Abstract: The quartz-vein-type Baiyinhan tungsten deposit is located at the eastern part of the Central Asian Orogenic Belt, NE China. Analyses of fluid inclusions, H-O isotope of quartz and Re-Os isotope of molybdenite were carried out. Three stages of mineralization were identified: The early quartz + wolframite + bismuth stage, the middle quartz + molybdenite stage and the late calcite + fluorite stage. Quartz veins formed in the three stages were selected for the fluid inclusion analysis. The petrographic observation and fluid inclusion microthermometry results revealed three types of fluid inclusions: CO₂-H₂O (C-type), liquid-rich (L-type) and vapor-rich (V-type). The homogenization temperatures of C-type, V-type and L-type inclusions were 233–374 °C, 210–312 °C, and 196–311 °C, respectively. The salinity of the three types of inclusions was identical, varying in the range of 5–12 wt%. The H-O isotope analyses results showed that quartz had δ¹⁸O and δD compositions of −2.6% to 4.3% and −97% to −82%, respectively, indicating that the ore-forming fluids were mainly derived from magmatic water with a minor contribution of meteoric water. The addition of meteoric water reduces the temperature and salinity of the ore-forming fluids, which leads to a decrease of the solubility of tungsten and molybdenum in the fluids and eventually the precipitation of minerals. Re-Os isotopic analysis of five molybdenite samples yielded an isochron age of 139.6 ± 7.6 Ma (2σ) with an initial ¹⁸⁷Os of −0.05 ± 0.57 (MSWD = 3.5). Rhenium concentrations of the molybdenite samples were between 3.1 ug/g and 8.5 ug/g. The results suggest that the metals of the Baiyinhan deposit have a crust origin, and the mineralization is one episode of the Early Cretaceous tungsten mineralization epoch which occurred at the eastern part of the Central Asian Orogenic Belt.

Keywords: Re-Os dating; fluid inclusions; H-O isotope; quartz-vein tungsten deposit; eastern Central Asian Orogenic Belt

1. Introduction

The eastern Central Asian Orogenic Belt (CAOB) in NE China is characterized by orogenic events of the Paleo-Asian domain superimposed by the magmatism of the Paleo-Pacific and Ohotsk Ocean tectonic domains, which resulted in extensive distribution of Mesozoic volcanic and granitic rocks.
together with widespread Cu, Mo, Au, Pb-Zn-Ag and Sn polymetal deposits [1–7]. In recent years, an increasing number of tungsten deposits have been discovered in this region, revealing a great potential of large-scale tungsten mineralization.

The previous geochronology studies of the tungsten mineralization in eastern CAOB have shown Triassic, Jurassic and Early Cretaceous ages [8–29] and are in close association with the magmatic activities. The mineralization includes porphyry, skarn and quartz-type deposits. The quartz-vein-type tungsten deposits can be divided into two subtypes: Quartz-wolframite and quartz-scheelite vein types. The Baiyinhan quartz-vein-type tungsten deposit belongs to the quartz-wolframite subtype.

At present, there is no unified understanding of the precipitation mechanism of tungsten in ore-forming fluids, especially whether CO$_2$ plays an important role in the migration and precipitation of tungsten. In this study, we selected the newly discovered Baiyinhan deposit, which has not been reported in any article to date. The Re-Os isotope test of molybdenite in the Baiyinhan quartz vein tungsten deposit was carried out to determine the ore-forming age and source of ore-forming materials. Fluid inclusions and quartz H-O isotopes were used to discuss the fluid evolution and fluid source of the deposit, especially the role of CO$_2$ in the migration and precipitation of tungsten.

