The two defaults scenario for stressing credit portfolio loss distributions

Dirk Tasche*

The impact of a stress scenario of default events on the loss distribution of a credit portfolio can be assessed by determining the loss distribution conditional on these events. While it is conceptually easy to estimate loss distributions conditional on default events by means of Monte Carlo simulation, it becomes impractical for two or more simultaneous defaults as then the conditioning event is extremely rare. We provide an analytical approach to the calculation of the conditional loss distribution for the CreditRisk$^+$ portfolio model with independent random loss given default distributions. The analytical solution for this case can be used to check the accuracy of an approximation to the conditional loss distribution whereby the unconditional model is run with stressed input probabilities of default (PDs). It turns out that this approximation is unbiased. Numerical examples, however, suggest that the approximation may be seriously inaccurate but that the inaccuracy leads to overestimation of tail losses and hence the approach errs on the conservative side.

1 Introduction

Stress test scenarios for credit risk typically are stated in terms of economic factors but sometimes involve defaults of larger counterparties or obligors (see e.g. BoE, 2015, Section 10.3.3). Default of a large obligor not only has a direct impact on the profit and loss of a bank and potentially also on its capital basis. Due to mutual dependence of default events the default of one or more obligors can have a significant impact on the loss distribution of the remaining portfolio, too. Determination of credit portfolio loss distributions conditional on defaults, therefore, can be considered a special stress testing technique. Such analysis, in particular, can help to decide whether a large exposure to a certain obligor is just a risk concentration because of its size or, even worse, also significant part of a sector or industry risk concentration. Loss distributions conditional on default of one or more obligors therefore are promising means to identify vulnerabilities of banks.

Techniques for measuring the impact of macro-economic stress scenarios on credit portfolio losses are well-established (see e.g. Bonti et al., 2006; Kalkbrener and Packham, 2015). In particular,
it is common and efficient to analyse such stress scenarios by means of Monte-Carlo simulation. In principle, it is easy to determine also the impact of the default of one or more obligors via a Monte-Carlo simulation approach: Just eliminate all simulation iterations from the sample in which the obligor(s) on whose default(s) conditioning is to be conducted have not defaulted. This is feasible in practice for one default, but becomes impracticable for two or more defaults.

An obvious approach to try and work around this problem would be to deploy an unstressed (i.e. unconditional) model for the analysis but to feed it with parameters like probabilities of default (PDs) and loss-given-default (LGD) that have been stressed in a separate exercise before. This approach – which may be called ‘stressed input parameters’ approach –, however, might fail to fully capture the dependence structure of the model and its changes under stress such that misjudgement of the stress impact could be the consequence.

This paper seeks to assess how accurate the results calculated with the ‘stressed input parameters’ approach are when compared to results from a fully-fledged conditional loss distribution approach. For that purpose we revisit the CreditRisk\(^+\) credit portfolio risk model (CSFB, 1997) and derive a representation of the loss distribution conditional on the default of two fixed obligors that allows for the computation of the distribution without Monte-Carlo simulation. Two numerical examples then suggest that results from the ‘stressed input parameters’ approach may be seriously inaccurate but tend to be inaccurate in a conservative direction and to overestimate tail losses.

Tasche (2004, equation (3.31)) showed how the loss distribution conditional on one default can be calculated analytically in the CreditRisk\(^+\) model with random loss severities. In this paper the related formulas for the case of two defaults are provided. Formulas for the cases of three or more defaults can be readily derived in the same way as the formula for the case of two defaults is derived. As a consequence of the likely lack of practical relevance of cases of three or more defaults scenarios, we do not provide the results for these cases here. Moreover, the paper is focused on the theoretical derivation of the main result on the loss distribution conditional on two defaults and its interpretation. The question of practical numerical implementation is only considered to such an extent as needed for the numerical examples.

The plan of this paper is as follows:

- As background and for introducing the notation, Section 2 provides a description of the CreditRisk\(^+\) model as presented in CSFB (1997) or Gundlach (2004). The CreditRisk\(^+\) model described here is enhanced to allow for random loss severities\(^1\).
- In Section 3 the results on the conditional loss distributions are presented and their application is discussed. To derive the results we revisit the approach used in Tasche (2004) to develop analytical representations of the Value-at-Risk and Expected Shortfall contributions of single obligors in CreditRisk\(^+\).
- In Section 4 we present the technical particulars of the ‘stressed input parameters’ approach and prove that the first moments of the resulting loss distributions are the same as the first moments of the proper loss distribution conditional on two defaults.
- Section 5 provides two numerical examples to shed light on the question of how close the results from the ‘stressed input parameters’ and conditional loss distribution approaches are in general.

\(^1\)Schmock (2008) describes a further generalisation of the model to include connected groups of obligors.
The paper concludes with summarising comments in Section 6.

2 An analytical credit portfolio model with random loss severities

The approach to the CreditRisk\(^+\) loss distribution as described in CSFB (1997) or Gundlach (2004) is driven by analytical considerations and – to some extent – hides the way in which the Poisson approximation is used to smooth the loss distribution. While preserving the notation of Gundlach (2004), therefore we review in this section the steps that lead to the formula for the generating function of the loss distribution in CSFB (1997) and Gundlach (2004). When doing so, we slightly generalize the methodology to the case of stochastic exposures – thus allowing for random loss severities – that are independent of the default events and the random factors expressing the dependence on sectors or industries. This generalization can be afforded at no extra cost as the result is again a generating function in the shape as presented in Gundlach (2004, equation (2.19)), the only difference being that the sector polynomials are composed another way.

Write \(1_A\) for the default indicator of obligor \(A\), i.e. \(1_A = 0\) if \(A\) does not default in the observation period and \(1_A = 1\) if \(A\) defaults. In CSFB (1997) and Gundlach (2004), an approximation is derived for the distribution of the portfolio loss variable \(X = \sum_A 1_A \nu_A\) with the \(\nu_A\) denoting deterministic potential losses. A careful inspection of the beginning of Section 5 of Gundlach (2004) reveals that the main step in the approximation procedure is to replace the \(\{0, 1\}\)-valued indicators \(1_A\) by integer-valued random variables \(D_A\) with the same expected values. These variables \(D_A\) are conditionally Poisson distributed given some economic factors \(S_1, \ldots, S_N\).

Here, we want to study the distribution of the more general loss variable \(X = \sum_A 1_A \mathcal{E}_A\), where \(\mathcal{E}_A\) denotes the random outstanding exposure of obligor \(A\). We assume that \(\mathcal{E}_A\) takes on non-negative integer values. However, just replacing \(1_A\) by \(D_A\) as in the case of deterministic potential losses does not yield a nice generating function – “nice” in the sense that the CreditRisk\(^+\) algorithms for extracting the loss distribution can be applied. We instead consider the approximate loss variable

\[
X = \sum_A \sum_{i=1}^{D_A} \mathcal{E}_{A,i},
\]

(2.1a)

where \(\mathcal{E}_{A,1}, \mathcal{E}_{A,2}, \ldots\) are independent copies of \(\mathcal{E}_A\). Thus, we approximate the terms \(1_A \mathcal{E}_A\) by conditionally compound Poisson sums. For the sake of brevity, we write

\[
Y_A = \sum_{i=1}^{D_A} \mathcal{E}_{A,i}
\]

(2.1b)

for the loss suffered due to obligor \(A\). A careful inspection of the arguments presented to derive Equation (2.19) of Gundlach (2004) now yields the following result on the generating function of the distribution of the loss variable \(X\).

