ABSTRACT – BACKGROUND: Despite advances in therapies, the prognosis of patients with advanced gastric cancer (GC) remains poor. Several studies have demonstrated the expression of estrogen receptor alpha (ERα); however, its significance in GC remains controversial. AIM: The present study aims to report a case series of GC with ERα-positive expression and describe their clinicopathological characteristics and prognosis. METHODS: We retrospectively evaluated patients with GC who underwent gastrectomy with curative intent between 2009 and 2019. ERα expression was assessed by immunohistochemistry through tissue microarray construction. Patients with ERα-negative gastric adenocarcinoma served as a comparison group. RESULTS: During the selected period, 6 (1.8%) ERα-positive GC were identified among the 345 GC patients analyzed. All ERα-positive patients were men, aged 34–78 years, and had Lauren diffuse GC and pN+ status. Compared with ERα-negative patients, ERα-positive patients had larger tumor size (p=0.031), total gastrectomy (p=0.012), diffuse/ mixed Lauren type (p=0.012), presence of perineural invasion (p=0.030), and lymph node metastasis (p=0.015). The final stage was IIA in one case, IIIA in three cases, and IIIB in two cases. Among the six ERα-positive patients, three had disease recurrence (peritoneal) and died. There was no significant difference in survival between ERα-positive and ERα-negative groups. CONCLUSIONS: ERα expression is less common in GC, is associated with diffuse histology and presence of lymph node metastasis, and may be a marker related to tumor progression and worse prognosis. Also, a high rate of peritoneal recurrence was observed in ERα-positive patients.

HEADINGS: Stomach Neoplasms. Estrogen Receptor alpha. Immunohistochemistry. Molecular Targeted Therapy. Prognosis
INTRODUCTION

Gastric cancer (GC) is the fourth most common type of cancer worldwide, ranking third in cancer mortality[^4]. It is diagnosed more frequently in advanced stages and, despite advances in therapies in recent years, the effectiveness of therapeutic options has still been low — both in locoregional and metastatic cancer[^11, 20, 21].

The use of a monoclonal antibody that interferes with the activation of human epidermal growth factor 2 (HER2) was the first step toward the target molecular therapy of GC. Trastuzumab has shown benefit in the survival of patients with metastatic GC[^3]. However, since the approval of trastuzumab, several studies have been conducted in investigating other target agents[^7, 14].

Estrogen is part of a class of steroids involved not only in the regulation of the reproductive system but also in the cardiovascular, neuroendocrine, and musculoskeletal systems. There are two subtypes of estrogen receptors (ERs): alpha (α) and beta (β), which have variable tissue distributions and different biological functions[^5, 6, 24].

The blockade of REα has the capacity to suppress the malignant behavior of GC cells in vitro through the modulation of the expression of p27, p21, p53, cyclin D1, and E-cadherin[^23]. However, some controversies regarding the expression of ERα in GC and its prognostic impact in these patients still remain[^8, 16].

Accordingly, although hormone therapy has been used for decades in tumors with positivity for hormone receptors, such as breast and prostate cancer, in GC, more studies are still needed to determine their clinicopathological and prognostic significance[^4]. Thus, the present study aims to report a case series of GC with ERα-positive expression and describe their clinicopathological characteristics and prognosis. Also, their characteristics and survival outcomes were compared with ERα-negative GC.

METHODS

All GC patients, who underwent gastrectomy with curative intent, between 2009 and 2019, were retrospectively evaluated from our medical database. Inclusion criteria were as follows: histological confirmation of gastric adenocarcinoma and formalin-fixed, paraffin-embedded (FFPE) blocks of tissue available for analysis. Exclusion criteria were as follows: palliative resections, emergency surgeries, and systemic metastatic disease (M1). Total or subtotal gastrectomy and lymph node dissection were performed based on the guidelines of the Japanese Gastric Cancer Association[^11] and in accordance with the guidelines of the Brazilian consensus[^4]. The pathological tumor stage was defined according to the 8th edition of TNM, as proposed by the International Union Against Cancer (UICC)[^1].

Clinical, surgical, and pathological variables, including sex, age (years), body mass index (BMI) (kg/m²), American Society of Anesthesiologists classification (I/II or III/IV), hemoglobin (g/dL), albumin (g/dL), the extent of resection, the extension of lymphadenectomy, tumor size (cm), histological Lauren type, lymphatic invasion, venous invasion, perineural invasion, number of lymph nodes, and pTNM stage, were evaluated.

Since this is a noninterventional and retrospective study, informed consent was not required from each patient. The study was approved by the Ethical Committee and Institutional Review Board (plataformabrasil.saude.gov.br; registration number CAAE: 38156720.0.0000.0068).