2. Geological Setting

The eastern CAOB is divided into four tectonic blocks: Erguna, Xing’an, Songliao and Jiamusi massifs, which are separated by the regional-scale Tayuan-Xiguitu, Hegenshan-Heihe and Mudanjiang faults, respectively [1] (Figure 1). The Baiyinhan tungsten deposit is located in the Liaoyuan massif and belongs to the southern part of the Da Hinggan Mountains polymetal metallogenic belt (SDMB) (Figure 2). The SDMB is bounded by the western Hegenshan Fault, the eastern Nenjiang Fault and the southern Xilamulun Fault (Figure 2). The SDMB is composed of the Permian strata and is overlain by the Mesozoic-Cenozoic volcanic and sedimentary rocks and intruded by Mesozoic intrusive rocks (Figure 2). The Permian strata are composed of four units [30]: (1) The Lower Permian Qingfengshan Formation, which consists of graywacke and siltstone with tufaceous intercalation; (2) the Lower Permian Dashizhai Formation, which is mainly composed of submarine lava and tuft (andesitic, felsic and basaltic) with arenite; (3) the Lower Permian Huanggangliang Formation, which consists of mix-beded sandstone and shale with limestone and tuft; and (4) the Upper Permian Linxi Formation, which is mainly composed of terrestrial sandstone, siltstone and mudstone.

The Mesozoic formations include Jurassic and Cretaceous strata. The Jurassic strata are composed of conglomerate, sandstone, siltstone, mudstone, coal bed, volcaniclastic rock, tuft, rhyolite and dacite. The Cretaceous strata consist of andesite, volcaniclastic rock, tuft, tuff sandstone, siltstone and basal conglomerate. The Cenozoic corresponds to continental red strata. The Major structures are the Erlian-Hegenshan Fault, the Xilamulun River Fault and the Nenjiang Fault [31,32].

A scatter of a late Paleozoic granite is exposed at the Haolibao mine area and at the northern part of the Xilamulun River [33]. Mesozoic granites include Triassic, Late Jurassic and Early Cretaceous granites [3]. The Mesozoic granites are characterized by low ($^{87}$Sr/$^{86}$Sr), and high $\varepsilon$Nd(t) values, showing that juvenile crust materials are the major source of the Mesozoic granites [1].

Fault: F1—Nengjiang Fault; F2—Yitong-Yilan Fault; F3—Dunhua-Mishan Fault; F4—Chifeng-Kaiyuan Fault; F5—Xilamulun River Fault; F6—Heganshan-Heihe Fault; F7—Xiguitu-Tayuan Fault. Locations: 1—Cuihongshan; 2—Gongpengzi; 3—Yangbishan; 4—Yangjingou; 5—Wudaogou; 6—Liudaogou; 7—Baishilazi; 8—Sanjiazi; 9—Dayana; 10—Honghuaerji; 11—Weilianhe; 12—Zishi; 13—Shamai; 14—Dongshanwan; 15—Xiaolaogualinzi; 16—Weilasituo; 17—Chamuhan; 18—Daolundaba; 19—Wulegerejidaban; 20—Xiaohaiqing.

The SDMB is an important polymetal metallogenic belt in China, and contains abundant porphyry Mo deposits, skarn Pb-Zn deposits, skarn Fe-Sn deposits, hydrothermal-vein-type Ag-polymetal, Sn-polymetal, Pb-Zn polymetal and Cu-polymetal deposits (Figure 2).
3. The Baiyinhan Tungsten Deposit

The Baiyinhan tungsten deposit occurs within the Yanshanian granite and is mainly composed of wolframite-bearing quartz veins (Figure 3). The Yanshanian granite (biotite granite, Figure 4A) is constituted of quartz (30–40%), K-feldspar (30–40%), plagioclase (~15%), biotite (~8%), and minor accessory minerals. The xenomorphic granular or granular quartz occurs as clusters, and the grain size varies from 0.2 mm to 2.0 mm. The grain size of K-feldspar varies from 0.5 mm to 2.0 mm and shows a xenomorphic granular texture. The grain size of plagioclase ranges from 0.5 mm to 1.5 mm.

The tungsten mineralization at Baiyinhan is spatially confined to gently dipping faults, with a striking length of 10–150 m. The tungsten ore bodies occur mainly as quartz veins, and five ore bodies have been defined (Figure 3). The features of these ore bodies are similar.

Figure 2. Regional geological map of south DaHinggan mountains showing the distribution of the metal ore deposits (modified from [34,35]).

Figure 3. Geological map of the Baiyinhan tungsten deposit.
with a length of several tens to 150 m and thickness of 0.2–1.8 m. The orebody has a WO$_3$ grade of 0.5–2.5%. These orebodies are mainly composed of tungsten-bearing quartz veins and minor greisen alteration rock.

