Abstract

Gradient-based approximate inference methods, such as Stein variational gradient descent (SVGD) \cite{liu2016stein}, provide simple and general purpose inference engines for differentiable continuous distributions. However, existing forms of SVGD cannot be directly applied to discrete distributions. In this work, we fill this gap by proposing a simple yet general framework that transforms discrete distributions to equivalent piecewise continuous distributions, on which the gradient-free SVGD is applied to perform efficient approximate inference. The empirical results show that our method outperforms traditional algorithms such as Gibbs sampling and discontinuous Hamiltonian Monte Carlo on various challenging benchmarks of discrete graphical models. We demonstrate that our method outperforms traditional algorithms such as Gibbs sampling and discontinuous Hamiltonian Monte Carlo on various challenging benchmarks of discrete graphical models. We design a simple yet general framework for transforming discrete distributions to equivalent continuous distributions, which is specially tailored for our purpose, so that we can conveniently construct differentiable surrogates when applying GF-SVGD.

We apply our proposed algorithm to a wide range of discrete distributions, such as Ising models and re-

1 INTRODUCTION

Discrete probabilistic models provide a powerful framework for capturing complex phenomena and patterns, especially in conducting logic and symbolic reasoning. However, probabilistic inference of high dimensional discrete distribution is in general NP-hard and requires highly efficient approximate inference tools.

Traditionally, approximate inference in discrete models is performed by either Gibbs sampling and Metropolis-Hastings algorithms, or deterministic variational approximation, such as belief propagation, mean field approximation and variable elimination methods \cite{pearl1988probabilistic, wainwright2008graphical}. However, both of these two types of algorithms have their own critical weaknesses: Monte Carlo methods provides theoretically consistent sample-based (or particle) approximation, but are typically slow in practice, while deterministic approximation are often much faster in speed, but does not provide progressively better approximation like Monte Carlo methods offers. New methods that integrate the advantages of the two methodologies is a key research challenge; see, for example, \cite{ Freedman1965, liu2016stein, liu2018kernelized}.

Recently, Stein variational gradient descent (SVGD, \cite{liu2016stein}) provides a combination of deterministic variational inference with sampling, for the case of continuous distributions. The idea is to directly optimize a particle-based approximation of the intractable distributions by following a functional gradient descent direction, yielding both practically fast algorithms and theoretical consistency. However, because SVGD only works for continuous distributions, a key open question is if it is possible to exploit it for more efficient inference of discrete distributions.

In this work, we leverage the power of SVGD for inference of discrete distributions. Our idea is to transform discrete distributions to piecewise continuous distributions, on which gradient-free SVGD, a variant of SVGD that leverages a differentiable surrogate distribution to sample non-differentiable continuous distributions, is applied to perform inference. To do so, we design a simple yet general framework for transforming discrete distributions to equivalent continuous distributions, which is specially tailored for our purpose, so that we can conveniently construct differentiable surrogates when applying GF-SVGD.
stricted Boltzmann machines. We find that our proposed algorithm significantly outperforms traditional inference algorithms for discrete distributions. In particular, our algorithm is shown to provide a promising tool for ensemble learn of binarized neural network (BNN) in which both weights and activation functions are binarized. Learning BNNs have been shown to be highly challenging, because standard backpropagation cannot be applied. We cast learning BNN as a Bayesian inference problem of drawing a set of samples (which forms an ensemble predictor) of the posterior distribution of weights, and apply our SVGD-based algorithm for efficient inference. We show that our method outperforms other widely-used ensemble methods such as bagging and AdaBoost in achieving highest accuracy with the same ensemble size on the binarized AlexNet.

In addition, we develop a new goodness-of-fit test for intractable discrete distributions based on gradient-free kernelized Stein discrepancy on the transformed continuous distributions using the simple transform constructed before. Our proposed algorithm outperforms discrete KSD (DKSD, [27]) and maximum mean discrepancy (MMD, [3]) on various benchmarks.

Related work on Sampling The idea of transforming the inference of discrete distributions to continuous distributions has been widely studied, which, however, mostly concentrates on leveraging the power of Hamiltonian Monte Carlo (HMC); see, for example, [11 22 23 25 7]. Our framework of transforming discrete distributions to piecewise continuous distribution is similar to [22], but is more general and tailored for the application of GF-SVGD. Related work on goodness-of-fit test Our goodness-of-fit testing is developed from KSD [13 3], which works for differentiable continuous distributions. Some forms of goodness-of-fit tests on discrete distributions have been recently proposed such as [21 5 25]. But they are often model-specialized and require the availability of the normalization constant. [27 8] is related to ours and will be empirically compared.

Outline Our paper is organized as follows. Section 2 introduces GF-SVGD and GF-KSD. Section 3 proposes our main algorithms for sampling and goodness-of-fit testing on discrete distributions. Section 4 provides empirical experiments. We conclude the paper in Section 5.

2 STEIN VARIATIONAL GRADIENT DESCENT

We first introduce SVGD [19], which provides deterministic sampling but requires the gradient of the target distribution. We then introduce gradient-free SVGD and gradient-free KSD [10], which can be applied to the target distribution with unavailable or intractable gradient.

Let \( p(x) \) be a differentiable density function supported on \( \mathbb{R}^d \). The goal of SVGD is to find a set of samples \( \{x_i\}_{i=1}^n \) (called ”particles”) to approximate \( p \) in the sense that

\[
\lim_{n \to \infty} \frac{1}{n} \sum_{i=1}^n f(x_i) = \mathbb{E}_p[f(x)],
\]

for general test functions \( f \). SVGD achieves this by starting with a set of particles \( \{x_i\}_{i=1}^n \) drawn from any initial distribution, and iteratively updates the particles by

\[
x_i \leftarrow x_i + \epsilon \phi^*(x_i), \quad \forall i = 1, \ldots, n,
\]

where \( \epsilon \) is a step size, and \( \phi : \mathbb{R}^d \to \mathbb{R}^d \) is a velocity field chosen to drive the particle distribution closer to the target. Assume the distribution of the particles at the current iteration is \( q \), and \( q_{\epsilon \phi} \) is the distribution of the updated particles \( x' = x + \epsilon \phi(x) \). The optimal choice of \( \phi \) can be framed as the following optimization problem:

\[
\phi^* = \arg\max_{\phi \in \mathcal{G}} \left\{ -\frac{d}{d\epsilon} \text{KL}(q_{\epsilon \phi} \| p) \bigg|_{\epsilon=0} = \mathbb{E}_{x \sim q}[A_p^\top \phi(x)] \right\},
\]

with \( A_p^\top \phi(x) = \nabla_x \log p(x)^\top \phi(x) + \nabla_x^\top \phi(x), \)

where \( \mathcal{F} \) is a set of candidate velocity fields, \( \phi \) is chosen in \( \mathcal{F} \) to maximize the decreasing rate on the KL divergence between the particle distribution and the target, and \( A_p \) is a linear operator called Stein operator and is formally viewed as a column vector similar to the gradient operator \( \nabla_x \).

In SVGD, \( \mathcal{F} \) is chosen to be the unit ball of a vector-valued reproducing kernel Hilbert space (RKHS) \( H = H_0 \times \cdots \times H_0 \), where \( H_0 \) is an RKHS formed by scalar-valued functions associated with a positive definite kernel \( k(x, x') \), that is, \( \mathcal{F} = \{ \phi \in H : ||\phi||_H \leq 1 \} \). This choice of \( \mathcal{F} \) makes it possible to consider velocity fields in infinite dimensional function spaces while still obtaining computationally tractable solution.

[19] showed that [2] has a simple closed-form solution:

\[
\phi^*(x') \propto \mathbb{E}_{x \sim q}[A_p k(x, x')],
\]

where \( A_p \) is applied to variable \( x \). With the optimal form \( \phi^*(x') \), the objective in [2] equals to

\[
\mathcal{D}_p(q \| p) \overset{def}{=} \max_{\phi \in \mathcal{G}} \left\{ \mathbb{E}_{x \sim q}[A_p^\top \phi(x)] \right\},
\]

where \( \mathcal{D}_p(q \| p) \) is the kernelized Stein discrepancy (KSD) defined in [18 3].
In practice, SVGD iteratively update particles \{x_i\} by
\[ x_i \leftarrow x_i + \frac{\Delta}{n} \Delta x_i, \] where,
\[
\Delta x_i = \sum_{j=1}^{n} \left[ \nabla \log p(x_j) k(x_j, x_i) + \nabla_x k(x_j, x_i) \right]. \quad (5)
\]

**Gradient-free SVGD** GF-SVGD [10] extends SVGD to the setting when the gradient of the target distribution does not exist or is unavailable. The key idea is to replace it with the gradient of the differentiable surrogate \( \rho(x) \), whose gradient can be calculated easily, and leverage it for sampling from \( p(x) \) using a mechanism similar to importance sampling.

The derivation of GF-SVGD is based on the following key observation,
\[
w(x)A_p^\top \phi(x) = A_p^\top (w(x)\phi(x)). \quad (6)
\]
where \( w(x) = \rho(x)/p(x) \). Eq. (6) indicates that the Stein operation w.r.t. \( p \), which requires the gradient of the target \( p \), can be transferred to the Stein operator of a surrogate distribution \( \rho \), which does not depend on the gradient of \( p \). Based on this observation, GF-SVGD modifies to optimize the following object,
\[
\phi^* = \arg \max_{\phi \in \mathbf{R}} \{ E_q[A_p^\top (w(x)\phi(x))] \}. \quad (7)
\]

Similar to the derivation in SVGD, the optimization problem [7] can be analytically solved; in practice, GF-SVGD derives a gradient-free update as \( x_i \leftarrow x_i + \frac{\Delta}{n} \Delta x_i \), where
\[
\Delta x_i \propto \sum_{j=1}^{n} w_j \left[ \nabla \log p(x_j) k(x_j, x_i) + \nabla_x k(x_j, x_i) \right], \quad (8)
\]
which replaces the true gradient \( \nabla \log p(x) \) with a surrogate gradient \( \nabla \log \rho(x) \), and then uses an importance weight \( w_j := \rho(x_j)/p(x_j) \) to correct the bias introduced by the surrogate. [10] observed that GF-SVGD can be viewed as a special case of SVGD with an “importance weighted” kernel, \( k(x, x') = \rho(x)/p(x)k(x, x')\rho(x')/p(x') \). Therefore, GF-SVGD inherits the theoretical justifications of SVGD [10]. GF-SVGD is proposed to apply to continuous-valued distributions.

**Gradient-Free KSD** As shown in [10], the optimal decrease rate of the KL divergence in (2) is
\[
\mathcal{D}^2(q, p) = E_{x, x' \sim q}[w(x)k(x, x')w(x')], \quad (9)
\]
where \( k(x, x') \) is defined as,
\[
\begin{align*}
\kappa(x, x') &= s_\rho(x)^\top k(x, x')s_\rho(x') + s_\rho(x)^\top \nabla_x k(x, x') \\
&+ s_\rho(x')^\top \nabla_{x'} k(x, x') + \nabla_x \cdot \nabla_{x'} k(x, x'),
\end{align*}
\]
where \( s_\rho(x) \) is score function of the surrogate \( \rho(x) \). Note that in order to estimate the KSD between \( q \) and \( p \), we only need samples \{x_i\} from \( q \), \( w(x) \) and the gradient of \( \rho(x) \). Therefore, we obtain a form of *gradient-free KSD*.

The goal of this paper is to develop a tool for goodness-of-fit testing on discrete distribution based on gradient-free KSD and a method for sampling on discrete-valued distributions by exploiting gradient-free SVGD.

### 3 MAIN METHOD

This section introduces the main idea of this work. We first provide a simple yet powerful way to transform the discrete-valued distributions to the continuous-valued distributions. Then we leverage the gradient-free SVGD to sample from the transformed continuous-valued distributions. Finally, we leverage the constructed transform to perform goodness-of-fit test on discrete distributions.