**Theorem 2.1** Define the “loss” variable \(X\) by (2.1a) and specify the distribution of \(X\) by the following assumptions:

(i) The approximate default indicators \(D_A\) are conditionally independent given a vector of “economic” factors \(S = (S_0, S_1, \ldots, S_N)\). The conditional distribution of \(D_A\) given \(S\) is
Poisson with intensity \( p_A^S = p_A \sum_{k=0}^{N} w_{Ak} S_k \) where \( p_A > 0 \) denotes the “probability of default” (PD) of obligor \( A \) and \( 0 \leq w_{Ak} \leq 1 \) are “factor loadings” such that \( \sum_{k=0}^{N} w_{Ak} = 1 \) for each obligor \( A \).

(ii) The idiosyncratic factor \( S_0 \) is a constant and equals 1. The factors \( S_1, \ldots, S_N \) are independent and Gamma-distributed\(^2\) with unit expectations \( \mathbb{E}[S_k] = 1 \) and parameters\(^3\) \((\alpha_k, \beta_k) = (\alpha_k, 1/\alpha_k)\) for \( k = 1, \ldots, N \).

(iii) The random variables \( E_{A,1}, E_{A,2}, \ldots \) are independent copies of a non-negative integer-valued random variable \( E_A \) and, additionally, are also independent of the \( D_A \) and \( S \). The distribution of \( E_A \) is given by its generating function

\[
H_A(z) = \mathbb{E}[z^{E_A}], \quad z \in \mathbb{C}, |z| \leq 1.
\] (2.2a)

Define for \( k = 0, 1, \ldots, N \) the sector polynomial \( Q_k \) by

\[
Q_k(z) = \frac{1}{\mu_k} \sum_A w_{Ak} p_A H_A(z),
\] (2.2b)

where the sector default intensities \( \mu_k \) are given by

\[
\mu_k = \sum_A w_{Ak} p_A.
\] (2.2c)

Then the generating function \( G_X(z) = \mathbb{E}[z^X], z \in \mathbb{C}, |z| \leq 1 \), of the loss variable \( X \) can be represented as

\[
G_X(z) = e^{\mu_0 (Q_0(z) - 1)} \prod_{k=1}^{N} \left( \frac{1 - \delta_k}{1 - \delta_k Q_k(z)} \right)^{\alpha_k},
\] (2.2d)

where the constants \( \delta_k \) are defined as \( \delta_k = \mu_k/(\mu_k + \alpha_k) \).

Remark 2.2

(i) The case of deterministic severities can be regained from Theorem 2.1 by choosing the exposures constant, e.g. \( E_A = \nu_A \). Then the generating functions of the exposures are just monomials, namely \( H_A(z) = z^{\nu_A} \).

(ii) Representation (2.2d) of the generating function of the portfolio loss distribution implies that the portfolio loss distribution can be interpreted as the distribution of a sum of \( N + 1 \) independent sector loss distributions that correspond to the economic factors \((S_0, S_1, \ldots, S_N)\).

The term \( e^{\mu_0 (Q_0(z) - 1)} \) is the generating function of a random variable with a compound\(^4\) Poisson distribution that can be realised as \( \sum_{i=1}^{T_0} \eta_{0,i} \) where \( T_0, \eta_{0,1}, \eta_{0,2}, \ldots \) are independent, \( T_0 \) is Poisson-distributed with intensity \( \mu_0 \), and \( \eta_{0,1}, \eta_{0,2}, \ldots \) are i.i.d. with generating function \( Q_0(z) \).

\(^2\)We call a positive random variable \( Y \) Gamma-distributed if it has a density \( f_Y(y) = \frac{y^{\alpha-1}}{\beta \Gamma(\alpha)} e^{-y/\beta}, y > 0 \) for some parameters \( \alpha > 0, \beta > 0 \). The function \( \Gamma \) denotes the familiar Gamma function generalising the factorial.

\(^3\)\( \beta_k = 1/\alpha_k \) is implied by the assumption that \( S_k \) has unit expectation.

\(^4\)See, e.g., Rolski et al. (1999) for background information on compound distributions and generating functions.
The terms \( \left( \frac{1-\delta_k}{1-\delta_k Q_k(z)} \right)^{\alpha_k} \), \( k = 1, \ldots, N \), are the generating functions of random variables with compound negative binomial distributions that can be realised as \( \sum_{i=1}^{T_k} \eta_{k,i} \) where \( T_k, \eta_{k,1}, \eta_{k,2}, \ldots \) are independent, \( T_k \) is negative binomially distributed\(^5\) with failure probability \( \delta_k \) and size parameter \( \alpha_k \), and \( \eta_{k,1}, \eta_{k,2}, \ldots \) are i.i.d. with generating function \( Q_k(z) \).

With this representation of the portfolio loss distribution as the convolution of compound Poisson and negative binomial distributions, the sector polynomials \( Q_k \) can be interpreted as the generating functions of typical loss severities in the respective sectors.

By means of Theorem 2.1 the loss distribution of the generalized model (2.1a) can be calculated in principle with the same algorithms as in the case of the original CreditRisk\(^+\) model. Once the probabilities \( P[X = x] \), \( x \) non-negative integer, are known, it is an easy task to calculate the loss quantiles \( q_\theta(X) \) as defined by

\[
q_\theta(X) = \min\{x \geq 0 : P[X \leq x] \geq \theta\},
\]

or related risk measures like Value-at-Risk or Expected Shortfall.

When working with Theorem 2.1, one has to decide whether random exposures shall be taken into account, and in case of a decision in favour of doing so, how the exposure distributions are to be modeled. Tasche (2004, Example 1) and Schmock (2008) present some possible choices of discrete exposure distributions. Gordy (2004) discusses an approximate but similar approach to random severities with continuous distributions.

Parametrisation of the factor model as described in Theorem 2.1 is non-trivial because the assumption of independent economic factors is unrealistic in practice. Vandendorpe et al. (2008) discuss how to derive appropriate factor loadings from default observations and their correlations. Han and Kang (2008) suggest introducing a further factor to model dependence of the economic factors without violating the assumptions of the framework. Their approach is generalised in Fischer and Dietz (2011). Other authors (e.g. Wang et al., 2015) propose extensions of the CreditRisk\(^+\) model that allow for realistic modelling of the dependencies between the economic factors but renounce the analytic tractability of the original model. Jakob and Fischer (2014) discuss the impact on the loss distribution of choosing different factor dependence structures in extended versions of the CreditRisk\(^+\) framework.

3 Loss distributions conditional on defaults

The purpose of this section is to provide formulas for the portfolio loss distribution conditional on defaults that can be represented in similar terms as the unconditional loss distribution and hence be evaluated with the familiar CreditRisk\(^+\) algorithms. The following theorem – a modification of Tasche (2004, Lemma 1) – yields the foundation of the results. Denote by \( I(E) \) the indicator variable of the event \( E \), i.e. \( I(E; m) = 1 \) if \( m \in E \) and \( I(E; m) = 0 \) if \( m \notin E \).

\(^5\)We call a random variable \( Y \) with values in the non-negative integers negative binomially distributed with size parameter \( a > 0 \) and failure probability \( 0 < p < 1 \) if \( P[Y = k] = \binom{a+k-1}{k} (1-p)^a p^k \) for \( k = 0, 1, 2, \ldots \). If the size parameter \( a \) of a negative binomial distribution is a positive integer then the distribution can be interpreted as the distribution of the number of failures in a series of independent identical experiments before the \( a \)-th success is observed.
Theorem 3.1 Define the approximate default indicators $D_A$ as in Theorem 2.1. Assume that $A(1), \ldots, A(r)$ are obligors such that $A(i) \neq A(j)$ for $i \neq j$. Under the assumptions and with the notation of Theorem 2.1 then we have

$$
\mathbb{E} \left[ I(X = x) \prod_{i=1}^{r} D_A(i) \right] = \mathbb{E} \left[ I(X = x - \sum_{j=1}^{r} \mathcal{E}_{A(j)} \prod_{i=1}^{r} p^S_{A(i)} \right]
$$

(3.1)

for any non-negative integer $x$, where the random variables $\mathcal{E}_{A(1)}, \ldots, \mathcal{E}_{A(r)}$ on the right-hand side of (3.1) are independent of the loss variable $X$ and the default intensities $p^S_{A(i)}$.