The V1 ore body is located at the southwest part of the ore deposit. It strikes EW and dips north at angles of 10–15°, with a length of 150 m and thickness of 0.1–1.5 m (Figure 3). The V2 ore body is smaller and located at the north of the V1 ore body (Figure 3). It also strikes EW and dips north at an angle of 15°, but the scale of V2 ore body is smaller and thinner than the V1 ore body. The V3, V4 and V5 ore bodies are located at the northern part of ore deposit (Figure 3). The V3 and V4 ore bodies strike NE, and the V5 ore body strike NS. These three ore bodies dip northwest at angles of 12–20°, with a length of several tens to 150 m and thickness of 0.2–1.8 m. The orebody has a WO$_3$ grade of 0.5–2.5%. These orebodies are mainly composed of tungsten-bearing quartz veins and minor greisen alteration rock.

The vein-type ore includes wolframite + pyrite + molybdenite (Figure 4C,D) and minor amounts of bismuthinite (Figure 4G). Gangue minerals consist of quartz and muscovite. The ore minerals occur in major veins and massive structures, along with minor drusy cavity structures (Figure 4F,H,I). The ore minerals are mainly euhedral and subhedral (Figure 4C–E,G). Alteration at Baiyinhan is well-developed and characterized by a fracture-controlled greisen alteration. A small proportion of tungsten mineralization occurs within the greisen (Figure 4E,H). Mineralogically, the greisen alteration comprises quartz and muscovite (Figure 4E).

Based on the structure, texture and mineralogy of the ore veins, three hydrothermal stages can be distinguished: (1) Wolframite + quartz vein stage; (2) molybdenite + quartz + pyrite stage and

**Figure 4.** Photographs of the biotite granite (A) and the mineralization (B–I) in the Baiyinhan deposit showing: (A) Biotite granodiorite; (B) Wolframite-bearing quartz vein within the granite (dipping to north); (C) Quartz + pyrite + wolframite vein; (D) Quartz + molybdenite + wolframite vein with drusy cavity; (E) Euhedral wolframite in greisen; (F) massive ore; (G) Bismuthinite in massive ore; (H) Veined wolframite in greisen; (I) Veined wolframite in quartz vein. Abbreviations: Bi—biotite, Pl—plagioclase, Kfs—K-feldspar, Mb—molybdenite, Py—pyrite, Gs—greisen, Qv—quartz vein, Qz—quartz, Wf—wolframite, Bm—bismuthinite.
(3) calcite + fluorite stage. The first stage of quartz-wolframite veins contains significant amounts of disseminated wolframite and minor bismuthinite, accompanying intense greisen alteration. The quartz is typically milky white, coarse-grained, anhedral and fractured. The wolframite is also commonly fractured and is locally cemented together with fractured quartz that was formed during the second and third stages of activity. The second hydrothermal stage is characterized by an enrichment in pyrite and molybdenite. The third stage is characterized by coarse translucent euhedral calcite and fluorite crystals occurring in fractures and veinlets, which crosscut earlier formed veins.

4. Sampling and Analytical Methods

4.1. Samples

Thirty-six samples of quartz veins were collected from the open pit, all of which were collected from the V3, V4 and V5 ore bodies in the north of the ore deposit for the study of fluid inclusions shape, type, abundance and spatial distribution. Twenty-one of these samples were used for the analysis of microthermometry of fluid inclusions, and 10 samples were used for H-O isotope analysis. Five molybdenite samples were also collected from the ore pile for Re-Os geochronology analysis.

4.2. Analytical Methods

The microthermometric measurements on the fluid inclusions were carried out using a Linkam THMS 600 programmable heating-freezing stage combined with a Zeiss microscope at the China University of Geosciences, Beijing (CUGB), China. The process has been described in detail by Yu et al. [36]. Salinities of H2O-NaCl [37] and CO2-bearing [38] fluids were calculated using the final melting temperatures of ice (Tm-ice) and clathrate (Tm-cla). The pressure of the fluid inclusions was calculated according to Steele et al. [39].