Assume we are interested in sampling from a given discrete distribution \( p_c(z) \), defined on a finite discrete set \( Z = \{a_1, \ldots, a_K\} \). We may assume each \( a_i \) is a \( d \)-dimensional vector of discrete values. Our idea is to construct a piecewise continuous distribution \( p_c(x) \) for \( x \in \mathbb{R}^d \), and a map \( \Gamma : \mathbb{R}^d \to Z \), such that the distribution of \( z = \Gamma(x) \) is \( p_c(x) \) when \( x \sim p_c \). In this way, we can apply GF-SVGD on \( p_c \) to get a set of samples \{\( x_i \)\}_{i=1}^n \sim p_c and apply transform \( z_i = \Gamma(x_i) \) to get samples \{\( z_i \)\}_{i=1}^n \sim p_c.

**Definition 1.** A piecewise continuous distribution \( p_c \) on \( \mathbb{R}^d \) and map \( \Gamma : \mathbb{R}^d \to Z \) is called to form a continuous parameterization of \( p_c \), if \( z = \Gamma(x) \) follows \( p_c(x) \) when \( x \sim p_c \).

This definition immediately implies the following result.

**Proposition 2.** The continuous distribution \( p_c \) and \( \Gamma \) form a continuous parameterization of discrete distribution \( p_c \) on \( Z = \{a_1, \ldots, a_K\} \), iff
\[
p_c(a_i) = \int_{\mathbb{R}^d} p_c(x) \mathbb{I}(a_i = \Gamma(x)) dx, \quad (11)
\]
for all \( i = 1, \ldots, K \). Here \( \mathbb{I}(\cdot) \) is the 0/1 indicator function, \( \mathbb{I}(t) = 0 \) iff \( t = 0 \) and \( \mathbb{I}(t) = 1 \) if otherwise.

**Constructing Continuous Parameterizations**

Given a discrete distribution \( p_c \), there are many different continuous parameterizations. Because exact samples of \( p_c \) yield exact samples of \( p_c \) following the
Algorithm 1 GF-SVGD on Discrete Distributions

Goal: Approximate a given distribution $p_\ast(x)$ (input) on a finite discrete set $Z$.

1) Decide a base distribution $p_0(x)$ on $\mathbb{R}^d$ (such as Gaussian distribution), and a map $\Gamma: \mathbb{R}^d \rightarrow Z$ which partitions $p_0$ evenly. Construct a piecewise continuous distribution $p_c$ by (15):

$$p_c(x) \propto p_0(x)p_\ast(\Gamma(x)).$$

2) Construct a differentiable surrogate of $p_c(x)$, for example, by $p(x) \propto p_0(x)$ or $p(x) \propto p_0(x)p_\ast(\Gamma(x))$, where $p_\ast$ and $\Gamma$ are smooth approximations of $p_\ast$ and $\Gamma$, respectively.

3) Run gradient-free SVGD on $p_c$ with differentiable surrogate $p$: starting from an initial $\{x_i\}_{i=1}^n$ and repeat

$$x_i \leftarrow x_i + \frac{1}{n} \sum_{j=1}^n w_j (\nabla p(x_j)k(x_j, x_i) + \nabla x_k(x_j, x_i)).$$

where $w_j = p(x_j)/p_0(x_j)$, and $k(x, x')$ is a positive definite kernel.

4) Calculate $z_i = \Gamma(x_i)$ and output sample $\{z_i\}_{i=1}^n$ for approximating discrete target distribution $p_\ast(z)$.

 definiton, we should prefer to choose continuous parameterizations whose $p_c$ is easy to sample using continuous inference method, GF-SVGD in particular in our method. However, it is generally difficult to find a theoretically optimal continuous parameterization, because it is difficult to quantitatively the notation of difficulty of approximate inference by particular algorithms, and deriving the mathematically optimal continuous parameterization may be computationally demanding and requires analysis in a case by case basis.

In this work, we introduce a simple yet general framework for constructing continuous parameterizations. Our goal is not to search for the best possible continuous parameterization for individual discrete distribution, but rather to develop a general-purpose framework that works for a wide range of discrete distributions and can be implemented in an automatic fashion. Our method also naturally comes with effective differentiable surrogate distributions with which GF-SVGD can perform efficiently.

Even Partition Our method starts with choosing a simple base distribution $p_0$, which can be the standard Gaussian distribution. We then construct a map $\Gamma$ that $evenly$ partition $p_0$ into several regions with equal probabilities.

**Definition 3.** A map $\Gamma: Z \rightarrow \mathbb{R}^d$ is said to even partition $p_0$ if we have

$$\int_{\mathbb{R}^d} p_0(x)I[a_i = \Gamma(x)]dx = \frac{1}{K},$$

for $i = 1, \ldots K$. Following [11], this is equivalent to saying that $p_0$ and $\Gamma$ forms a continuous relaxation of the uniform distribution $q_\ast(a_i) = 1/K$.

For simple $p_0$ such as standard Gaussian distributions, it is straightforward to construct even partitions using the quantiles of $p_0(x)$. For example, in the one dimensional case ($d = 1$), we can evenly partition any continuous $p_0(x)$, $x \in \mathbb{R}$ by

$$\Gamma(x) = a_i \quad \text{if} \quad x \in [\eta_{i-1}, \eta_i),$$

where $\eta_i$ denotes the $i/K$-th quantile of distribution $p_0$. In multi-dimensional cases ($d > 1$) and when $p_0$ is a product distribution:

$$p_0(x) = \prod_{i=1}^d p_{0,i}(x_i).$$

One can easily show that an even partition can be constructed by concatenating one-dimensional even partition: $\Gamma(x) = (\Gamma_1(x_1), \ldots, \Gamma_d(x_d))$, where $x = (x_1, \ldots, x_d)$ and $\Gamma_i(\cdot)$ an even partition of $p_{0,i}$.

A particularly simple case is when $z$ is a binary vector, i.e., $Z = \{\pm 1\}^d$, in which case $\Gamma(x) = \text{sign}(x)$ even partitions any distribution $p_0$ that is symmetric around the origin.