Tissue microarray construction and Immunohistochemistry

All hematoxylin and eosin (H&E)-stained slides were reviewed, and representative tissue samples were selected for each case. Three cores of tumor tissue and two cores of adjacent mucosa were punched out from FFPE blocks and arrayed in a new tissue microarray (TMA) block using a precision mechanized system. Sections (4-μm thick) from each TMA block were performed for H&E and immunohistochemical staining.

Immunohistochemistry (IHC) was performed using a Ventana Benchmark ULTRA automated staining system with a primary monoclonal antibody for ERα (Clone SP1; Ventana Medical Systems, Inc.; reference number: 790-4324), according to the manufacturer’s instructions.

Cases were evaluated based on brown cytoplasmic and/or nuclear staining, and the staining intensity was graded by the Allred score system (range 0–8)[^2], expressed as the sum of scores representing the proportion and staining intensity of negative and positive tumor cell nuclei. Cases with score 2 were designated as positive for ERα expression. The immunoreactivity was viewed by two pathologists independently in a blinded manner. If there was a difference between the two observers, these slides were reanalyzed by both investigators using a multihheaded microscope.

Statistical analysis

Descriptive statistics included frequencies with percentage for nominal variables and mean with ± standard deviation (SD) for continuous variables. Fisher’s exact test analysis was used for categorical data and t-test for continuous data. Survival was estimated using the Kaplan–Meier method, and differences in survival curves were examined using the log-rank test. Disease-free survival (DFS) was calculated from the date of surgery to the date of recurrence or the last follow-up. Overall survival (OS) was defined as the time between surgery and death of any cause or last follow-up. All data were analyzed using SPSS version 20.0 (SPSS Inc., Chicago, IL). Statistical significance was defined as p<0.05.

RESULTS

During the selected period, a total of 345 patients were included in the study and evaluated for ERα expression. The majority of GC patients were men (60%), with a mean age of 62.4 years. Subtotal gastrectomy was the most performed type of surgery and 83.7% of patients underwent D2 lymphadenectomy.

According to the ER evaluation, 6 (1.8%) patients were identified as ERα-positive. The remaining 339 (98.2%) patients with ERα-negative served as a comparison group (Figure 1).

Figure 1 - Immunohistochemical findings: (A) gastric adenocarcinoma positive for ERα and (B) adenocarcinoma negative for ERα staining (20×).
Table 1 shows the characteristics of the two ERa groups. Total gastrectomy (p=0.012), larger tumor size (p=0.031), diffuse/mixed Lauren type (p=0.012), presence of perineural invasion (p=0.030), and lymph node metastasis (p=0.215) were associated with ERa-positive group. There were no statistical differences regarding gender, age, number of lymph nodes dissected, and TNM between the groups.

Table 2 summarizes the characteristics of each six ERa-positive patients. All ERa-positive patients were men who aged 34–78 years. Also, all cases had Lauren diffuse GC and pN+ status. The final stage was IIA in one case, IIIA in three cases, and IIIB in two cases. All ERa-positive patients received some chemotherapy (CMT) regimen: (1) neoadjuvant CMT, (2) adjuvant CMT, or (3) palliative CMT.

Table 1 - Clinical and pathological characteristics of patients with gastric cancer according to the expression of ERa.

| Variables                        | ERa-negative | ERa-positive | P     |
|----------------------------------|--------------|--------------|-------|
| Sex                              | n=339 (%)    | n=6 (%)      |       |
| Women                            | 138 (40.7)   | 6 (100)      | 0.085 |

SD, standard deviation; ASA, American Society of Anesthesiologists; BMI, body mass index. P values in bold are statistically significant.

The median follow-up was 45.1 months, and the OS rate for the entire population was 53.1%. Among those six ERa-positive patients, three had disease recurrence and died. The site of recurrence in these three ERa-positive patients was peritoneal.

There was no difference in the OS rates between ERa-negative and ERa-positive groups (p=0.752). The median OS for ERa-positive patients was 26.3 months. Regarding DFS, no difference in survival was found between the groups (p=0.325). The median DFS for ERa-positive patients was 15 months (Figure 2).

**DISCUSSION**

GC is a heterogeneous disease, and during diagnosis, it is mostly in an advanced stage. The treatment of GC depends on factors such as biomarkers, TNM staging, and the patient’s condition. In addition, despite advances in therapies, the prognosis of advanced GC patients remains poor. Although the frequency of positivity was low, we found homogeneity in relation to the characteristics of the patients. All GCs that exhibited ERa-positive had poorly differentiated histology, diffuse type, and lymph node metastasis, in agreement with that reported in the literature. In fact, compared with other therapeutic targets, few studies have examined the expression of ERa in GC, so that there is still considerable controversy as to the expression level of ERa and its prognostic value in GC.