The H-O isotope analyses were accomplished with a MAT253 mass spectrometer at the Institute of Geology and Geophysics, Chinese Academy of Sciences. Oxygen was liberated from quartz through reaction with BrF5 [40] and converted to CO2 on a platinum-coated carbon rod. In accordance with the method described by Simon [41], H isotopic ratios of bulk fluid inclusions in quartz were measured by mechanically crushing ~5 g of quartz grains to a grain size of 1–5 mm. Samples were first degassed of labile volatiles and secondary fluid inclusions by heating under vacuum to 120 °C for 3 h. The released water was trapped and reduced to H2 by reaction with Zn. The analytical precision was better than ±0.2‰ (1σ) for δ18O and ±2‰ (1σ) for δD. H-O isotopic data were reported relatively to the Standard Mean Ocean Water standard. δ18O H2O of fluids were calculated using the equation for quartz-water isotopic equilibrium: 1000 × ln(αquartz-water) = (3.38 × 106)T−2 − 3.40, where T is the temperature in Kelvins [42], and the average fluid inclusion temperature of each stage was used to calculate the δ18O H2O value.

The Re-Os isotopic analyses were performed at the National Research Center of Geoanalysis, Chinese Academy of Geosciences. The details of the chemical procedure have been described by Du et al. [43,44], Shirey et al. [45] and Stein et al. [46] Five molybdenite samples from the Baiyinhan deposit were collected in the footrill. Microprobe screening of these samples revealed euhedral molybdenite crystals.

5. Results

5.1. Fluid Inclusion Petrography

Fluid inclusions were widely developed in the quartz veins (Figure 5). Most fluid inclusions were isolated or randomly clustered, had relatively regular shapes (polygonal, oval and semicircular) and were interpreted as primary in origin. However, secondary and pseudosecondary inclusions have also been observed as intergranular arrays or aligned along microfractures in transgranular crystal trails [47]. During this study, we focused on the primary inclusions. According to the composition of
inclusions and the phase state at room temperature [47,48], fluid inclusions in the Baiyinhan deposit can be divided into three types: C-, L- and V-type (Figure 5). On the basis of the microthermometry results of fluid inclusions, the discussion of fluid evolution corresponded to the aforementioned three hydrothermal stages.

![Figure 5. Photomicrographs of typical fluid inclusions in quartz from the Baiyinhan tungsten deposit. (A) Liquid-rich C-type inclusion. (B) Vapor-rich C-type inclusion. (C) V-type inclusions. (D) Clustered L-type inclusions. (E) Clustered C-type inclusions. Abbreviation: LCO2 = liquid CO2; LH2O = liquid H2O; VC02 = vapor CO2; VH2O = vapor H2O.](image)

5.1.1. C-Type (CO2-H2O Inclusions)

C-type inclusions were irregular-shaped to rounded and were ~4–20 μm in size. They usually consisted of three phases at room temperature. In the first phase, the proportion of CO2 was less than 50% (Figure 5A). In the second phrase, the proportion of CO2 was more than 50% and the proportion of VC02 was larger (Figure 5B). In the third phase, the proportion of CO2 was greater than 50% and the proportion of LC02 was larger (Figure 5E). Although some inclusions showed only two phases at room temperature, they turned into three phases during cooling. C-type inclusions occurred mainly in veins of early stages. Based on the ratio of liquid to vapor, C-type inclusions can be divided into liquid-rich and vapor-rich inclusions. The liquid-rich inclusions were homogenized to the liquid phase, and the most vapor-rich inclusions were homogenized to the vapor phase.

5.1.2. L-Type (Liquid-Rich Inclusions)

The L-type fluid inclusions were found in quartz veins from all stages. Most L-type inclusions contained liquid and a vapor bubble that occupied ~5–45 vol% of the inclusion (Figure 5D,E). They occurred as irregular to rounded forms of ~4–19 μm in size (mainly 5–9 μm; Figure 5D). In the early stage, different from C-type inclusions, only three L-type inclusions were observed. The massive development of L-type fluid inclusions occurred in the middle and late stages.