Weighting the Partitions Given an even partition of $p_0$, we can conveniently construct a continuous parameterization of an arbitrary discrete distribution $p_\ast$ by weighting each bin of the partition with corresponding probability in $p_\ast$, that is, we may construct $p_c(x)$ by

$$p_c(x) \propto p_0(x)p_\ast(\Gamma(x)),$$
where $p_0(x)$ is weighted by $p_*(\Gamma(x))$, the probability of the discrete value $z = \Gamma(x)$ that $x$ maps.

**Proposition 4.** Assume $\Gamma$ is an even partition of $p_0(x)$, and $p_*(x) \propto p_0(x)p_*(\Gamma(x))$, then $(p_*, \Gamma)$ is a continuous parameterization of $p_*$. 

**Constructing Differentiable Surrogate**

Given such a transformation, it is also convenient to construct differentiable surrogate $\rho$ of $p_c$ in (15) for GF-SVGD. by simply removing $p_*(\Gamma(x)))$ (so that $\rho = p_0$), or approximate it with some smooth approximation, based on properties of $p_*$ and $\Gamma$, that is,

$$
\rho(x) = p_0(x)\hat{p}_*(\hat{\Gamma}(x)),
$$

where $\hat{\Gamma}()$ denotes a smooth approximation of $\Gamma(x)$, and $\hat{p}_*$ is a continuous extension of $p_*(x)$ to the continuous domain $\mathbb{R}^d$. See Algorithm 1 for the summary of our main procedure.

**Illustration Using 1D Categorical Distribution**

Consider the 1D categorical distribution $p_*$ shown in Fig. 1 which takes $\{-1, 0, 1\}$ with probabilities $\{0.25, 0.45, 0.3\}$, respectively. We use the standard Gaussian base $p_0$ (blue dash), and obtain a continuous parameterization $p_c$ using (15), in which $p_0(x)$ is weighted by the probabilities of $p_*$ in each bin. Note that $p_c$ is a piecewise continuous distribution. In this case, we may naturally choose the base distribution $p_0$ as the differentiable surrogate function to draw samples from $p_c$ when using GF-SVGD.

**Algorithm 2 Goodness-of-fit testing (GF-KSD)**

**Input:** Sample $\{z_i\}_{i=1}^n \sim q_c$ and its corresponding continuous-valued $\{x_i\}_{i=1}^n \sim q_c$, and null distribution $p_c$. Base function $p_0(x)$ and bootstrap sample size $m$.

**Goal:** Test $H_0 : q_c = p_c$ vs. $H_1 : q_c \neq p_c$.

1. Compute test statistics $\hat{S}$ by (18).
2. Compute $m$ bootstrap sample $\hat{S}^b$ by (19).
3. Reject $H_0$ with significance level $\alpha$ if the percentage of $\{\hat{S}^b\}_{i=1}^m$ that satisfies $\hat{S}^b > \hat{S}$ is less than $\alpha$.

**3.1 Goodness-of-fit Test on Discrete Distribution**

Our approach implies a new method for goodness of fit test of discrete distributions, which we now explore. Given i.i.d. samples $\{x_i\}_{i=1}^n$ from an unknown distribution $q_c$, and a candidate discrete distribution $p_*$, we are interested in testing $H_0 : q_c = p_*$ vs. $H_1 : q_c \neq p_*$. Our idea is to transform the testing of discrete distributions $q_c = p_*$ to their continuous parameterizations. Let $\Gamma$ be a even partition of a base distribution $p_0$, and $p_c$ and $q_c$ are the continuous parameterizations of $p_*$ and $q_*$ following our construction, respectively, that is,

$$
p_c(x) \propto p_0(x)p_*(\Gamma(x)), \quad q_c(x) \propto p_0(x)q_*(\Gamma(x)).
$$

Obviously, $p_c = q_c$ implies that $p_* = q_*$ (following the definition of continuous parameterization). This allows us to transform the problem to a goodness-of-fit test of continuous distributions, which we is achieved by testing if the gradient-free KSD $\rho$ equals zero, $H_0 : q_c = p_c$ vs. $H_1 : q_c \neq p_c$.

In order to implement our idea, we need to convert the discrete sample $\{z_i\}_{i=1}^n$ from $q_c$ to a continuous sample $\{x_i\}_{i=1}^n$ from the corresponding (unknown) continuous distribution $q_c$. To achieve, note that when $x \sim q_c$, and $z = \Gamma(x)$, the posterior distribution $x$ of giving $z = a_i$ equals

$$
q(x \mid z = a_i) \propto p_0(x)\hat{p}_*(\hat{\Gamma}(\hat{x})) = \rho(x) \hat{p}_*(\hat{\Gamma}(\hat{x})),
$$

which corresponds to sampling a truncated version of $p_0$ inside the region defined $\{x : \Gamma(x) = a_i\}$. This can be implemented easily for the simple choices of $p_0$ and $\Gamma$. For example, in the case when $p_0$ is the product distribution in (11) and $\Gamma$ is the concatenation of the quantile-based partition in (13), we can sample $x \mid z = a_i$ by sample $y$ from Uniform$(\eta_{i-1}, \eta_i)$ and obtain $x$ by $x = F^{-1}(y)$ where $F^{-1}$ is the inverse CDF of $p_0$. To better understand how to transform the discrete data $\{z_i\}_{i=1}^n$ to continuous samples $\{x_i\}_{i=1}^n$, please refer to Appendix C for detail.

With the continuous data, the problem is reduced to testing if $\{x_i\}_{i=1}^n \sim q_c$ is drawn from $p_c$. We achieve this using gradient-free KSD, similar to [13][3]. In particular, using the surrogate $\rho(x)$ in (16), the GF-KSD between the transformed distributions $q_c$ and $p_c$ is

$$
S(q_c, p_c) = \mathbb{E}_{x, x' \sim q_c}[w(x)\kappa_\rho(x, x')w(x')], \quad (17)
$$

where $\kappa_\rho$ is defined in (10). Under mild conditions [13], it can similarly derived that $S(q_c, p_c) = 0$ iff $q_c = p_c$.

