Predictors of blood lead concentrations in the lead-free gasoline era
by Jesper B Nielsen, MSc, Philippe Grandjean, MD, Pou I Jørgensen, MSc

Nielsen JB, Grandjean P, Jørgensen P. Predictors of blood lead concentrations in the lead-free gasoline era. Scand J Work Environ Health 1998;24(2):153—6.

Objectives Blood lead concentrations in a Danish reference population were related to information from an extensive questionnaire on work, environment, and lifestyle.

Methods Data were gathered for 209 persons by means of a questionnaire and blood lead analyses.

Results The mean concentration of lead in blood was 0.167 μmol/l (ie, significantly lower than in previous studies). This finding is in accordance with the fact that less than 10% of the gasoline used in Denmark contains lead additives (up to 0.15 g/l). An important finding was that the well-documented predictors for lead in blood at higher concentration levels, such as age, gender, menopausal status, and intake of alcohol, are still valid in a low-level exposure situation. In addition, a strong and negative correlation was found between blood lead concentrations and dietary supplementation with vitamins and minerals.

Conclusions The present data indicate that lead exposure may still constitute a health risk in a small proportion of adult men and postmenopausal women.

Key terms age, alcohol consumption, gender, health risk, vitamin intake.

Evidence of neurotoxicity has increased the awareness concerning low-level, nonoccupational lead exposure. The lead concentration in whole-blood has been used as a proxy for the biologically active body burden of this metal (1). Blood lead (B-Pb) concentrations as low as 0.48 μmol/l have been associated with adverse effects on behavior and development in children (1). Furthermore, recent data suggest that B-Pb concentrations of about 0.38 μmol/l may be associated with decreased cognitive function in postmenopausal women (2).

Thus, despite the well-documented reductions in B-Pb levels in the general populations in many countries (3—5), lead remains a toxicologic issue, and the identification of variables affecting B-Pb concentrations remain important.

The objective of this study was to describe B-Pb concentrations in a reference population and relate the findings to information from an extensive questionnaire covering topics related to occupational exposure, traffic exposure, overall health, food habits, intake of alcohol, smoking and sociodemographic parameters. Furthermore, the results were related to a previous study on an identical population in Funen 5—6 years before (6).

Study population
A reference population was established in Funen, Denmark, consisting of 219 persons (110 men and 109 women) randomly selected from the Danish central register of residents according to the following criteria: 20 men and 20 women in each age decade between 20 and 89 years, half residing within the city and the other half within rural communities. No exclusion criteria were used, except the ability to fill out the questionnaire. As in a previous study (6), the participants were included consecutively, after they signed an informed consent form, until their respective subgroups were filled. The overall response rate was 70%, and among the respondents 44% accepted to participate. The participation rate was particularly low in the 2 oldest age decades (6% and 19%), and the anticipated number of subjects was not reached in these 2 age decades within the time limits of the study. Information regarding health, dietary habits (intake of meat, fruit, vegetables, coffee, tea, etc), use of dietary supplements (vitamins, minerals), alcohol consumption, smoking (including passive smoking), use of prescribed drugs, occupational exposures, hobbies, traffic, and housing situation were obtained by questionnaire and a subsequent interview. Approximately 60% of the sample group was currently employed. Other participants were students, retirees, or unemployed persons. Forty-three percent were current smokers, 23% were ex-smokers, and 32% had never smoked. According to these data, the sample group did not deviate from the general Danish population during the sampling period in 1994 (7, 8). The
reference population had previously been used to establish reference intervals for malondialdehyde (an indicator for lipid peroxidation) and antioxidative enzymes (9, 10).

**Methods**

**Lead analysis.** The B-Pb concentrations were read in duplicate against a blood-based standard curve with standard reference material SRM 955 (National Institute of Standards and Technology, Gaithersburg, Maryland, United States) as the primary standard. Seronorm Trace Element batches 901 and 902 (NycoMed, Oslo, Norway) were used as quality control materials. The total analytical imprecision (N = 38) was estimated to be 3.0% and 2.0% at B-Pb concentrations of 0.22 and 1.58 μmol/l, respectively. In the earlier study (6), the same 2 control materials were 0.23 and 1.63 μmol/l (ie, almost identical to the values obtained in the present study). A comparison of the 2 sample groups must thus be justified. The assigned values were 0.3 and 1.6 μmol/l for the 2 materials. The detection limit was 0.05 μmol/l.