5.1.3. V-Type (Vapor-Rich Inclusions)

The V-type fluid inclusions were rarely developed in all quartz veins. They contained two distinct phases, namely liquid H2O and vapor H2O. They were rounded rectangles, and the size ranged from ~3–12 μm (Figure 5C). The bubble usually accounted for >55 vol% of the inclusion. V-type fluid inclusions appeared mainly in the veins of middle and late stages.
5.2. Microthermometry

A summary of the microthermometric data obtained from fluid inclusions from the three mineralization stages is listed in Table 1, and the results are plotted in Figure 6.

| Stage | Type   | N | Tm\(_{\text{CO}_2}\) (°C) | Tm\(_{\text{ice}}\) (°C) | Tm\(_{\text{clath}}\) (°C) | Tm\(_{\text{CO}_2}\) (°C) | Tm\(_{\text{tot}}\) (°C) | Salinity (wt.%) | Pressure (bars) | Density (g/cm\(^3\)) |
|-------|--------|---|----------------------------|---------------------|-----------------|-----------------|-----------------|----------------|----------------|------------------|
| I     | L-type | 3 | −63.9 to −60.8             | −8.1 to −4.4        | 299–311         | 7.02–11.81      | 90–92           | 0.79–0.82       |                  |                  |
|       | C-type | 31| 3.9–7.9                    | 28.1–31.1           | 294–374         | 4.14–10.72      |                 |                  |                  |                  |
| II    | L-type | 72| −6.6 to −6.0               | −9.5 to −0.5        | 228–298         | 0.88–13.40      | 25–82           | 0.78–0.93       |                  |                  |
|       | V-type | 5 | −6.6 to −0.6               | −9.5 to −0.5        | 248–297         | 1.05–9.98       | 35–42           | 0.72–0.88       |                  |                  |
|       | C-type | 16| 6.4–8.1                    | 27.9–31.1           | 233–305         | 3.19–6.81       |                 |                  |                  |                  |
| III   | L-type | 103| −0.6                      | −9.4 to −0.3        | 171–244         | 0.53–13.29      | 8–34            | 0.84–0.96       |                  |                  |
|       | V-type | 4 | −0.6                       | −9.4 to −0.3        | 210–245         | 1.05–7.86       | 14–36           | 0.81–0.91       |                  |                  |

Table 1. Microthermometric data of fluid inclusions from the Baiyinhan tungsten deposit.

Abbreviations: N = numbers of measured fluid inclusion, Tm\(_{\text{CO}_2}\) = final melting temperature of solid CO\(_2\), Tm\(_{\text{clath}}\) = final melting temperature of CO\(_2\)-H\(_2\)O clathrate, Tm\(_{\text{CO}_2}\) = homogenization temperature of CO\(_2\) phases, Tm\(_{\text{tot}}\) = final melting temperature of ice, Tm\(_{\text{tot}}\) = total homogenization temperature, wt.% NaCl equiv. = weight percent NaCl equivalent.

In the quartz veins of the early stage, there were mainly C-type inclusions and only a few L-type inclusions. C-type inclusions yielded final melting temperatures of solid CO\(_2\) ranging from −63.9 to −60.8 °C, lower than the pure CO\(_2\) critical point of −56.6 °C. The melting temperatures of the clathrate were 3.9–7.9 °C, and the corresponding salinity were 4.14–10.72 wt% NaCl equiv. The homogenization temperatures of the CO\(_2\) phase were 28.1–31.1 °C, and the final homogenization temperatures ranging from 294 °C to 374 °C. Only three L-type inclusions were found in quartz from this stage, yielding ice-melting temperatures ranging from −8.1 °C to −4.4 °C, corresponding to salinities of 7.02–11.82 wt% NaCl equiv. The final homogenization temperatures ranged ~299–311 °C, and the bulk densities of the inclusions were 0.79–0.82 g/cm\(^3\). The pressure of L-type inclusions was ~80–92 bars.

The middle stage was dominated by L-type and C-type inclusions with minor V-type inclusions. C-type inclusions yielded final melting temperatures of solid CO\(_2\) ranging from −62.2 to −60.9 °C, and the corresponding salinity were 3.19–6.81 wt% NaCl equiv. Partial homogenization of CO\(_2\) phases occurred between 27.9 °C and 31.1 °C, and the final homogenization temperatures ranged ~233–305 °C. L-type inclusions yielded ice-melting temperatures ranging from −9.5 °C to −0.5 °C, corresponding to salinities of 0.88–13.40 wt% NaCl equiv. The final homogenization temperatures ranged ~228–298 °C, and the bulk densities of the inclusions ranged 0.78–0.93 g/cm\(^3\). The pressure of L-type inclusions was ~25–82 bars. V-type inclusions were the least abundant, yielding ice-melting temperatures ranging from −6.6 °C to −0.6 °C, corresponding to salinities of 1.05–9.98 wt% NaCl equiv. The final homogenization temperatures ranged ~248–297 °C, and the bulk densities of the inclusions ranged 0.72–0.88 g/cm\(^3\). The pressure of V-type inclusions was ~35–82 bars.