With $\{x_i\}_{i=1}^n$ from $q_c$, the GF-KSD between $q_c$ and $p_c$ can be estimated by the U-statistics,

$$
\hat{S}(q_c, p_c) = \frac{1}{(n-1)n} \sum_{1 \leq i < j \leq n} w(x_i)\kappa_\rho(x_i, x_j)w(x_j), \quad (18)
$$

In practice, we can employ the U-statistics $\hat{S}(q_c, p_c)$ to perform the goodness-of-fit test based on the similar result from [13][3], which replaces their KSD with gradient-free KSD in (17) and follow other procedure.

**Bootstrap Sample**

The asymptotic distribution of $\hat{S}(q_c, p_c)$ under the hypothesis cannot be evaluated. In order to perform goodness-of-fit test,
we draw random multinomial weights \( u_1, \cdots, u_n \sim \text{Multi}(n; 1/n, \cdots, 1/n) \), and calculate
\[
\hat{S}^*(q_c, p_c) = \sum_{i \neq j} (u_j - 1/n) w(x_i) \kappa_{p_c}(x_i, x_j) w(x_j) (u_j - 1/n).
\]
(19)

We repeat this process by \( m \) times and calculate the critical values of the test by taking the \((1-\alpha)\)-th quantile of the bootstrapped statistics \( \{\hat{S}^*(q_c, p_c)\} \). The whole procedure is summarized in Alg. 2.

4 EXPERIMENTS

We apply our algorithm to a number of large scale discrete distributions to demonstrate its empirical effectiveness. We start with illustrating our algorithm on sampling from a simple one-dimensional categorical distribution. We then apply our algorithm to sample from discrete Markov random field, Bernoulli restricted Boltzmann machine. Then we apply our method to learn ensemble models of binarized neural networks (BNN). Finally, we perform experiments on goodness-of-fit test.

4.1 Statistical Models

Ising Model The Ising model [13] is widely used in Markov random field. Consider an (undirected) graph \( G = (V, E) \), where each vertex \( i \in V \) is associated with a binary spin, which consists of \( z = (z_1, \cdots, z_d) \). The probability mass function is
\[
p(z) = \frac{1}{Z} \prod_{(i,j) \in E} \sigma_{i,j} z_i z_j, \quad z_i \in \{-1, 1\}, \quad \sigma_{i,j} \text{ is edge potential and } Z \text{ is normalization constant, which is infeasible to calculate when } d \text{ is high.}
\]

Bernoulli restricted Boltzmann Machine (RBM) Bernoulli RBM [11] is an undirected graphical model consisting of a bipartite graph between visible variables \( z \) and hidden variables \( h \). In a Bernoulli RBM, the joint distribution of visible units \( z \in \{-1, 1\}^d \) and hidden units \( h \in \{-1, 1\}^M \) is given by
\[
p(z, h) \propto \exp(-E(z, h))
\]
where \( E(z, h) = -(z^T W h + z^T b + h^T c) \), \( W \in \mathbb{R}^{d \times M} \) is the weight, \( b \in \mathbb{R}^d \) and \( c \in \mathbb{R}^M \) are the bias. Marginalizing out the hidden variables \( h \), the probability mass function of \( z \) is given by \( p(z) \propto \exp(-E(z)) \), with free energy \( E(z) = -z^T b - \sum_k \log(1 + \varphi_k) \), where \( \varphi_k = \exp(W_{k*}^T z + c_k) \) and \( W_{k*} \) is the \( k \)-th row of \( W \).

4.2 Investigation of the Choice of Transform

There are many choices of the base function \( p_0 \) and the transform. We investigate the optimal choice of the transform on categorical distribution in Fig. 2.

In Fig. 2(b, c, d), the base is chosen as \( p_0(x) = \sum_{\mu=1}^d \mu \mathcal{N}(x; \mu_1, 1) \) for different \( \mu \). The base \( p_0(x) \) in Fig. 2(a) can be seen as \( \mu = (0, 0, 0, 0, 0, 0) \). We observe that with simple Gaussian base in Fig. 2(a), the transformed target is easier to draw samples, compared with the multi-modal target in Fig. 2(c, d). This suggests that Gaussian base \( p_0 \) is a simple but powerful choice as its induced transformed target is easy to sample by GF-SVGD.

4.3 Experiments on Sampling

Ising Model We evaluate the mean square error (MSE) for estimating the mean value \( \mathbb{E}_p[x] \) in each dimension. As shown in Section 3, it is easy to map \( z \) to the piecewise continuous distribution of \( x \) in each dimension. We take \( \Gamma(x) = \text{sign}(x) \), with the transformed target \( p_\rho(x) \propto p_0(x)p_\rho(\text{sign}(x)) \). The base function \( p_0(x) \) is taken to be the standard Gaussian distribution on \( \mathbb{R}^d \). We apply GF-SVGD to sample from \( p_c(x) \) with the surrogate \( \rho(x) = p_0(x) \). The initial particles \( \{x_i\} \) is sampled from \( \mathcal{N}(-2, 1) \) and update \( \{x_i\} \) by 500 iterations. We obtain \( \{x_i\} \) by \( z_i = \Gamma(x_i) \), which approximates the target model \( p_\rho(z) \). We compared our algorithm with both exact Monte Carlo (MC) and Gibbs sampling which is iteratively sampled over each coordinate and use same initialization (in terms of \( z = \Gamma(x) \)) and number of iterations as ours.

Fig. 3(a) shows the log MSE over the log sample size. With fixed \( \sigma_\rho \) and \( \sigma_p \), our method has the smallest MSE and the MSE has the convergence rate \( \mathcal{O}(1/n) \). The correlation \( \sigma_\rho \) indicates the difficulty of inference. As \( |\sigma_\rho| \) increases, the difficulty increases. As shown in Fig. 3(b), our method can lead to relatively less MSE in the chosen range of correlation. It is interesting to observe that as \( \sigma_\rho \to 0 \), our method significantly outperforms MC and Gibbs sampling.

