Rare earth phosphates comprise a large family of compounds proposed as possible nuclear waste disposal forms. We report structural and thermodynamic properties of a series of rare earth rhabdophanes and monazites. The water content of the rhabdophanes, including both adsorbed and structural water, decreases linearly with increase in ionic radius of the rare earth. The energetics of the transformation of rhabdophane to monazite plus water and the enthalpy of formation of rhabdophane from the constituent oxides was determined by high temperature drop solution calorimetry. The former varies linearly with the ionic radius of the lanthanide, except for cerium. By combining the enthalpy of formation determined by high temperature drop solution calorimetry and the free energy of formation determined previously by solubility experiments, a complete set of thermodynamic data was derived for the rhabdophanes. They are thermodynamically metastable with respect to the corresponding monazites plus water at all temperatures under ambient pressure conditions. This conclusion strengthens the case for monazites being an excellent nuclear waste form.

Keywords: lanthanides, rhabdophanes, monazites, enthalpy, entropy, free energy of formation, stability

INTRODUCTION

Rare earth orthophosphates (REPO₄ · n H₂O, where RE is a rare earth element, i.e., lanthanide plus yttrium and scandium) are widespread minerals. Their hydrated forms are commonly known as rhabdophane (Mooney, 1948, 1950; Mesbah et al., 2014) and churchite (Kohlmann et al., 1994), while their anhydrous forms are monazite (Clavier et al., 2011) and xenotime (Ni et al., 1995). These phosphate minerals are a primary source of rare earths and thorium. They also contain significant amounts of uranium (McCarthy et al., 1980; Bregiroux et al., 2007). There is strong interest in monazites for geochronology (Schärer, 1984; Schärer et al., 1986; Gibson and Ireland, 1995; Bowring et al., 1998), as they are able to deliver a wide range of information through the isotopic dating of rocks based on the U-Th-Pb natural radioactive decay chain due to their very high chemical durability in weathering conditions. Moreover, monazites usually remain crystalline even after very long times (i.e., geological times of billions of years) of exposure to self-irradiation by their U and Th contents. This radiation resistance makes monazite ceramics promising candidates for the specific immobilization of tetravalent and trivalent actinides coming from the reprocessing of spent nuclear fuel or from the management of plutonium (Ewing, 1999).
From a structural point of view, phosphate materials containing light RE ranging from La to Gd form anhydrous monazite (REPO$_4$, monoclinic, P$2_1$/n) or hydrated rhabdophane (REPO$_4 \cdot$ n H$_2$O) (Mesbah et al., 2014). For heavier RE (Gd to Lu) plus Y, anhydrous xenotite (tetragonal, I$_4$/amd) is formed. Another hydrated phosphate is reported under the name of churchite (Assaoudi and Ennaciri, 1997) which crystallizes in the gypsum structure type in the monoclinic C$_2$/c space group. Three lanthanide elements (Gd, Tb, Dy) are able to form all four phosphate varieties (Boatner, 2002), which makes the preparation of single phase materials both very exciting and rather challenging based on the complex relationships among the four forms.

In the immobilization of actinides, a strong interplay between rhabdophane and monazite is often seen. Indeed, rhabdophanes is a very convenient synthetic precursor for monazite when using wet chemistry methods (Terr et al., 2003; Du Fou de Kerdaniel et al., 2007; Clavier et al., 2011). Due to their very low aqueous solubility, rhabdophanes are often precipitated from aqueous solution with quantitative recovery yields (Dacheux et al., 2013; Gause et al., 2016). Additionally, rhabdophanes are formed during the dissolution of monazites in various experimental conditions when reaching saturation conditions in solution (Clavier et al., 2006; Du Fou de Kerdaniel et al., 2007; Gause et al., 2016, 2018). Usually, rhabdophanes are precipitated at lower temperatures than monazites. Thus, rhabdophanes often act as sequestration phases for lanthanide and actinide elements, enhancing the very high chemical durability of monazites during dissolution and leaching.

Despite this broad interest in rhabdophane materials and their relation to the anhydrous monazite and xenotite phosphate polymorphs, there is very little information about their thermodynamic stability. Especially, the energetics of the transformation of rhabdophane to monazite needs to be investigated in order to constrain the mechanism and the temperature of transition. Thus, the aim of this paper is to determine the thermodynamic properties of rhabdophane phases and to compare their stability to that of monazites.

