relative Risks (RR) for Offspring Weight Outcomes Through Childhood and Adolescence by Categories of Average Number of Night Shifts Worked per Month During Pregnancy, Using Data From the Growing Up Today Study 2 from 2004 to 2013, Restricted to Singleton, Full Term Nirths (n=545).

| Category of Average Number of Night Shifts per Month | Participants | None | <3 nights/month | 3–9 nights/month | ≥10 nights/month | P trend | Any no. nights/month |
|------------------------------------------------------|--------------|------|----------------|-----------------|-----------------|---------|----------------------|
| MD | 95% CI | MD | 95% CI | MD | 95% CI | MD | 95% CI |
|------------------------------------------|-------------|-------|----------------|-----------------|-----------------|---------|----------------------|
| Basic model a | 0 (reference) | 352 | −54.19 | −209.96, 101.58 | −203.53 | −432.97, 25.92 | −46.27 | −210.25, 117.70 | 0.23 | −79.04 | −187.53, 29.45 |

Abbreviations: CI, confidence interval; MD, mean difference; MV, multivariable model; RR, relative risk

$^a$Adjusted for offspring gender (boy/girl) and gestational age ≥32 wks (yes/no)

$^b$Additionally adjusted for maternal age at pregnancy, smoking status before pregnancy (never, current, past), alternative healthy eating score (quintiles), physical activity (METs hours/week; quintiles), husband’s education (less than 2yr college, 4yr college, grad school), parity (nulliparity, 1, 2, ≥3 previous pregnancies), history of rotating night shift work (never, <3 yrs, 3–5 yrs, ≥6 yrs).

$^c$Additionally adjusted for BMI before pregnancy (<25, 25–29, ≥30 kg/m$^2$)

$^d$Overweight and obesity status defined according to the age-and sex specific cutoffs from the International Obesity Task Force.

$^f$All models are additionally adjusted for age at BMI measurement.