Bernoulli Restricted Boltzmann Machine The base function \( p_0(x) \) is the product of the p.d.f. of the standard Gaussian distribution over the dimension \( d \). Applying the map \( z = \Gamma(x) = \text{sign}(x) \), the transformed piecewise continuous target is \( p_\rho(x) \propto p_0(x)p_\rho(\text{sign}(x)) \). Different from previous example, we construct a simple and more powerful surrogate distribution \( \rho(x) \propto \tilde{p}(\sigma(y)p_0(x) \) where \( \tilde{p}(\sigma(y)) \) is differentiable approximation of \( p_\rho \) and \( \sigma \) is defined as
\[
\sigma(x) = \frac{2}{1 + \exp(-x)} - 1,
\]
and \( \sigma(x) \) approximates \( \text{sign}(x) \). Intuitively, it relaxes \( p_\rho \) to a differentiable surrogate with tight approximation.
We compare our algorithm with Gibbs sampling and discontinuous HMC(DMHC, [22]). In Fig. 4(a) W is drawn from \( N(0,0.05) \), both \( b \) and \( c \) are drawn from \( N(0,1) \). With \( 10^5 \) iterations of Gibbs sampling, we draw 500 parallel chains to take the last sample of each chain to get 500 ground-truth samples. We run Gibbs, DHMC and GF-SVGD at 500 iterations for fair comparison. In Gibbs sampling, \( p(z \mid h) \) and \( p(h \mid z) \) are iteratively sampled. In DHMC, a coordinate-wise integrator with Laplace momentum is applied to update the discontinuous states. We calculate MMD [8] between the ground truth sample and the sample drawn by different methods. The kernel in MMD is the exponentiated Hamming kernel from [27], defined as, \( k(z, z') = \exp(-H(z, z')) \), where \( H(z, z') := \frac{1}{2} \sum_{i=1}^{d} \mathbb{I}_{\{z_i \neq z'_i\}} \) is normalized Hamming distance. We perform experiments by fixing \( d = 100 \) and varying sample size in Fig. 4(a) and fixing \( n = 100 \) and varying \( d \). Fig. 4(a) indicates that the samples from our method match the ground truth samples better in terms of MMD. Fig. 4(b) shows that the performance of our method is least sensitive to the dimension of the model than that of Gibbs and DHMC. Both Fig. 4(a) and Fig. 4(b) show that our algorithm converges fastest.

### 4.4 Learning Binarized Neural Network

We slightly modify our algorithm to train binarized neural network (BNN), where both the weights and activation functions are binary \( \pm 1 \). BNN has been studied extensively because of its fast computation, energy efficiency and low memory cost [23, 12, 4, 29]. The challenging problem in training BNN is that the gradients of the weights cannot be backpropagated through the binary activation functions because the gradients are zero almost everywhere.

We train an ensemble of \( n \) neural networks (NN) with the same architecture (\( n \geq 2 \)). Let \( w_i^b \) be the binary weight of model \( i \), for \( i = 1, \cdots, n \), and \( p_i(w_i^b; D) \)
Figure 5: Goodness-of-fit test on Ising model (a, b) and Bernoulli RBM (c, d) with significant level α = 0.05. In (a, b), $p_*$ and $q_*$ has temperature $T$ and $T'$ respectively. In (c, d), $p_*$ has $W \sim \mathcal{N}(0, 1/M)$ and $q_*$ has $W + \epsilon$, where $\epsilon \sim \mathcal{N}(0, \sigma')$. $b$ and $c$ in $p_*$ and $q_*$ are the same. In (a, c) we vary the parameters of $q_*$. We fix the models and vary the sample size $n$ in (b, d). We test $H_0 : q_* = p_*$ vs. $H_1 : q_* \neq p_*$. 

Figure 6: Comparison of different methods using AlexNet with binarized weights and activation on CIFAR10 dataset. We compare our GF-SVGD with BNN [12], BNN+ [4] and BENN [29]. "BAG" denote models are independently trained and linearly averaged the softmax output for prediction. Performance is based on the accuracy of different models w.r.t. ensemble size $n$ on test data.

be the target probability model with softmax layer as last layer given the data $D$. Learning the target probability model is framed as drawing $n$ samples $\{w_i^b\}_{i=1}^n$ to approximate the posterior distribution $p_*(w^b; D)$. We train an ensemble of $n$ neural networks (NN) with the same architecture ($n \geq 2$). Let $w_i^b$ be the binary weight of model $i$, for $i = 1, \cdots , n$, and $p_*(w^b; D)$ be the target probability model with softmax layer as last layer given the data $D$. Learning the target probability model is framed as drawing $n$ samples $\{w_i^b\}_{i=1}^n$ to approximate the posterior distribution $p_*(w^b; D)$. This involves sampling $\{w_i^b\}_{i=1}^n$ from discrete distributions $p_*(w^b; D)$, where our proposed sampling algorithm can be applied. Please refer to Appendix E for the detail.

We test our ensemble algorithm by using binarized AlexNet [15] on CIFAR-10 dataset. We use the same setting for AlexNet as that in [29], which can be found in Appendix E. We compare our ensemble algorithm with typical ensemble method using bagging and AdaBoost (BENN, [29]), BNN [12] and BNN+ [4]. Both BNN and BNN+ are trained on a single model with same network. From Fig. 6 we can see that all three ensemble methods (GF-SVGD, BAG and BENN) improve test accuracy over one single model (BNN and BNN+). To use the same setting for all methods, we don’t use data augmentation or pre-training. Our ensemble method has the highest accuracy among all three ensemble methods. This is because our ensemble model are sufficiently interactive during training and our ensemble models $\{w_i\}$ in principle are approximating the posterior distribution $p(w; D)$.