Proof. We provide the proof only for the case $r = 2$ as the proof for general $r$ is not much different but the notation would be more cumbersome. Hence assume that two obligors $A(1) \neq A(2)$ have been selected. The assumptions on independence and conditional independence from Theorem 2.1 then imply

$$
\mathbb{E} [D_A(1)D_A(2)I(X = x)]
$$

$$
= \sum_{k_1=1}^{\infty} \sum_{k_2=1}^{\infty} k_1 k_2 \mathbb{P} [D_A(1) = k_1, D_A(2) = k_2, \sum_{B \neq A(1), B \neq A(2)} Y_B + \sum_{i=1}^{k_1} \mathcal{E}_{A(i),1} + \sum_{j=1}^{k_2} \mathcal{E}_{A(2),j} = x]
$$

$$
= \sum_{k_1=1}^{\infty} \sum_{k_2=1}^{\infty} k_1 k_2 \mathbb{E} \left[ \left( \frac{p^S_{A(1)}}{k_1!} e^{-p^S_{A(1)}} \right) \left( \frac{p^S_{A(2)}}{k_2!} e^{-p^S_{A(2)}} \right),
\sum_{B \neq A(1), B \neq A(2)} Y_B + \sum_{i=1}^{k_1} \mathcal{E}_{A(i),1} + \sum_{j=1}^{k_2} \mathcal{E}_{A(2),j} = x \bigg| S\right]
$$

$$
= \sum_{k_1=1}^{\infty} \sum_{k_2=1}^{\infty} \mathbb{E} \left[ p^S_{A(1)} p^S_{A(2)}
\sum_{B \neq A(1), B \neq A(2)} Y_B + \sum_{i=1}^{k_1+1} \mathcal{E}_{A(i),1} + \sum_{j=1}^{k_2+1} \mathcal{E}_{A(2),j} = x \bigg| S\right]
$$

$$
= \mathbb{E} \left[ I(X = x - \mathcal{E}_{A(1)} - \mathcal{E}_{A(2)}) p^S_{A(1)} p^S_{A(2)} \right],
$$

as stated in (3.1).

q.e.d.

As the variable $D_A$ approximates obligor $A$'s default indicator the conditional expectation $\mathbb{E}[D_A \mid X = x]$ can be interpreted as an approximation of the conditional probability of obligor $A$'s default given that the portfolio loss $X$ assumes the value $x$. Tasche (2004, Corollary 1) observed the following result for $\mathbb{E}[D_A \mid X = x]$. It can be readily derived from Theorem 3.1.

Notation. For any positive integers $i \leq n$ define the $n$-dimensional $i$-th unit vector $e_i^{(n)}$ by

$$
e_i^{(n)} = (0, \ldots, 0, 1, 0, \ldots, 0).
$$

Where the dimension is known from the context we write $e_i = e_i^{(n)}$ for short.
Corollary 3.2 (Probability of default conditional on portfolio loss)

Adopt the setting and the notation of Theorem 2.1 and Theorem 3.1. Write \( P_\alpha[X \in \cdot] \) for \( P[X \in \cdot] \) in order to express the dependence of the portfolio loss distribution upon the exponents \( \alpha = (\alpha_1, \ldots, \alpha_N) \) in (2.2d). Assume that \( x \) is an integer such that \( P_\alpha[X = x] > 0 \). Then, in the CreditRisk+ framework, the conditional probability of obligor \( A \)’s default given that the portfolio loss \( X \) assumes the value \( x \) can be approximated by

\[
E[D_A | X = x] = p_A \frac{w_{A0} P_\alpha[X = x - \tilde{E}_A] + \sum_{j=1}^N w_{Aj} P_{\alpha + e_j}[X = x - \tilde{E}_A]}{P_\alpha[X = x]},
\]

(3.2)

where \( \tilde{E}_A \) stands for a random variable that has the same distribution as \( E_A \) but is independent of \( X \).

Intuitively, one might think that \( P[D_A > 0 | X = x] \) would be a better approximation of the conditional probability of default of obligor \( A \) than \( E[D_A | X = x] \). However, there is no such relatively simple representation of \( P[D_A > 0 | X = x] \) as (3.2) is for \( E[D_A | X = x] \). Moreover, by the assumption on the conditional Poisson distribution of \( D_A \) we have

\[
E[P[D_A > 0 | X]] = P[D_A > 0] < p_A = E[E[D_A | X]].
\]

(3.3)

Hence the bias of \( P[D_A > 0 | X = x] \) with respect to \( P[A \text{ defaults} | X = x] \) is likely to be greater than the bias of \( E[D_A | X = x] \).

The probabilities in the numerator of the right-hand side of (3.2) must be calculated by convolution if the loss severities \( E_A \) are non-deterministic. In any case, Corollary 3.2 can be used for constructing the portfolio loss distribution conditional on the default of an obligor. Observe that by the very definition of conditional probabilities it follows that

\[
P[X = x | A \text{ defaults}] = P[A \text{ defaults} | X = x] \frac{P[X = x]}{p_A}.
\]

(3.4)

Since by Corollary 3.2 an approximation for \( P[A \text{ defaults} | X = x] \) is provided, the term-wise comparison of (3.2) and (3.4) yields

\[
P_\alpha[X = x | A \text{ defaults}] \approx w_{A0} P_\alpha[X = x - \tilde{E}_A] + \sum_{j=1}^N w_{Aj} P_{\alpha + e_j}[X = x - \tilde{E}_A].
\]

(3.5)

Note that according to (3.5), the conditional distribution \( P_\alpha[X = \cdot | A \text{ defaults}] \) of the portfolio loss \( X \) given that \( A \) defaults may be computed as a weighted mean of stressed portfolio loss distributions. The stresses are expressed by the exponents \( \alpha_j + 1 \) in the generating functions of \( P_{\alpha + e_j}[X = \cdot] \), \( j = 1, \ldots, N \). In actuarial terms, incrementing the size parameter of a negative binomial claim number distribution (cf. Remark 2.2) means to give the claim number distribution a heavier tail. Hence, this way the number of claims (sector-related defaults in CreditRisk+ terms) tends to be larger after the stress was applied. No change due to stress, however, occurs to the sector loss severity distributions as characterised by the sector polynomials \( Q_j \). This is no surprise as the loss severities in the setting of this paper are assumed to be independent of the economic factors that drive the sector default frequencies.

\(^6\)Of course, the distribution also depends on \( \mu_0, Q_0, \ldots, Q_N \), and \( \delta_1, \ldots, \delta_N \). However, these input parameters are considered constant in Corollary 3.2.
Remark 3.3

(i) By (3.5) stressed portfolio loss distributions can be evaluated, conditional on the scenarios that single obligors have defaulted. If, for instance, the portfolio Value-at-Risk changes dramatically when obligor A’s default is assumed, then one may find that the portfolio depends too strongly upon A’s condition.

(ii) Equation (3.5) reflects a write-off or special provision due to obligor A’s default. This is a consequence of the fact that on the right-hand side of the equation loss distributions of the shape \( X + \tilde{E}_A \) appear, thus implying that losses \( X \) are added to a loss socket \( \tilde{E}_A \) caused by obligor A’s first default. However, usually in banks occurred losses are not taken into account for the determination of risk metrics (like quantiles as defined by (2.3)) but are deducted from the banks available capital buffer. In that sense (3.5) does not appropriately reflect banks’ practice.