**Statistics.** Statistical analyses were performed using SPSS 6.1 software (SPSS, Chicago, Illinois, United States). Goodness-of-fit to normal distribution was assessed by probit plot and K-S-test. The logarithmic transformation of the B-Pb concentrations approached a Gaussian distribution. Pearson’s correlation coefficient was used to assess associations between B-Pb concentrations and age. The differences in the mean values were analyzed by the independent sample’s t-test, and multiple regression analysis was performed using the stepwise regression procedure with P in = 0.05 and P out = 0.10 (a modified forward regression that permits reexamination, at every step, of the variables incorporated into the model in previous steps).

**Results**

**Blood lead levels.** The mean B-Pb concentration of the population was 0.167 μmol/l, with a mean of 0.191 μmol/l for the men and 0.143 μmol/l for the women (table 1).

**Age and gender.** The B-Pb concentrations increased with age (table 1). They were generally higher for the men than for the women, and this difference was significant in the 2 youngest age decades (table 2). The B-Pb correlated positively with age among the women (table 1), whereas the correlation was weaker and not statistically significant for the men (table 1). Further analysis of the female participants revealed that the mean B-Pb was significantly higher for women who had reached menopause than for women who had not (table 3).

**Life-style exposures.** Regular smokers had slightly elevated B-Pb levels, as compared with nonsmokers (table 3), and inhalation did not affect the B-Pb levels of the smokers (P = 0.475). People with a weekly alcohol consumption below 5 drinks had significantly lower B-Pb concentrations than those with higher alcohol intake (table 3). Furthermore, people who daily took vitamins or vitamins with minerals had a significantly lower B-Pb level than people who never used this kind of supplementation (table 3).

**Residence and traffic.** There were no significant associations between B-Pb and residence in urban versus rural areas. Furthermore, neither traffic intensity at home nor the time used daily for commuting affected the B-Pb to any significant extent.

**Occupational exposures.** Sixteen persons indicating that they were exposed to metal dust or metal fumes had elevated B-Pb concentrations as compared with unexposed workers, but the difference was not significant (table 3). The B-Pb concentrations of persons exposed to exhaust gases were higher than those of unexposed persons, and the difference was of borderline significance (table 3).

**Multiple regression.** As the participation rates were low for people over 70 years of age, this group was excluded from the model, as was also 1 person with a reported weekly alcohol consumption of 70 drinks. From the predictors that were significant in the bivariate analysis, the following 4 variables were accepted by the model: gender, age, weekly alcohol consumption, and daily use of vitamins or vitamins with minerals (table 4). Further analysis revealed no indication of colinearity between the variables. Smoking did not add signifi-

Table 1. Mean values of blood lead in a reference population and the correlation with age.

| Age (years) | Men | Women |
|------------|-----|-------|
| Blood lead concentration (μmol/l) | Mean | SD | Correlation coefficient (r) | Significance |
| 20—29 | 0.129 | 0.101 | 0.283 | < 0.001 |
| 30—39 | 0.174 | 0.094 | 0.191 | 0.001 |
| 40—49 | 0.191 | 0.145 | 0.22 | 0.194 |
| 50—59 | 0.182 | 0.130 | 0.21 | 0.070 |
| 60—69 | 0.178 | 0.156 | 0.17 | 0.411 |
| 70—79 | 0.151 | 0.137 | 0.770 |
| 80—89 | 0.310 | 0.155 | 0.2 | 0.361 |
| 20—89 | 0.169 | 0.117 | 0.109 | 0.001 |

Table 2. Geometric means of the blood lead (B-Pb) concentration in the reference population. Comparison between men and women.

| Age (years) | Men | Women |
|-------------|-----|-------|
| Geometric mean B-Pb concentration (μmol/l) | N | Geometric mean B-Pb concentration (μmol/l) | N | t-test, 2-tailed |
| 20—29 | 0.129 | 20 | 0.075 | 21 | 0.003 |
| 30—39 | 0.174 | 20 | 0.094 | 19 | 0.001 |
| 40—49 | 0.191 | 20 | 0.145 | 22 | 0.194 |
| 50—59 | 0.182 | 21 | 0.130 | 21 | 0.070 |
| 60—69 | 0.178 | 20 | 0.156 | 17 | 0.411 |
| 70—79 | 0.151 | 8 | 0.137 | 7 | 0.770 |
| 80—89 | 0.310 | 1 | 0.155 | 2 | 0.361 |
| 20—89 | 0.169 | 110 | 0.117 | 109 | 0.001 |
Affect B-Pb in the population. Be expected that life-style factors to a larger degree would homogeneous exposures from the general environment, it can be expected that lifestyle factors to a larger degree would affect B-Pb in the population.

