Abstract

We present a generic and executable formalization of signature-based algorithms (such as Faugère’s $F_5$) for computing Gröbner bases, as well as their mathematical background, in the Isabelle/HOL proof assistant. Said algorithms are currently the best known algorithms for computing Gröbner bases in terms of computational efficiency. The formal development attempts to be as generic as possible, generalizing most known variants of signature-based algorithms, but at the same time the implemented functions are effectively executable on concrete input for efficiently computing mechanically verified Gröbner bases. Besides correctness the formalization also proves that under certain conditions the algorithms a-priori detect and avoid all useless reductions to zero, and return minimal signature Gröbner bases.

To the best of our knowledge, the formalization presented here is the only formalization of signature-based Gröbner basis algorithms in existence so far.

Keywords: Gröbner bases, signature-based algorithms, interactive theorem proving, Isabelle/HOL

1. Introduction

Gröbner bases, introduced by Buchberger (1965), are a ubiquitous tool in computer algebra and beyond, as they allow to effectively solve many problems related to multivariate polynomial rings and ideals. Finding Gröbner bases is a computationally difficult task, and therefore many researchers have attempted to design more and more efficient algorithms over the years. This, finally, lead to the first signature-based algorithm, the $F_5$ algorithm invented by Faugère (2002). Nowadays, $F_5$ and its relatives are the most efficient algorithms for computing Gröbner bases, implemented in many modern computer algebra systems.

1The research was funded by the Austrian Science Fund (FWF): P 29498-N31.
The work presented in this paper focuses on yet another implementation of signature-based algorithms, but this time not in a computer algebra system but in the proof assistant Isabelle/HOL (Nipkow et al. (2002)). The distinctive feature of our implementation is its formal verification by the inference kernel of Isabelle. This, of course, necessitated formalizing also the vast theory behind signature-based algorithms, eventually leading to an extensive, generic and executable formalization of an important topic in modern computer algebra. Even more, it is the—to the best of our knowledge—first-ever formalization of this theory in any proof assistant. As such, it constitutes the ultimate certificate that the existing informal theory is indeed correct, without even the slightest mistake or overlooked gap.

In the remainder we assume familiarity with the basics of Gröbner bases theory, including polynomial reduction, S-polynomials, the definition of Gröbner bases, and Buchberger’s algorithm. Although we present the key definitions, theorems and algorithms of the signature-based approach to Gröbner bases in this paper, readers totally new to the subject might also want to have a glance at the excellent survey article by Eder and Faugère (2017), which we took as the template for our formalization. We must also stress that besides Faugère, many more researchers have worked on signature-based algorithms, resulting in a great variety of such algorithms. Giving an exhaustive overview of all variations of signature-based algorithms in existence is out of scope here, though; see again Eder and Faugère (2017) instead.

The motivation and distinctive feature of signature-based algorithms is detecting and avoiding many more useless zero-reductions while computing Gröbner bases than other algorithms—and in some cases even all useless reductions. This saves a lot of computation time and thus leads to a drastic speed-up. How all this relates to signatures, and what signatures are in the first place, will be explained in Sections 3–5.

The main motivation for the formalization was to verify a state-of-the-art algorithm for computing Gröbner bases. That task could be expected to be challenging due to the inherent complexity of the underlying mathematical theory, illustrated by the fact that termination of the original F_5 algorithm was an open problem for a decade until it was settled by Galkin (2012). Our formal development of the theory may also serve as the basis for further theoretical investigations, e.g. by implementing, testing and verifying new improvements of the formalized algorithms, as well as for further formalizations in the vast area of Gröbner bases.

Summarizing, the key features of the work presented here are as follows:

- The formalization is generic, in the sense that we consider rewrite bases and allow for arbitrary term orders and rewrite orders (Section 5). According to Eder and Faugère (2017) this set-up covers most, if not all, existing variations of signature-based algorithms.

- All algorithms are proved to be totally correct w. r. t. their specifications. In particular, the algorithm for computing rewrite bases (Algorithm 1) is shown to terminate for every input (Section 6.1).

- Besides correctness, we also prove that under certain conditions the algorithm indeed avoids all useless zero-reductions, and that with a particular choice of the rewrite order it returns minimal signature Gröbner bases (Section 7).
• All formally verified algorithms are efficiently executable on concrete input. ‘Effi-
cient’ means that, for instance, the algorithms operate only on sig-poly-pairs rather
than full module elements (Section 8).

The entire formalization is freely available online (Maletzky (2018)), as an entry of Is-
abelle’s Archive of Formal Proofs (AFP).

1.1. Organization of the Paper

The rest of the paper is organized as follows: Section 2 gives a brief overview of Isabelle/HOL, to make the paper as self-contained as possible. Section 3 presents the preliminaries of signature-based algorithms, Section 4 introduces σ-reduction and sig-
nature Gröbner bases, Section 5 defines rewrite bases and S-pairs and establishes the connection between them, Section 6 presents the main algorithms and hints why they are totally correct, and Section 7 contains two results concerning the ‘optimality’ of the algorithms. Each of these sections first presents the various concepts and theorems in common mathematical style, before showing how they are formalized in Isabelle/HOL.