(iii) To deal with the issue observed in (ii), note that Theorem 2.1 and Corollary 3.2 also can be applied to the case \( E_A = 0 \). In particular, dependencies within the portfolio are then still adequately reflected by obligor A’s conditional default intensity \( p_{SA} \). While \( E_A = 0 \) in Theorem 2.1 effectively eliminates any impact of obligor A on the unconditional portfolio loss distribution, (3.5) clearly demonstrates the impact of the dependence between A and the rest of the portfolio on the conditional portfolio loss distribution.

While Theorem 3.1 can be used to study the portfolio loss distributions conditional on any number of defaults, we confine ourselves in the following corollary and its consequences to considering only the case of two defaults as we already did in the proof of Theorem 3.1. The formulas for conditioning on three or more defaults can be derived in the same way as the formula for the case of two defaults. The cases of three or more defaults, however, are notationally and computationally much more inconvenient, presumably much less relevant for practice, and do not add much more theoretical insight compared to the case of two defaults.

Corollary 3.4 (Joint probability of default conditional on portfolio loss)

Adopt the setting and the notation of Corollary 3.2. Let \( A(1) \neq A(2) \) denote two obligors who have been selected in advance. Assume that \( x \) is an integer such that \( P_\alpha[X = x] > 0 \). Then, in the CreditRisk\(^+\) framework, the conditional joint probability of obligor A(1)’s and obligor A(2)’s default given that the portfolio loss \( X \) assumes the value \( x \) may be approximated by

\[
\mathbb{E}[D_{A(1)} D_{A(2)} | X = x] = \frac{P_{A(1)} P_{A(2)}}{P_\alpha[X = x]} \left( w_{A(1)0} w_{A(2)0} \mathbb{P}_\alpha[X = x - \tilde{E}_{A(1)} - \tilde{E}_{A(2)}] + \sum_{j=1}^{N} \left( w_{A(1)0} w_{A(2)j} + w_{A(1)j} w_{A(2)0} \right) \mathbb{P}_{\alpha+e_j}[X = x - \tilde{E}_{A(1)} - \tilde{E}_{A(2)}] + \sum_{j=1}^{N} w_{A(1)j} w_{A(2)j} \frac{\alpha_j + 1}{\alpha_j} \mathbb{P}_{\alpha+2e_j}[X = x - \tilde{E}_{A(1)} - \tilde{E}_{A(2)}] + \sum_{i=1}^{N} \sum_{\substack{j=1, \ j \neq i}}^{N} w_{A(1)i} w_{A(2)j} \mathbb{P}_{\alpha+e_i+e_j}[X = x - \tilde{E}_{A(1)} - \tilde{E}_{A(2)}] \right) \tag{3.6}
\]

where \( \tilde{E}_A \) for \( A = A(1) \) and \( A = A(2) \) stands for a random variable that has the same distribution as \( E_A \) but is independent of \( X \).
While (3.6) in general looks like a straightforward extension of (3.2), there is a subtle difference in the terms involving $\mathbb{P}_{\alpha + 2\epsilon}(X = \tilde{E}(1) - \tilde{E}(2))$ which reflect double stress in the same sector. This double stress is enforced by the additional factors $\frac{\alpha_1}{\alpha_2} > 1$.

**Proof of Corollary 3.4.** We derive (3.6) by comparing the coefficients of two power series. The first one is $\mathbb{E}[D_{A(1)} D_{A(2)} z^X] = \sum_{k=0}^{\infty} \mathbb{E}[D_{A(1)} D_{A(2)} I(X = k)] z^k$, the second one is an expression that is equivalent to $\mathbb{E}[D_{A(1)} D_{A(2)} z^X]$ but involves generating functions similar to (2.2d).

Recall that we denote the generating function of $\mathcal{E}_A$ by $H_A(z)$. By means of Theorem 3.1 and the independence of the random exposures, we can compute

$$
\mathbb{E}[D_{A(1)} D_{A(2)} z^X] = \sum_{k=0}^{\infty} \mathbb{E}[p_{A(1)}^S p_{A(2)}^S I(X + \mathcal{E}_{A(1)} + \mathcal{E}_{A(2)} = k)] z^k
$$

$$
= \mathbb{E}[p_{A(1)}^S p_{A(2)}^S z^{X + \mathcal{E}_{A(1)} + \mathcal{E}_{A(2)}}]
$$

$$
= \mathbb{E}[p_{A(1)}^S p_{A(2)}^S z^X] \mathbb{E}[z^{\mathcal{E}_{A(1)}}] \mathbb{E}[z^{\mathcal{E}_{A(2)}}]
$$

$$
= \mathbb{E}[p_{A(1)}^S p_{A(2)}^S z^X] H_{A(1)}(z) H_{A(2)}(z). \quad (3.7a)
$$

Recall the definitions of the intensities $p_A^S$, the sector default intensities $\mu_k$ and the sector polynomials $Q_k$ from Theorem 2.1. By making use of the fact that the economic factors $(S_1, \ldots, S_N)$ are Gamma-distributed with parameters $(\alpha_k, 1/\alpha_k)$, $k = 1, \ldots, N$, and that $S_0 = 1$ we obtain for $\mathbb{E}[p_{A(1)}^S p_{A(2)}^S z^X]$ (cf. the proof of (3.25c) in Tasche (2004))

$$
\mathbb{E}[p_{A(1)}^S p_{A(2)}^S z^X] = \mathbb{E}[p_{A(1)}^S p_{A(2)}^S \mathbb{E}[z^X | S]]
$$

$$
= p_{A(1)} p_{A(2)} \sum_{i=0}^{N} \sum_{j=0}^{N} w_{A(1)i} w_{A(2)j} \mathbb{E}[S_i S_j \prod_{k=0}^{N} \exp(S_k \mu_k (Q_k(z) - 1))]. \quad (3.7b)
$$

Denote by

$$
G^{(\alpha)}_X(z) = \sum_{k=0}^{\infty} \mathbb{P}_{\alpha}[X = k] z^k \quad (3.8)
$$

the generating function of $X$ according to (2.2d) as a function of the exponents $\alpha = (\alpha_1, \ldots, \alpha_N)$ on the right-hand side of the equation as has been explained in Corollary 3.2. Observe then that

$$
\mathbb{E}[S_0^2 \prod_{k=0}^{N} \exp(S_k \mu_k (Q_k(z) - 1))] = G^{(\alpha)}_X(z)
$$

$$
\mathbb{E}[S_0 S_j \prod_{k=0}^{N} \exp(S_k \mu_k (Q_k(z) - 1))] = G^{(\alpha + \epsilon_j)}_X(z), \ j \geq 1
$$

$$
\mathbb{E}[S_i S_j \prod_{k=0}^{N} \exp(S_k \mu_k (Q_k(z) - 1))] = G^{(\alpha + \epsilon_i + \epsilon_j)}_X(z), \ i \neq j
$$

$$
\mathbb{E}[S_j^2 \prod_{k=0}^{N} \exp(S_k \mu_k (Q_k(z) - 1))] = \frac{\alpha_j + 1}{\alpha_j} G^{(\alpha + 2 \epsilon_j)}_X(z), \ j \geq 1. \quad (3.9)
$$
Note that $G_X(z) H_{A(1)}(z) H_{A(2)}(z)$ is the generating function of the sequence $P_{\alpha}[X + \tilde{E}_{A(1)} + \tilde{E}_{A(2)} = 0], P_{\alpha}[X + \tilde{E}_{A(1)} + \tilde{E}_{A(2)} = 1], \ldots$ (i.e. of the distribution of $X + \tilde{E}_{A(1)} + \tilde{E}_{A(2)}$). Combining this observation with (3.7a), (3.7b), and (3.9) implies (3.6) by power series comparison. q.e.d.