**EXPERIMENTAL METHODS**

**Material Preparation**

Rhabdophane samples REPO$_4 \cdot$ n H$_2$O (RE = La to Gd) were synthesized by mixing 4 mmol of lanthanide chloride with 5 mol L$^{-1}$ H$_3$PO$_4$ solution, obtained by dilution of the concentrated stock solution to produce a RE:PO$_4$ molar ratio of 1:1.03. The mixtures were stirred for 15 min at 60°C, transferred into a Teflon container and placed in an oven for 2 weeks at 90°C. The formed powders were then washed twice with deionized water followed by ethanol and then separated from the solution by centrifugation. Finally, they were dried at room temperature overnight in air. Each monazite sample was obtained by thermal conversion of its rhabdophane analog by heating 200 mg of each synthesized precursor at 1,100°C for 6 h in air.

Both sets of samples (rhabdophanes and monazites) were stored in airtight containers at room temperature the period of approximately a year separating synthesis and calorimetry.

**Powder X-ray Diffraction**

The rhabdophane and monazite powders were analyzed by powder X-ray diffraction (PXRD) using a Bruker D8 Advance diffractometer equipped with copper radiation (Cu K$_{\alpha 1,2}$, $\lambda$ = 1.54184 Å) and using reflection geometry in a parallel mode. All the powder patterns were collected between 5 and 120° (2θ) with a total counting time of about 3 h. Additionally, a powder pattern of pure silicon was collected in similar conditions and was used as a standard to extract the instrumental function. The resulting data were refined by the Rietveld method with the use of the FullProf_Suite package (Rodriguez-Carvajal, 1993). During the refinement, different profile and structure parameters were allowed to vary. An anisotropic size model was added for each phase to simulate microstructural effects. The PXRD patterns corresponding to the synthesized compounds were refined in the rhabdophane structure type (LnPO$_4 \cdot$ 0.667 H$_2$O) crystallizing in the monoclinic C2 space group (Mesbah et al., 2014). In the same manner, the PXRD patterns obtained after the thermal treatment were refined in the monazite structure type (monoclinic system in the P$2_1$/n space group).

**Thermodynamic Measurements and Data Analysis**

Water content was obtained by mass loss evaluation after thermogravimetric analysis (TGA) coupled with differential scanning calorimetry (DSC) experiments on a Netzsch STA 449C. The instrument was calibrated using sapphire heat capacity measurement. 15–20 mg of powder was heated in air at 10°C min$^{-1}$ from 30 to 1,000°C to fully eliminate water and convert the rhabdophane into monazite. The correction was performed by a “blank run” with an empty crucible prior to the experiment.

High temperature drop solution calorimetry was performed using a custom-built Tian-Calvet twin calorimeter (Navrotsky, 1977, 1997, 2014). Molten sodium molybdate (3Na$_2$O - 4MoO$_3$) solvent at 700°C (for all lanthanides except praseodymium) and lead borate (2PbO - B$_2$O$_3$) at 800°C (for praseodymium) were used. Approximately 5 mg of sample was hand-pressed into a pellet to drop from room temperature into 20 g of molten solvent. Oxygen was bubbled (5 mL min$^{-1}$) through the solvent and flushed (70 mL min$^{-1}$) through the gas space above it to enhance dissolution and maintain an oxidizing atmosphere. During the
calorimetric experiment, any H$_2$O evolved into the gas phase and was removed from the calorimeter, and the sample was dissolved to form a dilute solution of rare earth oxide and P$_2$O$_5$ in the calorimetric solvent. The measured signal of heat flow over time was integrated using CALISTO (Setaram) software to calculate the enthalpy of drop solution. The methodology is essentially the same than that used in earlier studies of RE phosphates and related materials (Hirsch et al., 2017; Neumeier et al., 2017).

RESULTS AND DISCUSSION

Structural Description of the Samples

Analysis of the PXRD patterns (Figure 1A) confirms that all the synthesized samples were single phases crystallizing with the rhabdophane structure type (Mesbah et al., 2014, 2017). Thermal conversion of the samples over 1,000°C always led to the formation of pure monazite compounds (Figure 1B). For all samples, the refined unit cell parameters from Rietveld refinement are gathered in Table 1 and the variation of the unit cell volumes of the rhabdophane and monazite structures are depicted in Figure 2.