The late stage was dominated by L-type inclusions with minor V-type inclusions. L-type inclusions yielded ice-melting temperatures ranging from −9.4 °C to −0.3 °C, corresponding to salinities of 0.53–13.29 wt% NaCl equiv. The final homogenization temperatures ranged ~171–244 °C, and the bulk densities of the inclusions ranged 0.84–0.96 g/cm\(^3\). The pressure of L-type inclusions was ~8–34 bars. Only four L-type inclusions were found in the late stage, yielding ice-melting temperatures ranging from −5.0 °C to −0.6 °C, corresponding to salinities of 1.05–7.86 wt% NaCl equiv. The final homogenization temperatures ranged ~210–245 °C, and the bulk densities of the inclusions ranged 0.81–0.91 g/cm\(^3\). The pressure of V-type inclusions was ~14–36 bars.
The δ\textsuperscript{18}O and δD values of hydrothermal quartz samples range from 8.5‰ to 10.2‰ and -97‰ to -92‰, respectively. The calculated δ\textsuperscript{18}O\textsubscript{H2O} of fluids varied from -2.6‰ to 4.3‰.

### Table 2. Hydrogen and oxygen isotopic compositions of quartz from the Baiyinhan tungsten deposit.

| Sample No. | Mineral | Stage  | δD (‰) | δ\textsuperscript{18}O\textsubscript{quartz} (‰) | Th (°C) | δ\textsuperscript{18}O\textsubscript{water} (‰) |

5.3. H-O Isotopes

Among the 21 quartz vein samples that were analysed for microthermometry, 9 of them were selected and analysed for the O (quartz) and H (fluid inclusions) isotopes. The H-O isotope ratios are listed in Table 2. The δ\textsuperscript{18}O and δD values of hydrothermal quartz samples ranged 8.5–10.2‰ and -97‰ to -92‰, respectively. The calculated δ\textsuperscript{18}O\textsubscript{H2O} of fluids varied from -2.6‰ to 4.3‰.
5.4. Re-Os Isochron Ages

The abundance of Re and Os and the osmium isotopic compositions of molybdenite from the quartz-vein-type ores of Baiyinhan are shown in Table 3. The concentration range of Re was 3108–8486 ng/g and that of \(^{187}\)Os was 4.52–12.53 ng/g. The Baiyinhan tungsten deposit had low Re and Os contents. The Re content of the Baiyinhan deposit was less than that in the porphyry Mo deposit (where the average value ranged from 14–68 µg/g) [49]. Five samples gave a model age of 137–141 Ma and a weight mean age of 138.8 ± 1.6 Ma (Table 3). Data, processed using the ISOPLOT/Ex program [50], yielded an isochron age of 139.6 ± 7.6 Ma and with MSWD = 3.5 (Figure 7).

Table 3. Re-Os isotope data for molybdenite samples from the Baiyinhan tungsten deposit.

| Sample No. | Weight (g) | Re (ng/g) | Uncertainty | \(^{187}\)Re (ng/g) | Uncertainty | \(^{187}\)Os (ng/g) | Uncertainty | Model Age (Ma) | Uncertainty |

Enriched \(^{185}\)Os and \(^{186}\)Re were obtained from the Oak Ridge National Laboratory. Decay constant: λ (\(^{187}\)Re) = 1.666 \times 10^{-11}/year [51]. The uncertainty in each individual age determination was about 1.02% including the uncertainty of the decay constant of \(^{187}\)Os, uncertainty in isotope ratio measurement, and spike calibration. BYH-13, -14, -15 were sampled from the V3 orebody, BYH-16, -18 were sampled from the V4 orebody.

Figure 7. Re-Os isochron plot for molybdenite samples from the Baiyinhan tungsten deposit.