As Corollary 3.2 can be used for constructing the portfolio loss distribution conditional on the default of one obligor, Corollary 3.4 can be used for the portfolio loss distribution conditional on the joint default of two obligors. Again by the definition of conditional probabilities it follows that

$$
\mathbb{P}[X = x \mid A(1) \text{ and } A(2) \text{ default}] = 
\mathbb{P}[A(1) \text{ and } A(2) \text{ default} \mid X = x] \frac{\mathbb{P}[X = x]}{\mathbb{P}[A(1) \text{ and } A(2) \text{ default}]}. \quad (3.10)
$$

Since by Corollary 3.4 an approximation for $\mathbb{P}[A(1) \text{ and } A(2) \text{ default} \mid X = x]$ is provided, the term-wise comparison of (3.6) and (3.10) yields

$$
P_{\alpha}[X = x \mid A(1) \text{ and } A(2) \text{ default}] \approx \frac{P_{A(1)} P_{A(2)}}{\mathbb{P}[A(1) \text{ and } A(2) \text{ default}]} \left( w_{A(1)0} w_{A(2)0} P_{\alpha}[X = x - \tilde{E}_{A(1)} - \tilde{E}_{A(2)}] + \right.
$$

$$
\sum_{j=1}^{N} (w_{A(1)0} w_{A(2)j} + w_{A(1)j} w_{A(2)0}) P_{\alpha + \epsilon_j} [X = x - \tilde{E}_{A(1)} - \tilde{E}_{A(2)}] + 
$$

$$
\sum_{j=1}^{N} \frac{w_{A(1)j} w_{A(2)j}}{\alpha_j} \frac{\alpha_j + 1}{\alpha_j} P_{\alpha + 2\epsilon_j} [X = x - \tilde{E}_{A(1)} - \tilde{E}_{A(2)}] + 
$$

$$
\sum_{i=1}^{N} \sum_{j=1, j \neq i}^{N} w_{A(1)i} w_{A(2)j} P_{\alpha + \epsilon_i + \epsilon_j} [X = x - \tilde{E}_{A(1)} - \tilde{E}_{A(2)}] \right). \quad (3.11a)
$$

Making use of the well-known result (see Gundlach, 2004, Section 2.3)

$$
\mathbb{E}[D_{A(1)} D_{A(2)}] = P_{A(1)} P_{A(2)} \left( 1 + \sum_{k=1}^{N} \frac{w_{A(1)k} w_{A(2)k}}{\alpha_k} \right), \quad A(1) \neq A(2), \quad (3.11b)
$$

(3.11a) can be slightly simplified to

$$
P_{\alpha}[X = x \mid A(1) \text{ and } A(2) \text{ default}] \approx \frac{1}{1 + \sum_{k=1}^{N} \frac{w_{A(1)k} w_{A(2)k}}{\alpha_k}} \left( w_{A(1)0} w_{A(2)0} P_{\alpha}[X = x - \tilde{E}_{A(1)} - \tilde{E}_{A(2)}] + 
$$

$$
\sum_{j=1}^{N} (w_{A(1)0} w_{A(2)j} + w_{A(1)j} w_{A(2)0}) P_{\alpha + \epsilon_j} [X = x - \tilde{E}_{A(1)} - \tilde{E}_{A(2)}] + 
$$

$$
\sum_{j=1}^{N} \frac{w_{A(1)j} w_{A(2)j}}{\alpha_j} \frac{\alpha_j + 1}{\alpha_j} P_{\alpha + 2\epsilon_j} [X = x - \tilde{E}_{A(1)} - \tilde{E}_{A(2)}] + 
$$

$$
\sum_{i=1}^{N} \sum_{j=1, j \neq i}^{N} w_{A(1)i} w_{A(2)j} P_{\alpha + \epsilon_i + \epsilon_j} [X = x - \tilde{E}_{A(1)} - \tilde{E}_{A(2)}] \right). \quad (3.11c)
$$
Comments similar to the comments on (3.5) also apply to (3.11c). The conditional distribution $\mathbb{P}_{\alpha}[X = x \mid A(1) \text{ and } A(2) \text{ default}]$ of the portfolio loss $X$ given that obligors $A(1)$ and $A(2)$ default can be computed as a weighted mean of stressed or double-stressed portfolio loss distributions. The stresses, however, are not only expressed by the exponents $\alpha_j + 1$ and $\alpha_j + 2$ in the generating functions of $\mathbb{P}_{\alpha + e_j}[X = \cdot]$ and $\mathbb{P}_{\alpha + e_i + e_j}[X = \cdot]$, $i, j = 1, \ldots, N$, but also by the factors $\frac{\alpha_j + 1}{\alpha_j} > 1$ appearing on the right-hand side of (3.11c). Obviously, as a consequence of the $(N + 1)^2$ terms on the right-hand side of (3.11c) instead of the only $N + 1$ terms of the right-hand side of (3.5), it is much more expensive to calculate the loss distributions conditional on two defaults than to calculate the loss distributions conditional on simple defaults.

Observe that Remark 3.3 also applies to (3.11c). Hence it makes sense to do the calculations for (3.11c) with loss severities $\mathcal{E}_{A(1)} = 0$ and $\mathcal{E}_{A(2)} = 0$ to reflect the risk management attitude not to take account of occurred losses for the determination of living portfolio risk metrics.

## 4 The ‘stressed probabilities of default’ approach

Under the CreditRisk$^+$ framework, equation (3.11c) provides the algorithm needed for the calculation of the portfolio loss distribution conditional on the default of two obligors. However, if $N$ denotes the number of economic factors in the model, formula (3.11c) requires the computation of $\frac{(N+1)(N+2)}{2}$ slightly different loss distributions which could be tedious if $N$ is large. In this section, therefore, we look at the ‘cheaper’ alternative approach where the loss distribution is calculated only once according to Theorem 2.1 and all parameters but the unconditional probabilities of default $p_A$ remain unchanged. In this ‘stressed probabilities of default’ approach the $p_A$ are replaced by probabilities of default conditional on the default of the two obligors. The approach is based on the following three-events version of (3.11b).

**Proposition 4.1** Define the approximate default indicators $D_A$ as in Theorem 2.1. Assume that $A(1), A(2), A(3)$ are obligors such that $A(i) \neq A(j)$ for $i \neq j$. Under the assumptions and with the notation of Theorem 2.1 then we have

$$\mathbb{E}[D_{A(1)} D_{A(2)} D_{A(3)}] = P_{A(1)} P_{A(2)} P_{A(3)} \left( 1 + 2 \sum_{k=1}^{N} \frac{w_{A(1)k} w_{A(2)k} w_{A(3)k}}{\alpha_k^2} + \sum_{k=1}^{N} \frac{w_{A(1)k} w_{A(2)k} w_{A(3)k}}{\alpha_k} \right).$$