The unit cell volume of rhabdophanes evolves linearly with increase of the ionic radius from La to Gd, which is in agreement with earlier observations (Mesbah et al., 2014, 2017). Indeed, the unit cell volume decreases when heavier elements are incorporated, reflecting the variation of the ionic radius along the lanthanide series (i.e., contraction of the 4f orbitals). (Shannon, 1976). Similar behavior is also observed for the anhydrous monazite, as shown in Figure 2.

Dehydration Processes and Transformation of Rhabdophane to Monazite

Prior to further thermodynamic investigations all samples were studied by TG-DSC. This allowed understanding the dehydration process and the rhabdophane-monazite transition. It also confirmed the exact degree of hydration just prior to calorimetry, which is needed for the calculation of enthalpies of formation. All samples show several steps of dehydration as endothermic processes leading to dehydrated rhabdophane structure, which then exothermically transforms into monazite structure at higher temperatures (see TG and DSC data in Figure 3).

As shown in Table 2, both water contents and dehydration schemes were found to vary depending on the lanthanide element considered. Generally, there is a linear increase in temperature of dehydration and transition with respect to ionic radius (Figure 4). The measured water content ranged from 0.804 (La) to 0.533 (Gd) in the samples prepared during this work. Previous studies (Mesbah et al., 2014) report similar values ranging from 0.6 to 1.0 mole of water. This variation could come from the modification of the size of the channels in the rhabdophane structure when larger lanthanides are present that are able to have more water molecules in their coordination sphere. Due to the possibility of the intermediate hydrated compounds discussed in the abovementioned work, at least two distinct steps between ambient temperature and 250 °C can be noted, first leading to the stabilization of \( \text{LnPO}_4 \cdot 0.5 \text{H}_2\text{O} \) phase (monoclinic, C2) then finally to the anhydrous form \( \text{LnPO}_4 \) (hexagonal, P3\(_12\)1) as follows:

\[
\text{REPO}_4 \cdot n \text{H}_2\text{O}_{\text{monoclinic, C2}} \quad \Downarrow
\]

\[
\text{REPO}_4 \cdot 0.5 \text{H}_2\text{O}_{\text{monoclinic, C2}} + (n - 0.5) \text{H}_2\text{O} \quad (1)
\]

\[
\Downarrow
\]

\[
\text{REPO}_4(\text{hexagonal, P3}_12\text{1}) + 0.5 \text{H}_2\text{O}
\]

All intermediate products were irreversibly converted to monazites at temperatures ranging from 700 to 950 °C. Such transformation was associated with an exothermic peak on all
DTA curves. The variation of the temperature associated with the rhabdophane → monazite transition is shown as a function of the ionic radius in Figure 4. It is in a good agreement with the data previously reported (Kijkowska, 2003), showing a decrease with an increase of lanthanide ionic radius. However, since the transformation was not reversed, it is unknown whether the observed temperature represents an equilibrium reaction. Considering possible differences in synthesis procedures among these studies and error in temperature determination, reported differences as high as ±10°C are not surprising. The general agreement between current and prior temperatures suggests that, even if kinetically controlled, the dehydration process appears similar in several separately prepared materials.

FIGURE 4 | Variation of the temperatures of dehydration of rhabdophanes (T1 and T2) and transformation to monazite (T3) determined by TGA (open symbols) and from literature (filled symbols) (Kijkowska, 2003) as a function of ionic radius of lanthanide.

The enthalpy of dehydration was found as the heat absorbed during water loss from DSC by integration of the peaks associated with water loss. This process occurs at the temperature of dehydration T2 and represents the reaction:

\[
\text{REPO}_4 \cdot n \text{H}_2\text{O} (\text{hydrated rhabdophane, T}_2) \downarrow \Delta H_{\text{dehydr}}
\]

\[
\text{REPO}_4 (\text{dehydrated rhabdophane, T}_2) + n \text{H}_2\text{O} (\text{gas, T}_2)
\]

The enthalpies of dehydration were calculated from DSC by integration of the peaks associated with water loss. The enthalpy of dehydration is relatively constant with an average value of 50.3 ± 1.8 kJ mol\(^{-1}\) of RE and 74.6 ± 1.8 kJ mol\(^{-1}\) of water.