4.5 Experiments on Goodness-of-fit Testing

We perform goodness-of-fit tests on Ising model and Bernoulli RBM in Fig. 5 which shows type-II error rate (False negative error). The data $\{z_i\}_{i=1}^n$ is transformed to its corresponding continuous-valued samples $\{y_i\}_{i=1}^n$, $y_i \in [0, \frac{1}{2}]$, if $z_i = 1$; $y_i \in [\frac{1}{2}, 1]$, if $z_i = 1$. Let $F$ be the c.d.f. of Gaussian base $p_0$. By the same variable transform induced from $F$, we obtain data $x = F^{-1}(y)$ and the transformed $p_*(x)$. The surrogate $\rho$ is chosen as that in sampling. Fig. 5 shows that our GF-KSD performs much better than DKSD [27] and MMD [8] when the sample size $n$ is relatively small and the difference between $q_*$ and $p_*$ is within some range.

5 CONCLUSION

In this paper, we propose a simple yet general framework to perform approximate inference and goodness-of-fit test on discrete distributions. We demonstrate the effectiveness of our proposed algorithm on a number of discrete graphical models. Based on our sampling method, we propose a new promising approach for learning an ensemble model of binarized neural networks. Future research includes applying our ensemble method to train BNN with larger networks such as VGG net and larger dataset such as ImageNet dataset and extending our method to learn deep generative models with discrete distributions.

A Additional Experimental Result

Result on Categorical Distribution We apply our algorithm to sample from one-dimensional categorical distribution $p_\nu(z)$ shown in red bars in Fig. 7 defined on $Z := \{-1, -0.5, 0, 0.5, 1\}$ with corresponding probabilities $\{0.1, 0.2, 0.3, 0.1, 0.3\}$. The blue dash line is the surrogate distribution $\rho(x) = p_0(x)$, where the base function $p_0(x)$ is the p.d.f. of standard Gaussian distribution. The red dash line is the transformed piecewise continuous density $p_\nu(x) \propto p_0(x)p_\nu(\Gamma(x))$, where $\Gamma(x) = a_i$ if $x \in [\eta_{i-1}, \eta_i)$ and $\eta_i$ is $i/5$-th quantile of standard Gaussian distribution. We apply Algorithm 1 to draw a set of samples $\{x_i\}_{i=1}^n$ (shown in green dots) to approximate the transformed target distribution. Then we can obtain a set of samples $\{z_i\}_{i=1}^n$ by $z_i = \Gamma(x_i)$, to get an approximation of the original categorical distribution.

![Figure 7: Evolution of real-valued particles $x_i$ in green dots) by our discrete sampler in Alg. 1 on a one-dimensional categorical distribution. (a-d) shows particles $\{x^i\}$ at iteration 0, 10, 50 and 100 respectively.

As shown in Fig. 7, the empirical distribution of the discretized sample $\{z_i\}_{i=1}^n$ (shown in green bars) aligns closely with the true distribution (the red bars) when the algorithm converges (e.g., at the 100-th iteration).

Results on Bernoulli RBM The probability model is given in (20) and the score function is derived in Section 5.3. We also evaluate the sample quality based on the mean square error (MSE) between the estimation and the ground truth value. From Fig. 8(a), we can see that when fixing the dimension of the distribution $p_\nu(z)$, our sampling method has much lower MSE than Gibbs and DHMC. In Fig. 8(b), as the dimension of the model increases, our sampling method has relatively better MSE than that of Gibbs and DHMC.

![Figure 8: Bernoulli RBM with number of visible units $M = 25$. In (a), we fix the dimension of visible variables $d = 100$ and vary the number of samples $\{z_i\}_{i=1}^n$. In (b), we fix the number of samples $n = 100$ and vary the dimension of visible variables $d$. We calculate the MSE for estimating the mean $E[z]$ (lower is better).]
\[ \Omega = \sum \text{according to the rank of its density ratio in the population.} \]

Algorithm 3: Transform Discrete Samples to Continuous Samples for Goodness-of-fit Test

In this section, we provide the procedure of our principled ensemble algorithm to train binarized neural network. We train an ensemble of \( n \) neural networks (NN) with the same architecture \((n \geq 2)\). Let \( w_i^k \) be the binary weight of model \( i \), for \( i = 1, \cdots, n \), and \( p_o(w_i^k; D) \) be the target probability model with softmax layer as last layer given the data \( D \). Learning the target probability model is framed as drawing \( n \) samples \( \{w_i^k\}_{i=1}^n \) to approximate the posterior distribution \( p_o(w_i^k; D) \). We apply multi-dimensional transform \( F \) to transform the original discrete-valued target to the target distribution of real-valued \( w \in \mathbb{R}^d \). Let \( p_0(w) \) be the base function, which is the product of the p.d.f. of the standard Gaussian distribution over the dimension \( d \). Based on the derivation in Section 3, the distribution of \( w \) has the form \( p_c(w; D) \propto p_o(\text{sign}(w); D)p_0(w) \) with weight \( w \) and the sign function is applied to each dimension of \( w \). To backpropagate the gradient to the non-differentiable target, we construct a surrogate probability model \( \rho(w; D) \) which approximates \( \text{sign}(w) \) in the transformed target by \( \sigma(x) \) and relax the binary activation function \( \{-1, 1\} \) by \( \sigma \), where \( \sigma \) is defined by (21), denoted by \( \tilde{p}(\sigma(w); D)p_0(w) \). Here \( \tilde{p}(\sigma(w); D) \) is a differentiable approximation of \( p_o(\text{sign}(w); D) \). Then we apply GF-SVGD to update \( \{w_i\} \) to approximate the transformed target distribution of \( p_c(w; D) \) of \( w \) as follows, \( w_i \leftarrow w_i + \frac{1}{n} \Delta w_i, \forall i = 1, \cdots, n \), where \( \Delta w_i = -\frac{\sum_j \gamma_j [\nabla_w \log \rho(w_j; D_i)k(w_j, w_i) + \nabla_w k(w_j, w_i)]}{\gamma_i} \) (22)

where \( D_i \) is batch data \( i \) and \( \mu_j = \rho(w_j; D_i)/p_c(w_j; D_i) \), \( H(t) \overset{\text{def}}{=} \sum_j \gamma_j \mathbb{1}(\mu_j \geq t) / n \), \( \gamma_j = (H(w_j))^{-1} \) and \( \Omega = \sum_j \gamma_j \). Note that we don’t need to calculate the cumbersome term \( p_0(w) \) as it can be canceled from the ratio between the surrogate distribution and the transformed distribution. In practice, we find a more effective way to estimate this density ratio denoted by \( \gamma_j \). Intuitively, this corresponds to assigning each particle a weight according to the rank of its density ratio in the population. Algorithm on Appendix can be viewed as a new form of ensemble method for training NN models with discrete parameters.