The first therapeutic target identified for GC treatment was HER-2. HER-2, also called ERB-2, is a tyrosine kinase receptor that, when mutated, has an effect on oncogenesis. It alters cell proliferation, cell differentiation, and program death and cell mobility. In addition, it is correlated with the progressive and metastatic potential of the tumor. After the results of the ToGA trial, trastuzumab (anti-HER2 antibody) was approved for use in patients with positive expression for HER-2.

In contrast, ER is a class of steroids that is involved in several functions of the body. In addition to regulating the development and growth of the human reproductive system, it also plays a role in the physiology of the cardiovascular, skeletal, and neuroendocrine systems. Through its receptors, ERa and ERB, estrogen is able to translate signals into transcriptional responses. It is worth noting that both receptors, despite similar structures, have different functions.

Estrogen plays a role through genomic and nongenomic pathways. In the genomic pathway, when estrogen is bound to its receptor, it is translocated into the nucleus, in which elements bind to the genomic DNA, regulating an expression of genes. While in the nongenomic pathway, ERs interact with other signaling molecules, such as PI3K/Akt, or mitogen-activated protein kinase. ERs, namely, ERa and ERB, act in both pathways.

Hormone receptors are extremely important in the role of oncogenesis in hormone-dependent tumors. In breast cancer, for example, ERa promotes tumorigenesis and progression of the tumor, while ERB expression is generally associated with inhibition of invasion, proliferation, and programmed cell death. In GC, however, the prognostic role of ER still remains controversial.

Tokunaga et al. were the first authors to study the correlation between hormone receptors and GC. In their study, the presence of estrogen and progesterone receptors...
was reported in 20% of gastric tumors. In addition, the results suggested that the GC could be influenced by hormonal factors.

Regarding the frequency of expression reported in the literature, it can be noted that the rate of ERα expression in GC quite varies. Xu et al. observed an ERα positivity of 22.7% in patients with GC. However, the high frequency can be attributed to the predominance of tumors with undifferentiated histology among the evaluated patients (~80% of cases). In addition, the authors considered the weak cytoplasmic expression as positive.

In turn, Tang et al. observed the positive expression of ERα in 6% of the samples (9/150). Remarkably, there are studies in which no expression of ERα was found in GC, and other studies in which tumor exhibited only low level of expression.

In our study, similar to some previous studies, the frequency of ERα expression in GC patients was <2%. This can be explained in part by the high frequency of intestinal tumors in our cohort.

Presently, inconsistent associations of ERs with GC have been reported. Results from a meta-analysis showed that the rate of positivity for ERβ expression in GC was higher than ERα, with different patterns in subtypes of tumors. GC positive for ERα was associated with poorly differentiated adenocarcinoma and worse OS. In contrast, the ERβ positivity could have a protective effect against the invasiveness.

In the present study, from a cohort of 345 patients with GC, 6 (1.8%) were classified as ERα-positive. Positivity for ERα was associated with tumor size, diffuse/mixed Lauren histological...
type, presence of perineural invasion, and lymph node metastasis. Despite presenting the characteristics associated with a worse prognosis and advanced disease, there was no significant difference in survival outcomes. However, this can be attributed to the low number of patients positive for ERα in the present series.

There were some limitations in the present study, inherent in retrospective studies, like selection bias, which could interfere in results considering the interaction between variables. Only patients undergoing surgical resection were included. Thus, we do not know whether the expression of ERα has differences in patients undergoing palliative treatment. Still, variations in results compared with other studies are predicted due to different evaluation criteria for IHC results and antibody clones used.

Still, the analysis only considered ERα, the subtype which is more associated with GC prognosis in literature. Variations can also be attributed with respect to tumor sampling. In this study, patients were assessed through the TMA construction. This may increase the chance of false-negative results in the case of markers where the expression is restricted. However, we followed the guidelines and, as suggested, we used three tissue cores of tumor from each patient which are recommended for an adequate assessment of tumor heterogeneity.

CONCLUSIONS

The expression of ERα in GC was associated with diffuse histology and presence of lymph node metastasis and may suggest a role as a marker related to tumor progression and worse prognosis. Also, a high rate of peritoneal recurrence was observed in ERα-positive patients. Since the frequency of ERα expression seems to be low, studies that involve larger cohorts are requested in the future considering the interaction between variables. Only patients undergoing surgical resection were included. Thus, variations in results compared with other studies are predicted due to different evaluation criteria for IHC results and antibody clones used.

Studies that involve larger cohorts are requested in the future considering the interaction between variables. Only patients undergoing surgical resection were included. Thus, variations in results compared with other studies are predicted due to different evaluation criteria for IHC results and antibody clones used.