**Proof.** The assumption on the Poisson distribution of the $D_A$ conditional on the vector of economic factors $S = (S_0, S_1, \ldots, S_N)$ implies $\mathbb{E}[D_A \mid S] = p_A^S$ with $p_A^S$ defined as in Theorem 2.1. By the conditional independence of $A(1), A(2), A(3)$ therefore it follows that

$$\mathbb{E}[D_{A(1)} D_{A(2)} D_{A(3)}] = \mathbb{E}[p_{A(1)}^S p_{A(2)}^S p_{A(3)}^S] = P_{A(1)} P_{A(2)} P_{A(3)} \sum_{j=0}^{N} \sum_{k=0}^{N} \sum_{\ell=0}^{N} w_{A(1)j} w_{A(2)k} w_{A(3)\ell} \mathbb{E}[S_j S_k S_{\ell}].$$
Recall that by assumption we have $E[S_k] = 1$ for all $k = 1, \ldots, N$ and $\sum_{k=0}^{N} w_{Ak} = 1$ for all obligors $A$. This implies

$$
\frac{E[D_{A(1)} D_{A(2)} D_{A(3)}]}{P_{A(1)} P_{A(2)} P_{A(3)}} = 1 + \sum_{k=0}^{N} \sum_{\ell=0, \ell \neq k}^{N} w_{A(1)k} w_{A(2)\ell} w_{A(3)k} \text{var}[S_k] \\
+ \sum_{k=0}^{N} \sum_{\ell=0, \ell \neq k}^{N} w_{A(1)\ell} w_{A(2)k} w_{A(3)k} \text{var}[S_k] \\
+ \sum_{k=0}^{N} \sum_{\ell=0, \ell \neq k}^{N} w_{A(1)k} w_{A(2)k} w_{A(3)k} \text{var}[S_k] \\
+ \sum_{k=0}^{N} w_{A(1)k} w_{A(2)k} w_{A(3)k} (E[S_k^3] - 1)
$$

$$
= 1 + \sum_{k=0}^{N} w_{A(1)k} w_{A(2)k} (1 - w_{A(3)k}) \text{var}[S_k] \\
+ \sum_{k=0}^{N} w_{A(1)k} (1 - w_{A(2)k}) w_{A(3)k} \text{var}[S_k] \\
+ \sum_{k=0}^{N} (1 - w_{A(1)k}) w_{A(2)k} w_{A(3)k} \text{var}[S_k] \\
+ \sum_{k=0}^{N} w_{A(1)k} w_{A(2)k} w_{A(3)k} (E[S_k^3] - 1).
$$

From the assumption that $S_k$ is Gamma-distributed with parameter vector $(\alpha_k, 1/\alpha_k)$, it follows that $\text{var}[S_k] = 1/\alpha_k$ and $E[S_k^3] - 1 = 3/\alpha_k + 2$. This implies the assertion. q.e.d.

Since in the CreditRisk+ framework the default indicator for an obligor $A$ is approximated by the conditional Poisson variable $D_A$, the joint probability of default $P[A(1) \text{ and } A(2) \text{ and } A(3) \text{ default}]$ of three obligors is approximated by

$$
P[A(1) \text{ and } A(2) \text{ and } A(3) \text{ default}] \approx E[D_{A(1)} D_{A(2)} D_{A(3)}].
$$

Hence Proposition 4.1 and (3.11b) provide us with a simple approximation formula for one obligor’s probability of default conditional on two other obligors’ joint default:

$$
P[B \text{ defaults} | A(1) \text{ and } A(2) \text{ default}] \approx 
1 + \sum_{k=1}^{N} \frac{ \sum_{k=1}^{N} w_{Bk} w_{A(1)k} w_{A(2)k} }{\alpha_k} + \sum_{k=1}^{N} \frac{ \sum_{k=1}^{N} w_{Bk} \sum_{k=1}^{N} w_{A(1)k} \sum_{k=1}^{N} w_{A(2)k} }{\alpha_k},
$$

(4.1)

for any three different obligors $B$, $A(1)$ and $A(2)$. Thanks to Proposition 4.1 and Equation (4.1), we can describe in precise technical terms the two above mentioned approaches to the calculation of the loss distribution conditional on two defaults.
Definition 4.2 In the setting and with the notation of Theorem 2.1, assume that there are two obligors \( A(1) \) and \( A(2) \) with exposures \( E_{A(1)} = E_{A(2)} = 0 \). Call this setting the two defaults scenario.

(i) The portfolio loss distribution defined by the right-hand-side of (3.11c) is called the ‘two defaults scenario’ loss distribution.

(ii) Replace in (i) of Theorem 2.1 the probabilities of default \( p_A \) by the conditional probabilities of default \( \Pr[A \text{ defaults} \mid A(1) \text{ and } A(2) \text{ default}] \) as given by (4.1) and keep all other parameters in the theorem unchanged. The resulting portfolio loss distribution is called ‘stressed probabilities of default’ loss distribution.

Intuitively, it is clear that the expected value \( E[X] \) of the portfolio loss \( X \) should be the same under both loss distributions from Definition 4.2. However, since the right-hand-sides of both (3.11c) and (4.1) are only approximations to the conditional probabilities on the left-hand-sides of the equations, the fact that the two expected values are equal must be formally proven.

Proposition 4.3 Under the ‘two defaults scenario’, denote by \( P_{\text{Two}} \) the distribution of Definition 4.2 (i) and by \( P_{\text{Prob}} \) the distribution of Definition 4.2 (ii). Then it holds that \( E_{\text{Two}}[X] = E_{\text{Prob}}[X] \).

Proof. For the sake of a clear notation, we denote all obligors but \( A(1) \) and \( A(2) \) with the letter \( B \). Under the independence assumptions of Theorem 2.1, by construction of \( P_{\text{Prob}} \) Equation (2.1a) implies that

\[
E_{\text{Prob}}[X] = \sum_B \Pr[B \text{ defaults} \mid A(1) \text{ and } A(2) \text{ default}] \Pr[E_B] = \sum_B \Pr[B \text{ defaults} \mid A(1) \text{ and } A(2) \text{ default}] \Pr[E_B]
\]

\[
= \sum_B \Pr[B \text{ defaults} \mid A(1) \text{ and } A(2) \text{ default}] \Pr[E_B] \left( 1 + 2 \sum_{k=1}^N \frac{w_{Bk} w_{A(1)k} w_{A(2)k}}{\alpha_k} + \sum_{k=1}^N \frac{w_{Bk} w_{A(1)k} + w_{Bk} w_{A(2)k} + w_{A(1)k} w_{A(2)k}}{\alpha_k} \right)
\]

\[
= \sum_B \Pr[B \text{ defaults} \mid A(1) \text{ and } A(2) \text{ default}] \Pr[E_B] \left( 1 + \alpha \sum_{k=1}^N \frac{w_{A(1)k} w_{A(2)k}}{\alpha_k} \right).
\]

(4.2)

For \( E_{\text{Two}}[X] \), we obtain from (3.11c) that

\[
E_{\text{Two}}[X] = \left( 1 + \sum_{k=1}^N \frac{w_{A(1)k} w_{A(2)k}}{\alpha_k} \right)^{-1} \left( w_{A(1)0} w_{A(2)0} E_0[X] + \right.
\]

\[
\sum_{j=1}^N \left( w_{A(1)j} w_{A(2)j} + w_{A(1)j} w_{A(2)0} \right) E_{\alpha+j}[X] + \right.
\]

\[
\sum_{j=1}^N w_{A(1)j} w_{A(2)j} \frac{\alpha_j + 1}{\alpha_j} E_{\alpha+2\epsilon_j}[X] + \sum_{i=1}^N \sum_{j=1, j \neq i}^N w_{A(1)i} w_{A(2)j} E_{\alpha+\epsilon_i+\epsilon_j}[X] \right).
\]

(4.3)

The distributions of \( X \) referred to in the expected values on the right-hand-side of (4.3) are specified by the generating function (2.2d). As explained in Remark 2.2 (ii), for instance the distribution of \( X \) under \( \Pr_{\alpha+2\epsilon} \) is given by the convolution of a compound Poisson distribution...
with expected value $\sum_B w_{B0} p_B \mathbb{E}[\mathcal{E}_B]$ and $N$ compound negative binomial distributions with expected values

$$\frac{\alpha_k \delta_k}{1 - \delta_k} \sum_B w_{Bk} p_B \mathbb{E}[\mathcal{E}_B] = \sum_B w_{Bk} p_B \mathbb{E}[\mathcal{E}_B], \quad k = 1, \ldots, N, k \neq j,$$

$$\frac{(\alpha_j + 2) \delta_j}{1 - \delta_j} \sum_B w_{Bj} p_B \mathbb{E}[\mathcal{E}_B] = \frac{\alpha_j + 2}{\alpha_j} \sum_B w_{Bj} p_B \mathbb{E}[\mathcal{E}_B], \quad k = j.$$