6. Discussion

6.1. Evolution of Ore-Forming Fluids-the Important Role of CO2

The study of fluid inclusions shows that the ore-forming fluid of the Baiyinhan tungsten deposit is a NaCl-H2O-CO2 system with medium temperature and low salinity. The temperature of the fluid gradually decreased from the early stage to the late stage. As indicated from the types and abundance of fluid inclusions in the three stages, the early stage was mainly characterized by high-temperature CO2-rich inclusions, and the middle stage was mainly composed of gas-liquid two-phase inclusions, while the late stage only contained low-temperature gas-liquid two-phase inclusions. The content of CO2 in the ore-forming fluid tended to decrease with the evolution of the fluid.

CO2 is the most abundant gas composition in fluid inclusions in many typical wolframite deposits [52,53]. Rios et al. [54], Li et al. [55] and Chen et al. [48] also found primary fluid inclusions containing CO2 in wolframite, which shows that CO2 is closely related to the dissolution and migration of tungsten. Experimental research has shown that the carbonate or CO2 in the fluid is conducive to the dissolution and migration of tungsten [52,56,57]. Higgins [58] stated that tungsten may migrate in the form of carbonate and bicarbonate in CO2-rich fluids under the condition of high temperature.
and high pressure. The experimental study on the crystallization of tungsten-manganese ore in alkali carbonate solution showed that tungsten exists mainly in the form of WO$_4^{2-}$ in the hydrothermal system, and the solubility of wolframite is affected by the pH value of the system. The effect of alkali carbonate or CO$_2$ on the solubility of wolframite cannot be attributed to complexation because it can affect the pH value of the fluid, resulting in the change of tungsten solubility [55]. At the same time, CO$_2$ can act as pH buffer [59, 60], and the high content of CO$_2$ in the fluid can maintain the stability and enhance the migration of tungsten [61].

It can be seen from the pressure calculation of the three stages (Table 1) that the pressure of the fluid inclusion gradually decreased. A large number of liquid-rich inclusions were developed in the deposit. There was an obvious negative correlation between density and homogenization temperature (Figure 8). These characteristics may have been caused by the CO$_2$ dissipation during the process of temperature and pressure reduction, resulting in the gradual decrease of CO$_2$ content and increase of fluid density, and the evolution of fluids into a NaCl-H$_2$O system [62–64]. The CO$_2$-rich fluid formed during the hydrothermal differentiation in the late magmatism can carry sufficient ore-forming element tungsten. During the migration of ore-forming fluid along the fractures developed in the area, the addition of meteoric water precipitation and decrease of temperature and pressure leads to the immiscibility of the fluid. The escape of CO$_2$ results in the change of pH and the decrease of the solubility of tungsten, which leads to the precipitation and enrichment of WO$_4^{2-}$ in the ore-forming fluid by combining with cations such as Fe$^{2+}$ and Mn$^{2+}$ [65–68]. The dilution and escape of CO$_2$ can effectively enrich the ore-forming elements and even cause the fluid to supersaturate in an instant [69, 70]. The content of CO$_2$ in the ore-forming fluid of the Baiyinhan deposit tends to decrease with the evolution of the fluid, which is similar to that of the Grey River tungsten deposit and Parrila tungsten-tin deposit [71, 72]. It also further explains the important role of CO$_2$ in tungsten migration, and that the precipitation and enrichment of wolframite were closely related to the dispersion of CO$_2$ at the Baiyinhan deposit.

![Figure 8. Temperature-density diagram for fluid inclusions from the Baiyinhan tungsten deposit.](image)

6.2. Source of Ore-Forming Fluids and Materials

The H-O isotopes of fluid inclusions show that the samples from three stages have an obvious evolutionary trend, gradually transitioning from early residual magmatic water to late meteoric water (Figure 9). The three samples in the early stage were plotted in the lower part of the residual magma water, and their $\delta^D$ values were lower than the range of the residual magma water. There are two possible explanations for the low fluid $\delta^D$ value for the Baiyinhan deposit: One is the existence of CH$_4$ observed from the Raman test of fluid inclusions and the hydrogen isotope exchange between CH$_4$ and H$_2$ in the fluid, which leads to the fluid depletion of $\delta^D$ [73]. However, in the hydrothermal system containing CH$_4$, the proportion of water was much larger than that of CH$_4$ and H$_2$. Therefore,
this process has a trivial impact on hydrogen isotope production [73]. Another possibility is that in
actual geological conditions, when magma intrudes into the shallow part of the surface, it is likely to
mix with meteoric water directly or indirectly [74]. The mixing of meteoric water and magmatic water
has a significant impact on H-O isotopes, and the effect on hydrogen is generally greater than that
on oxygen [75]. The second possibility well explains the fact that the δD values of H-O isotopes in
quartz in the early stage of the deposit consistently fell in the lower part of the residual magmatic water.
Therefore, we conclude that the initial fluid of the Baiyinhan tungsten deposit was a mixture of residual
magmatic water and meteoric water. With the migration and evolution of the fluid, the proportion of
meteoric water gradually increased.