Enthalpy of transition was obtained by integration of the exothermic peak at T3. This process corresponds to the following reaction:

\[
\text{REPO}_4 (\text{dehydrated rhabdophane, T}_3) \downarrow \Delta H_{\text{trans}}
\]

\[
\text{REPO}_4 (\text{monazite, T}_3)
\]

Enthalpy of reaction of hydrated rhabdophane to monazite plus water was estimated from DSC measurements using the following relation:

\[
\Delta H_{\text{DSC, react}} = \Delta H_{\text{dehydr}} - \Delta H^0_{\text{vapor}} \times n + \Delta H_{\text{trans}}
\]

where \(\Delta H^0_{\text{vapor}} = 44\) kJ mol\(^{-1}\) is standard enthalpy of vaporization of water at 25°C.

The enthalpy of reaction (\(\Delta H^{\text{ox-melt}}_{\text{react}}\)) which is associated with the reaction from rhabdophane to monazite plus liquid water
at room temperature was obtained by high temperature drop solution calorimetry.

\[
\text{REPO}_4 \cdot n \text{H}_2\text{O} \quad \text{(hydrated rhabdophane, 25 °C)} \\
\downarrow \Delta H_{\text{react}}^{\text{ox-melt}} \\
\text{REPO}_4 \quad \text{(monazite, 25 °C)} + n \text{H}_2\text{O (liquid, 25 °C)}
\]

\[\Delta H_{\text{react}}^{\text{ox-melt}} = \Delta H_{\text{react}}^{\text{ox}} - \Delta H_{\text{f,el}}^{\text{ox}} - n \Delta H_{\text{water}}^{\text{25–700}} \quad (5)\]

The enthalpy associated with this transformation was calculated from drop solution enthalpy using the following equation:

\[\Delta H_{\text{react}}^{\text{ox-melt}} = \Delta H_{\text{react}}^{\text{ox}} - \Delta H_{\text{f,el}}^{\text{ox}} - n \Delta H_{\text{water}}^{\text{25–700}} \quad (6)\]

where \(\Delta H_{\text{react}}^{\text{ox}}\) and \(\Delta H_{\text{f,el}}^{\text{ox}}\) stand for enthalpy of drop solution of rhabdophane and monazite in sodium molybdate at 700°C and \(\Delta H_{\text{water}}^{\text{25–700}}\) is heat uptake by water when it is heated inside the calorimeter from 25 to 700°C (this reaction and overall thermodynamic data from high temperature drop solution calorimetry experiments will be described in more details in the following sections).

The values calculated from DSC data are listed in Table 2, which also gives values from high temperature drop solution calorimetry. The enthalpies of reaction associated with the transformation of rhabdophane to monazite plus water are also plotted in Figure 5.

Enthalpy of reaction calculated from drop solution enthalpy becomes slightly less endothermic with increasing RE ionic radius except for the cerium sample, which deviates from the general trend for reasons that remain unclear. Since both Ce-bearing monazite and rhabdophane appear to contain only trivalent cerium, difference in oxidation state is not expected to be involved during the transformation. One of the possible reasons for the anomalous behavior of cerium may be that Ce-containing samples have more complex surface structures (Takita et al., 1998; Huang and Fabris, 2007) that could affect the energetics. The values estimated from DSC scans slightly deviate from those found by high temperature drop solution calorimetry, but this might be the consequence of estimations and the integration errors which accompany DSC experiments. Nevertheless, overall values are in reasonable agreement from both experiments and are close to zero. The data suggest that rhabdophane is energetically metastable or at best only marginally stable with respect to monazite plus water. As noted below, similar conclusions can be drawn about the free energy of the reaction, implying thermodynamic metastability.

### TABLE 3 | Enthalpy of drop solution (\(\Delta H_{\text{ds}}\)), formation from oxides (\(\Delta H_{\text{f,ox}}\)), and elements (\(\Delta H_{\text{f,el}}\)) at 25°C for rhabdophanes and monazites.

*drop solution enthalpy in lead borate at 800°C. Enthalpies of formation of Pr-containing rhabdophane and monazite from oxides are calculated using thermodynamic cycle from high temperature drop solution experiments with lead borate at 800°C.