Algorithm 3: GF-SVGD on training BNN

**Inputs:** training set \( D \) and testing set \( D_{test} \)

**Outputs:** classification accuracy on testing set.

**Initialize** full-precision models \( \{w_i\}_{i=1}^n \) and its binary form \( \{w_i^b\}_{i=1}^n \) where \( w_i^b = \text{sign}(w_i) \).

**while** not converge do
- Sample \( n \) batch data \( \{D_i\}_{i=1}^n \).
- Calculate the true likelihood \( p_c(w_i; D_i) \propto p_o(\text{sign}(w_i); D_i)p_0(x) \).
- Relax \( w_i \) with \( \sigma(w_i) \).
- Relax each sign activation function to the smooth function defined in (21) to get \( \tilde{p} \).
- Calculate the surrogate likelihood \( p_c(w_i^b; D_i) \propto \tilde{p}(\sigma(w_i); D_i)p_0(x) \).
- \( w_i \leftarrow w_i + \Delta w_i, \forall i = 1, \cdots, n \), where \( \Delta w_i \) is defined in (22).
- Clip \( \{w_i\} \) to interval \((-1, 1)\) for stability.
**end while**

- Calculate the probability output by softmax layer \( p(w_i^b; D_{test}) \).
- Calculate the average probability \( f(w_i; D_{test}) = \sum_{i=1}^n p(w_i^b; D_{test}) \).

**Output** test accuracy from \( f(w_i; D_{test}) \).

C Transform Discrete Samples to Continuous Samples for Goodness-of-fit Test

Let \( F \) be the c.d.f. of Gaussian base density \( p_0 \). Let us first illustrate how to transform one-dimensional samples \( \{z_i\}_{i=1}^n \) to continuous samples.

1. Given discrete data \( \{z_i\}_{i=1}^n \). Let \( \{a_j\}_{j=1}^K \) are possible discrete states. Assume \( K \) is large so that for any \( z_i \), we have \( z_i = a_j \) for one \( j \).
2. For any \( z_i \) such as \( z_i = a_j \), randomly sample \( y_i \in [\frac{i-1}{K}, \frac{i}{K}] \). We obtain data \( \{y_i\}_{i=1}^n \).
3. Apply \( x = F^{-1}(y) \), we obtain data \( \{x_i\}_{i=1}^n \).

For \( x = (x_1, \cdots, x_d) \), let \( F(x) = (F_1(x_1), \cdots, F_d(x_d)) \), where \( F_i \) is the c.d.f. of Gaussian density \( p_{0,i}(x_i) \). We apply the above one-dimensional transform to each dimension of \( \{z_i\}_{i=1}^n \). \( z_i = (z_i^1, \cdots, z_i^d) \). We can easily obtain the continuous data \( \{x_i\}_{i=1}^n \).
D Proofs

In the following, we prove proposition 4.

Proposition 4 Assume $\Gamma$ is an even partition of $p_0(x)$, and $p_c(x) = K p_0(x) p_*(\Gamma(x))$, where $K$ serves as a normalization constant, then $(p_c, \Gamma)$ is a continuous parameterisation of $p_*$. 

Proof. We just need to verify that (11) holds.

\[
\int p_c(x) \mathbb{I}[a_i = \Gamma(x)] dx = K \int p_0(x) p_*(\Gamma(x)) \mathbb{I}[a_i = \Gamma(x)] dx = K \int p_0(x) p_*(a_i) \mathbb{I}[a_i = \Gamma(x)] dx = K p_*(a_i) \int p_0(x) \mathbb{I}[a_i = \Gamma(x)] dx = p_*(a_i),
\]

where the last step follows (12).

E Detail of Experiments and Network Architecture

In all experiments, we use RBF kernel $k(x, x') = \exp(-\|x - x'\|^2/h)$ for the updates of our proposed algorithms; the bandwidth $h$ is taken to be $h = \text{med}^2 / (2 \log(n + 1))$ where med is the median of the current $n$ particles. Adam optimizer [14] is applied to our proposed algorithms for accelerating convergence. $\epsilon = 0.0001$ works for all the experiments.

We use the same AlexNet as [29], which is illustrated in the following.

| Layer | Type   | Parameters                  |
|-------|--------|-----------------------------|
| 1     | Conv   | Depth: 96, K: 11 x 11, S: 4, P:0 |
| 2     | Relu   | -                           |
| 3     | MaxPool| K: 3 x 3, S: 2              |
| 4     | BatchNorm | -                         |
| 5     | Conv   | Depth: 256, K: 5 x 5, S: 1, P:1 |
| 6     | Relu   | -                           |
| 7     | MaxPool| K: 3 x 3, S: 2              |
| 8     | BatchNorm | -                        |
| 9     | Conv   | Depth: 384, K: 3 x 3, S: 1, P:1 |
| 10    | Relu   | -                           |
| 11    | Conv   | Depth: 384, K: 3 x 3, S: 1, P:1 |
| 12    | Relu   | -                           |
| 13    | Conv   | Depth: 256, K: 3 x 3, S: 1, P:1 |
| 14    | Relu   | -                           |
| 15    | MaxPool| K: 3 x 3, S: 2              |
| 16    | Dropout| $p = 0.5$                   |
| 17    | FC     | Width=4096                  |
| 18    | Relu   | -                           |
| 19    | Dropout| $p = 0.5$                   |
| 20    | FC     | Width=4096                  |
| 21    | Relu   | -                           |
| 22    | FC     | Width=10                    |

Table 1: Architecture of AlexNet. "K" denotes kernel size; "S" denotes stride; "P" denotes padding.