Substituting all these expected values into (4.3) and taking into account that $\sum_{k=0}^N w_{Bk} = 1$ for all $B$ gives

$$\left( 1 + \sum_{k=1}^N \frac{w_{A(1)k} w_{A(2)k}}{\alpha_k} \right) \mathbb{E}_{\text{Two}}[X]$$

$$= w_{A(1)0} w_{A(2)0} \sum_B p_B \mathbb{E}[\mathcal{E}_B] +$$

$$\sum_{j=1}^N \left( w_{A(1)j} w_{A(2)j} \right) \left( \sum_B p_B \mathbb{E}[\mathcal{E}_B] + \frac{1}{\alpha_j} \sum_B p_B w_{Bj} \mathbb{E}[\mathcal{E}_B] \right) +$$

$$\sum_{j=1}^N \frac{w_{A(1)j} w_{A(2)j}}{\alpha_j} \left( \sum_B p_B \mathbb{E}[\mathcal{E}_B] + \frac{1}{\alpha_j} \sum_B p_B w_{Bj} \mathbb{E}[\mathcal{E}_B] \right) +$$

$$\sum_{i=1}^N \sum_{j=1, j \neq i}^N \frac{w_{A(1)i} w_{A(2)j}}{\alpha_i} \left( \frac{1}{\alpha_j} \sum_B p_B w_{Bj} \mathbb{E}[\mathcal{E}_B] + \frac{1}{\alpha_i} \sum_B p_B w_{Bi} \mathbb{E}[\mathcal{E}_B] \right).$$

Some algebra shows that the sum of the terms after the last “=” sign divided by the factor $1 + \sum_{k=1}^N \frac{w_{A(1)k} w_{A(2)k}}{\alpha_k}$ is equal to the right-hand-side of (4.2). $\text{q.e.d.}$

Why are the ‘two defaults scenario’ loss distribution $\mathbb{P}_{\text{Two}}$ and the ‘stressed probabilities of default’ loss distribution $\mathbb{P}_{\text{Prob}}$ of Definition 4.2 different despite the first order equality of the two demonstrated in Proposition 4.3? They differ because $\mathbb{P}_{\text{Prob}}$ does not account for correct conditional joint probabilities of default for two or more obligors. Nonetheless, it is not clear how much the two loss distribution can differ, given that their first moments are equal. In the next section, we will consider two simple numerical examples to compare the two loss distributions and assess how different they may be.

Another question refers to the nature of the input parameters $p_A$ in Theorem 2.1, i.e. the unconditional PDs of the obligors in the portfolio. In principle, these PDs should be ‘through-the-cycle’
(TTC) PDs\(^7\) in the CreditRisk\(^+\) framework. Does then make sense to use conditional PDs as input parameters to the model as in the ‘stressed PDs’ approach? Actually, this question misses the point. For ‘stressed PDs’ only is meant to be a technical workaround for more demanding approaches like Monte-Carlo simulation and the calculation of the proper loss distribution conditional on two defaults (the ‘two defaults scenario’ distribution).

5 Numerical examples

The first example we consider is a homogeneous portfolio with a one-factor dependence structure. For the factor, we choose a standard deviation of 0.8 which according to Merino and Nyfeler (2004) is in the centre of the range of observable default rate volatilities. Since the factor is assumed to be Gamma-distributed with mean 1, a standard deviation of 0.8 implies that the factor is Gamma-distributed with parameters \((\alpha, \beta) = (1/0.8^2, 0.8^2) = (1.5625, 0.64)\).

Example 5.1 We assume the setting of Theorem 2.1 with the following specifics:

- There are \(n\) obligors \(B_1, \ldots, B_n\) all with PD \(p = 1\%\). There is one economic factor \(S\) such that the conditional Poisson distribution of the default indicator \(D_{B_i}\) is given by the intensity \(p_{B_i}^S = pS\) for all \(i = 1, \ldots, n\).
- Two further obligors \(A_1\) and \(A_2\) with the same characteristics as the other obligors are known to have defaulted.
- The factor \(S\) is Gamma-distributed with parameters \((1.5625, 0.64) = (\alpha, 1/\alpha)\).
- The exposure to each of the obligors but the defaulters is 1. Hence we have \(H_{B_i}(z) = z\) for the generating functions of the exposures for all \(i\). The exposures to the two defaulters \(A_1\) and \(A_2\) are 0.

Having all exposures equal to 1 means that in this case the portfolio ‘loss’ distribution is actually the distribution of the number of defaults in the portfolio, i.e. we have

\[
X = \sum_{i=1}^{n} D_{B_i}.
\]

By Remark 2.2 (ii), it follows that in the CreditRisk\(^+\) framework the unconditional distribution of \(X\) is negative binomial and as such given by

\[
P[X = x] = \frac{\Gamma(\alpha + x)}{\Gamma(\alpha) x!} \left(1 - \frac{np}{np + \alpha}\right)^\alpha \left(\frac{np}{np + \alpha}\right)^x, \quad x = 0, 1, 2, \ldots.
\]

Equation (3.11c) implies that the distribution of \(X\) conditional on the default of \(A_1\) and \(A_2\) is approximated by

\[
P[X = x | A_1 \text{ and } A_2 \text{ default}] = \frac{\Gamma(\alpha + 2 + x)}{\Gamma(\alpha + 2) x!} \left(1 - \frac{np}{np + \alpha}\right)^{\alpha+2} \left(\frac{np}{np + \alpha}\right)^x, \quad x = 0, 1, 2, \ldots.
\]

\(^7\)See Jobst and Tasche (2012) for a formal definition of TTC PDs and a discussion of TTC v. PIT (point-in-time) PDs.
Again by Remark 2.2 (ii), it follows that the ‘stressed probabilities of default’ distribution $Q$ of $X$ in the sense of Definition 4.2 is given by $q = \frac{p(\alpha+2)}{\alpha}$ and

$$Q[x] = \frac{\Gamma(\alpha + x)}{\Gamma(\alpha) x!} \left( 1 - \frac{nq}{nq + \alpha} \right)^\alpha \left( \frac{nq}{nq + \alpha} \right)^x, \quad x = 0, 1, 2, \ldots$$

Figure 1 shows the three distributions from Example 5.1 for the case $n = 100$. It is no surprise that compared to the unconditional distribution the masses of the other two distributions are significantly shifted to the right. But the ‘stressed input PDs’ distribution seems to have heavier tails than the ‘two defaults scenario’ distribution.

Table 1 affirms this observation. The results from the table suggest that the difference between the ‘two defaults scenario’ and ‘stressed input PDs’ distributions increases with growing portfolio size. The ‘stressed input PDs’ distribution becomes markedly more widespread and heavier-tailed than the ‘two defaults scenario’ distribution. A possible explanation could be that the ‘two defaults scenario’ more appropriately takes account of diversification effects in the higher order joint probabilities of default that strongly impact the tail of the distribution because ‘two defaults’ is constructed as a proper conditional distribution.