Discussion

With the use of an identical analytical method for blood samples from a random selection of the general population, a mean B-Pb concentration of 0.24 (SD 0.13) μmol/l was obtained in 1988—1989, whereas the current mean B-Pb concentration was 0.17 μmol/l. Thus the B-Pb has decreased significantly during the 5—6 years between samplings. The reduced B-Pb concentrations can primarily be attributed to reductions in the amount of lead used in gasoline. During the latest sampling period, about 90% of cars used unleaded gasoline, and no more than 0.15 g/l was added to the leaded qualities. Thus the reduced B-Pb concentration in the general population can be seen as the remarkable success of a preventive effort. Identical findings have been reported from other countries, including the United States, Canada, Italy, and Taiwan (3—5, 11).

Age and gender significantly affect B-Pb (3, 6, 11, 12). These observations are confirmed in the present study under low-level exposure circumstances, where the B-Pb of the men was, on the average, about 0.05 μmol/l higher than that of the women and age seemed to be significantly correlated with the B-Pb concentration. However, the correlation with age was only significant for the women. Thus B-Pb levels seem to increase only up to an age of about 50 years among men, whereas they tend to continue increasing in women also after 50 years of age. Some of the age-related increase may be due to accumulated lead from previous exposures originating from gasoline with high lead contents. The increased B-Pb level in women over 50 years of age has previously been linked to menopause (6, 13), and the present study confirms the results of these previous studies as postmenopausal women had significantly higher B-Pb levels than premenopausal women. The increased B-Pb level in postmenopausal women may be of relevance, as mild cognitive deficits have been reported in older women with B-Pb levels as low as 0.38 μmol/l (2). In our Danish population, about 4% of the women had B-Pb concentrations above 0.38 μmol/l, as did 7% of the men. Although the number of participants with an increased B-Pb was too low to reach a firm conclusion, the data indicate that a small proportion of the general population may still have an increased lead exposure, despite the fact that mean levels of B-Pb have decreased to indeed very low levels.

Previously, lead levels could be related to well-known exposure sources from work or traffic exhaust. The present study demonstrates that differences related to residence, traffic, and work are of only marginal importance in relation to B-Pb. With decreasing occupational exposures and more homogeneous exposures from the general environment, it can be expected that lifestyle factors to a larger degree would affect B-Pb in the population.

Table 3. Geometric mean blood lead (B-Pb) concentration in selected groups of the reference population.

| Alcohol intake | N | Different from previous group (P) |
|----------------|----|----------------------------------|
| < 5 drinks per week | 87 | 0.099 |
| > 4 drinks per week | 130 | 0.177 |

Table 4. Multiple regression using a stepwise regression procedure and In(lead) as a dependent variable. The population was restricted to people below 70 years of age with a weekly alcohol consumption below 60 drinks.

| Vitamin and mineral | Regression coefficient | Standard error | P-value |
|---------------------|-----------------------|----------------|---------|
| Age | 0.009 | 0.003 | 0.0058 |
| Vitamin and mineral supplementation | −0.163 | 0.050 | 0.0014 |
| Weekly alcohol consumption | 0.016 | 0.004 | 0.0004 |

Smoking and alcohol consumption have been previously demonstrated to be positively associated with B-Pb concentrations (3, 5, 6). Our data confirm these observations. Thus people having more than 4 drinks per week had 80% higher B-Pb concentrations on average than people with lower alcohol consumption, and regular smokers had higher average B-Pb levels than nonsmokers. An interesting observation was the very strong negative association between the daily use of vitamins and minerals and the observed B-Pb. A partial correlation analysis and an analysis for collinearity did not show any relation to other lifestyle factors. Complex relations between B-Pb concentrations and nutritional status have been previously described for human populations, for which individual factors such as zinc, iron, selenium, calcium, and vitamins B and D have been demonstrated to affect B-Pb (1). However, at present, no definite biological explanation for the
association can be suggested, and the association may be spurious or due to confounding.

The regression model for the population included only the variables gender, age, alcohol consumption, and daily intake of vitamins as significant independent variables. With a correlation coefficient of 0.6, about 34% of the variance in B-Pb was explained by these 4 variables. The limited number of predictors is probably due to the improved control of lead released to the environment. This preventive effort is also the reason for the reduced standard deviation and the small range of B-Pb concentrations within our current population [eg, in comparison with the population investigated in Denmark 8 years ago (6)].