FIGURE 7 | Standard enthalpy of formation at 25°C from oxides (A) and from elements (B) of rhabdophanes (circles) and monazites (rhombus).
in Table 2 probably reflect kinetic rather than thermodynamic control. The dehydrated rhabdophanes are energetically less stable than the initial fully hydrated forms. These observations, including the variable water contents, are consistent with relatively loose binding of water in the rhabdophane structure.

Heats of Formation
The values of drop solution enthalpy (Figure 6) increase linearly with ionic radii for both sets of materials except for Pr and Ce containing samples. It was discussed previously (Hirsch et al., 2017) that praseodymium phosphates do not dissolve well at 700°C in sodium molybdate, which results in more endothermic values for the drop solution enthalpy we observed. More exothermic values of drop solution enthalpy of cerium phosphates are the result of cerium oxidation (Ce³⁺ → Ce⁴⁺) in the solvent. This effect for monazite CePO₄ and also the observed linear trend were discussed previously (Ushakov et al., 2001).

Thermodynamic cycles (see Supporting info Tables A1a–c) were built to calculate standard enthalpies of formation of rhabdophanes and monazites from oxides and elements. Complex nature of Ce and Pr samples in the solvent was assessed in separate cycles. Ushakov et al. (2001) published a thermodynamic cycle for PrPO₄ monazite using the assumption that Pr₂O₅ oxidizes to Pr₆O₁₁ in sodium molybdate solvent at 700°C. However, this was not based on convincing evidence but rather on the observation that Pr₂O₃ does not dissolve well while Pr₆O₁₁ appears to dissolve rapidly. In order to avoid this uncertainty, a thermodynamic cycle based on the dissolution of Pr₂O₃ in lead borate at 800°C (where it dissolves rapidly) was used here to calculate the enthalpy of formation for both monazite and rhabdophane of praseodymium. All the measured and calculated values are given in Table 3.

Figure 7 shows that the standard enthalpies of formation of rhabdophanes from oxides become more exothermic with increasing RE radius, as seen previously for monazites (Ushakov et al., 2001). Neither, Pr nor Ce show anomalous behavior since we compensate for the oxidation effects in the solvent by the thermodynamic cycles. The difference in the value for La-monazite from Ushakov et al. (2001) was discussed in a recent study on LaₓPr₁₋ₓPO₄ monazite solid solutions (Hirsch et al., 2017) and was attributed to experimental problems (insufficient gas bubbling through the calorimetric solvent). Enthalpy of formation from elements for the Eu-containing samples deviates from the trend, as shown in previous work (Ushakov et al., 2001), for unknown reasons.

Combining Solubility and Calorimetric Data for Rhabdophanes
A systematic study of the solubility of the same rhabdophane samples, LnPO₄ · n H₂O (Ln = La to Dy) was performed by Gausse et al. (2016) using over- and under-saturated experiments at different temperatures (25–90°C). These experiments can be used to obtain the standard Gibbs free energy of formation
TABLE 4 | Thermodynamic data at 25°C calculated from solubility experiments for rhabdophanes and using data from (Navrotsky et al., 2015) for monazites. Standard molar entropies are given as calculated from enthalpy and free energy of formation from oxides \(\Delta S_{m(\text{ox})}\) with Equation (9) and from elements \(\Delta S_{m(\text{el})}\) with Equation (10).

All errors in the table are propagated as two standard deviations of the mean.

FIGURE 10 | Standard entropy (A) and Gibbs energy (B) of reaction of rhabdophane to monazite plus water at 25°C plotted against ionic radius of lanthanide element.

and, from its temperature dependence, both the enthalpy, and entropy of formation. Alternatively, the Gibbs free energy at 25°C from solubility experiments can be combined with the enthalpy of formation measured by high temperature drop solution calorimetry to obtain the entropy of formation at 25°C without relying on the temperature dependence of solubility data. This second approach is probably more accurate because the solubility data can be obtained only over a relatively small temperature range and the thermodynamic analysis of solubility data requires knowledge of or assumptions about the thermodynamic behavior of the aqueous species at higher temperatures.