Figure 9. The quartz δD versus δ18O diagram of the Baiyinhan tungsten deposit (Primary Magmatic
H2O after Taylor, [76]; high-temperature vapours after Giggenbach, [77]; residual magmatic H2O after
Taylor, [73]).

The Re content in molybdenite from the W-Mo-bearing quartz veins in the Baiyinhan tungsten
deposit is consistent with many porphyry Mo deposits but is significantly smaller than those from
porphyry Cu-Mo deposits [78]. The average Re contents of molybdenites from porphyry Cu–Mo
deposits and porphyry Mo deposits range from 118–19,800 ug/g, and 4–68 ug/g, respectively [76].
The Re content in molybdenites decreases gradually from the mantle source to a mixture of mantle
and crust and then to the crustal source [79,80]. The Re contents of molybdenite from the Baiyinhan
tungsten deposit ranged from 3.1–8.4 ug/g with an average of 7.1 ug/g (Table 3). The relatively lower
Re contents of molybdenites form the Baiyinhan tungsten deposit may indicate that the ore-forming
materials source of the ore-bearing quartz vein was a crust source.

6.3. The Significance of Re-Os Age of the Baiyinhan Tungsten Deposit

The analysis of five molybdenite samples yielded an isochron age of 139.6 ± 7.6 Ma with an initial
187 Os of −0.05 ± 0.57. It was shown that the initial 187 Os values from the molybdenite were close to zero,
and the Re-Os isochron ages reflected the time of sulfide deposition [46,79,80]. Some W (-Mo) deposits
were discovered in the eastern part of the CAOB in recent years. The ages of W (-Mo) mineralization
in the eastern part of the CAOB were reported and recognized in three periods (Figure 10): Triassic
(~230 Ma), Early-Middle Jurassic (198–170 Ma) and Early Cretaceous (~140 Ma). The Baiyinhan deposit
was formed in the early Cretaceous with an Re-Os age of 139.6 ± 7.6 Ma, which further indicates
that the early Cretaceous is an important metallogenic period with great metallogenic prospect in the
eastern part of the CAOB.
Figure 10. Ages of W-(Mo) deposits in NE China (data from [11,23,81–86] and this paper).

7. Conclusions

(1). The Baiyinhan quartz vein tungsten deposit occurs within the Yanshanian granite. The ore mineral assemblage is wolframite + pyrite + molybdenite ± bismuthinite. The greisen is the main hydrothermal alteration in the deposit.

(2). The thermometric analysis of inclusions showed that the fluid presented a medium-temperature and a low-salinity H$_2$O-CO$_2$-NaCl system. The ore-forming temperature in the three stages gradually decreased, and the CO$_2$ content gradually decreased with the fluid evolution. The mineralization was closely related to CO$_2$ dispersion. The H-O isotope of quartz showed that the ore-forming fluid was a mixture of residual magmatic water and meteoric water.

(3). Five molybdenite samples yielded an isochron age of 139.6 ± 7.6 Ma (MSWD = 3.5), and model ages for individual analyses ranged from ~138–141Ma. Combined with the regional mineralization age data, the tungsten mineralization of the Baiyinhan deposit indicates that the Early Cretaceous is an important tungsten mineralization epoch in the eastern CAOB.

Author Contributions: Conceptualization, R.W. and Q.Z.; formal analysis, R.W.; investigation, R.W., Q.Z. and Y.G.; resources, Q.Z. and J.L.; writing—original draft preparation, R.W.; writing—review and editing, Q.Z. and Z.Z.; visualization, R.W.; supervision, Q.Z.; funding acquisition, Q.Z.