With the following example, we study a more heterogenous portfolio, with a range of different PDs, different exposures and dependence created by two economic factors. We choose standard
Table 1: Characteristics of unconditional, conditional on two defaults and ‘stressed input PDs’ distributions of numbers of defaults in portfolios of $n = 10$, $n = 100$ and $n = 1000$ obligors. All obligors have unconditional PD 1%. The model is one-factor CreditRisk$^+$ with factor standard deviation 0.8.

| $n$ = 10 | Unconditional | ‘Two defaults scenario’ | ‘Stressed input PDs’ |
|----------|---------------|------------------------|----------------------|
| Probability of no default | 0.9076 | 0.8017 | 0.8083 |
| Mean | 0.1000 | 0.2280 | 0.2280 |
| Standard deviation | 0.3262 | 0.4925 | 0.5111 |
| 99%-quantile | 1 | 2 | 2 |

| $n$ = 100 | Unconditional | ‘Two defaults scenario’ | ‘Stressed input PDs’ |
|-----------|---------------|------------------------|----------------------|
| Probability of no default | 0.4616 | 0.1716 | 0.2451 |
| Mean | 1.0000 | 2.2800 | 2.2800 |
| Standard deviation | 1.2806 | 1.9337 | 2.3679 |
| 99%-quantile | 5 | 8 | 10 |

| $n$ = 1000 | Unconditional | ‘Two defaults scenario’ | ‘Stressed input PDs’ |
|------------|---------------|------------------------|----------------------|
| Probability of no default | 0.0438 | 0.0008 | 0.0137 |
| Mean | 10.0000 | 22.8000 | 22.8000 |
| Standard deviation | 8.6023 | 12.9892 | 18.8546 |
| 99%-quantile | 39 | 63 | 87 |

deviations of 0.4 and 1.2 respectively for the two factors. According to Merino and Nyfeler (2004), this choice reflects the lower and upper bounds of the range of observable default rate volatilities.

Example 5.2 We assume the setting of Theorem 2.1, this time with the following specifics:

- There are 60 obligors $B_1, \ldots, B_{60}$ all with PD $p_i = 2.5\%$, 30 obligors $B_{61}, \ldots, B_{90}$ all with PD $p_i = 1\%$ and 10 obligors $B_{91}, \ldots, B_{100}$ all with PD $p_i = 0.5\%$. There are two economic factors $S_1$ and $S_2$ such that the conditional Poisson distribution of the default indicator $D_{B_i}$ is given by the intensity $p_{S_{B_i}}^S = p_i (w_i S_1 + (1-w_i) S_2)$ with $w_i = 0.75$ for all $i = 1, \ldots, 100$.

- Two further obligors $A_1$ and $A_2$ are known to have defaulted. We assume they had PDs $q_i = 1\%$, $i = 1, 2$ and that their default intensities were given by $q_{A_i}^S = q_i (v_i S_1 + (1-v_i) S_2)$. We assume $v_1 = v_2$. Results are calculated for two different values of $v_1$, namely $v_1 = 0.75$ and $v_1 = 0.25$.

- The factor $S_1$ is Gamma-distributed with parameters $(1/1.2^2, 1.2^2) = (\alpha_1, 1/\alpha_1)$, $S_2$ is Gamma-distributed with parameters $(1/0.4^2, 0.4^2) = (\alpha_2, 1/\alpha_2)$.

Due to the heterogeneity of the portfolio in Example 5.2, it is not possible to represent the loss distribution of the loss variable $X$ in closed form. In order to calculate the unconditional, conditional on the two defaults and ‘stressed probabilities of default’ distributions of $X$ as in Example 5.1, therefore we take recourse to numerically inverting the respective characteristic functions by Fast Fourier Transform (FFT)$^8$. In all three cases, the shape of the characteristic functions $\phi_X(t)$ and $\psi_X(t)$ can be inferred from the characteristic functions $\phi_{1/\alpha_1}(t)$ and $\phi_{1/\alpha_2}(t)$ of the factors $S_1$ and $S_2$ used in the simulation.

$^8$Alternatively, we could have made use of refined versions of the Panjer algorithm as described in Haaf et al. (2004) or Gerhold et al. (2010, Section 5.5).
Table 2: Characteristics of unconditional, conditional on two defaults and ‘stressed input PDs’ loss distributions of the portfolio described in Example 5.2. The model is two-factors CreditRisk$^+$. 

|                      | Unconditional | ‘Two defaults scenario’ | ‘Stressed input PDs’ |
|----------------------|---------------|-------------------------|----------------------|
| Probability of no default | 0.2986        | 0.1769                  | 0.1731               |
| Mean                 | 4.0000        | 6.7173                  | 6.7173               |
| Standard deviation   | 6.4900        | 9.0172                  | 9.2574               |
| 99%-quantile         | 30            | 41                      | 43                   |

|                      | Unconditional | ‘Two defaults scenario’ | ‘Stressed input PDs’ |
|----------------------|---------------|-------------------------|----------------------|
| Probability of no default | 0.2986        | 0.0545                  | 0.0801               |
| Mean                 | 4.0000        | 11.4514                 | 11.4514              |
| Standard deviation   | 6.4900        | 11.5349                 | 13.8041              |
| 99%-quantile         | 30            | 52                      | 64                   |

The function of the distribution is given by (2.2d) with $z = e^{it}$, $t \in \mathbb{R}$. The algorithm we apply for the calculations is described in Section 4.7 of Rolski et al. (1999). The moderate size of the portfolio and the relatively small total exposure of the portfolio allow us to choose the total exposure plus 1 as the truncation point for the discrete Fourier transform. Indeed, the probabilities of the high losses close to the total exposure are so small that there is no need for any refinements of the algorithm to control the aliasing error (Embrechts and Frei, 2009, Section 2.2).

Table 2 shows the results of the calculations for Example 5.2. Results are reported for two different scenarios of dependence between the defaults and the rest of the portfolio:

- ‘Weak dependence of defaults and portfolio’ scenario. By construction, the obligors $B_i$ in the portfolio depend stronger on the economic factor $S_1$ (weight 0.75) than on the factor $S_2$ (weight 0.25). In the ‘weak dependence’ scenario, the defaulters $A_1$ and $A_2$ depend weakly on $S_1$ (weight 0.25) and stronger on $S_2$ (weight 0.75).

- ‘Strong dependence of defaults and portfolio’ scenario. Here the defaulters have the same dependence on the economic factors as the obligors in the portfolio.

In both dependence scenarios, the impact of conditioning on defaults on the tails of the loss distributions is strong but it is much stronger in the case of strong dependence. In the weak dependence scenario the shapes of the conditional ‘two defaults scenario’ loss distribution and the ‘stressed input PDs’ distribution seem to be almost equal. In contrast, in the strong dependence scenario the tail of the ‘stressed input PDs’ distribution appears to be much heavier than the tail of the ‘two defaults scenario’ distribution. Note that as stated in Proposition 4.3 in both Table 1 and Table 2 the means of the ‘two defaults scenario’ and the ‘stressed input PDs’ distributions always are equal.

6 Conclusions

We have studied the way in which defaults impact a credit portfolio loss distribution in the CreditRisk+ framework, by looking at the loss distribution conditional on some – one or two in this paper – of defaults. While the derived formulas are not necessarily easy to implement, they provide nonetheless insight into the details of how the default scenarios impact the conditional portfolio loss distribution.

The results of this paper can be used for specific stress scenario analyses that are intended to identify whether large credit exposures besides having an obvious size impact additionally contribute to sector risk concentrations. Another more indirect application of the results would be to use them to check the accuracy of alternative approaches to such default scenario analyses. One potential alternative approach is Monte Carlo portfolio simulation which would suffer from rare event effects when deployed for estimating loss distributions conditional on two or more defaults.

Another alternative could be to calculate for each obligor the probability of default conditional on the joint default of a fixed set of obligors and then to use these conditional probabilities of default as input parameters to a portfolio model. This “stressed probabilities of default” approach is unbiased but ignores the exact dependence between the default events of the obligors considered defaulted under the scenario and the economic factors commonly used for modeling dependence in credit portfolio models. Therefore, the approach is principally inaccurate. Numerical examples show that the inaccuracy may be significant but tends to overestimate tail losses and hence to err on the conservative side.