The values of standard Gibbs free energy of formation from elements \(\Delta G_{\text{el}}\), of Gausse et al. (2016) were calculated considering that the water content per formula unit was 0.667 for the whole series. In the present work the water content, \(n\), was measured by TGA and was found to vary from 0.533 (for Gd) to 0.804 (for La), thus the values from Gausse et al. (2016) were recalculated according to a new water content. These new values were used to find standard Gibbs free energy at 25°C of formation from oxides:

\[
\Delta G_{\text{ox}}^\circ \text{ (LnPO}_4 \cdot n \text{ H}_2\text{O)} = \\
\Delta G_{\text{el}}^\circ \text{ (LnPO}_4 \cdot n \text{ H}_2\text{O)} - \frac{1}{2} \Delta G_{\text{el}}^\circ \text{ (Ln}_2\text{O}_3) - \frac{1}{2} \Delta G_{\text{el}}^\circ \text{ (H}_2\text{O)} 
\]

Then, the enthalpies of formation of rhabdophanes and monazites from oxides obtained from high temperature drop solution calorimetry in the previous section were used to
calculate entropies of formation from oxides 25°C.

\[
\Delta S_{\text{f,ox}}^o = \frac{\Delta H_{\text{f,ox}}^o - \Delta G_{\text{f,ox}}^o}{298.15} \tag{8}
\]

The values of standard free energy and entropy of formation from oxides are plotted on Figure 8.

The values of standard entropy of formation of monazites from oxides are slightly negative and the small magnitudes are reasonable for solid state reactions in which no gases are consumed or produced, while those for rhabdophanes are more negative, reflecting the confinement of liquid water.

Using standard entropies of oxides, those of rhabdophanes and monazites were calculated as

\[
S_{\text{m}}^o(\text{ox}) (\text{LnPO}_4 \cdot n \text{ H}_2\text{O}) = \Delta S_{\text{f,ox}}^o (\text{LnPO}_4 \cdot n \text{ H}_2\text{O}) + \frac{1}{2} S_{\text{m}}^o (\text{Ln}_2\text{O}_3) \\
+ \frac{1}{2} S_{\text{m}}^o (\text{P}_2\text{O}_5) + n \times S_{\text{m}}^o (\text{H}_2\text{O}(l)) \tag{9}
\]

These are plotted against ionic radius in Figure 9. We also calculated standard entropy from enthalpy and free energy of formation from elements to check the consistency of the data as:

\[
S_{\text{m}}^o (\text{el}) (\text{LnPO}_4 \cdot n \text{ H}_2\text{O}) = \Delta S_{\text{f,el}}^o (\text{LnPO}_4 \cdot n \text{ H}_2\text{O}) + S_{\text{m}}^o (\text{Ln, cr}) \\
+ S_{\text{m}}^o (\text{P, cr}) + 2 \times S_{\text{m}}^o (\text{O}_2, g) + \\
+ n \times \left[ \frac{1}{2} S_{\text{m}}^o (\text{O}_2, g) + S_{\text{m}}^o (\text{H}_2, g) \right] \tag{10}
\]

All thermodynamic data used and calculated this far are compiled in Table 4. Auxiliary data (values for elements and oxides) are given in supporting info (Table A2).

Using these standard molar entropies and entropy of liquid water, we calculated entropies and, further, using the enthalpy of reaction estimated from high temperature drop solution calorimetry (Table 2), free energies of reaction of rhabdophane to monazite plus water:

\[
\Delta G_{\text{react}}^o = \Delta H_{\text{f,ox}}^o - 298.15 \times \Delta S_{\text{f,react}}^o \tag{12}
\]

These values are plotted on Figure 10 and given in Table 5.

The enthalpies of reaction of a series of rhabdophanes were measured by high temperature drop solution calorimetry and the energetics of dehydration and transformation to monazite plus water were determined by DSC. Combined with free energies from solubility measurements, the data allow the calculation of entropies of formation and standard entropies of rhabdophane phases. Rhabdophanes are metastable with respect to the corresponding monazites plus water at all temperatures under ambient pressure conditions. However, presumably due to a more rapid kinetics of precipitation,

rhabdophane is often formed initially leaching of phosphate based ceramics, especially for temperatures representative of long-term repositories. This rapid formation of rhabdophane, followed by slower conversion to monazite, can contribute to the significant delay of actinide and rare earth releases in environment. Additionally, monazite, once formed, can be very effective in radionuclide confinement without any rapid back-transformation to hydrous phases, even on long time scales.