Section 8 then, explains how the formalized algorithms can be executed on concrete input and provides a comparison of the running times of these algorithms to other algo-
rithms implemented in Isabelle/HOL and in Mathematica. Section 9 finally, concludes the paper by giving quantitative information on the formalization effort and listing re-
lated and future work.

2. Brief Overview of Isabelle/HOL

The purpose of this section is to give a brief overview of the most important aspects of Isabelle/HOL that are necessary for understanding the rest of the paper. Further information and documentation can be found in Paulson (1994); Nipkow et al. (2002); Wenzel (2018) and on the Isabelle homepage. Readers already familiar with Isabelle can safely skip this section.

Isabelle is a generic proof assistant: it serves as a framework for implementing differ-
ent object logics, such as first-order logic or higher-order logic, in one single system. As such, it provides the basic infrastructure needed for automated and interactive theorem proving in general: a small inference kernel based on higher-order unification, theory-
and proof contexts, a document preparation interface, and many more. Isabelle/HOL is a concrete object logic implemented in Isabelle, namely classical higher-order predicate logic. Being the most actively developed object logic of Isabelle, it comes with a library of hundreds of useful mathematical concepts, such as numbers, sets, lists, abstract algebraic structures, etc., which new formalizations can build upon.

Formalizing a mathematical theory in Isabelle/HOL normally proceeds by definitional theory extensions: new concepts are defined, properties of these concepts and their relation to existing concepts are proved, and so on; arbitrary axiomatizations, though possible in principle, are usually avoided to eliminate the risk of introducing inconsistencies to the theory. Our formalization goes without any such axiomatizations.

2.1. Definitions

New constants can be introduced either via explicit non-recursive definitions or as recursive functions. A simple example of the former is the following:

\[ 
\text{definition} \quad \text{subset-eq} :: \alpha \text{ set} \Rightarrow \alpha \text{ set} \Rightarrow \text{bool} \quad (\text{infix } \subseteq) \\
\text{where} \quad \text{subset-eq} \; A \; B \leftarrow (\forall a \in A. \; a \in B) 
\]

This definition introduces a new constant, \text{subset-eq}, of type \( \alpha \text{ set} \Rightarrow \alpha \text{ set} \Rightarrow \text{bool} \). That means, it is a function taking two sets of element-type \( \alpha \) as arguments and returning a boolean value. Greek letters like \( \alpha \) always denote type variables; hence, \text{subset-eq} is a polymorphic function that cannot only be applied to sets of a particular element-type, but to all sets. The type constructors \text{set} and \text{bool} are built into Isabelle/HOL. The ‘infix’ clause following the type is optional and instructs Isabelle to record the short infix notation \( \subseteq \) for \text{subset-eq}. The actual definition of \text{subset-eq} comes after the ‘where’ keyword: \text{subset-eq} holds for two arguments \( A \) and \( B \) if, and only if, every element \( a \) of \( A \) is also an element of \( B \). Note that free variables in definitions, theorems, etc. are implicitly universally quantified, and that \( \forall \) and \( \in \) are built-in constants with the usual meaning. Therefore, \text{subset-eq} is indeed the usual subset relation; of course, it is a built-in constant of Isabelle/HOL, too.

As can be seen, Isabelle uses Curried notation for denoting function application: in the definition, \text{subset-eq} is applied to \( A \) and \( B \) by mere juxtaposition, without parentheses. Parentheses only become necessary in nested function applications, as in \( f \; (g \; x) \).

What can also be seen in the above definition is that single arrows are used to denote equivalences and implications: \( \rightarrow \) for logical implication, \( \leftrightarrow \) for equivalence.

**Notation 2.1.** Within enclosing informal text, we will adopt the standard mathematical notation for function application when writing Isabelle code. For instance, we shall write \text{subset-eq}(A, B) rather than \text{subset-eq} A B, because the latter does not fit very well with informal text. Furthermore, names of constants will be typeset in \text{sans serif} font to distinguish them from variables, which will be typeset in \text{italics}, as usual.

As an example of a recursive definition, consider the following:

\[ 
\text{function} \quad \text{set} :: \alpha \text{ list} \Rightarrow \alpha \text{ set} \quad \text{where} \\
\text{set} \; [] = {} \\
\text{set} \; (x \; \# \; xs) = \{x\} \cup \text{set} \; xs 
\]

This command defines a polymorphic function \text{set} which maps lists (built-in type constructor \text{list}) to the set of their elements, which is achieved by structural recursion on the shape of the argument: if it is empty, the empty set is returned; otherwise, the list consists of a head \( x \) and a tail \( xs \), in which case \text{set} is applied to \( xs \) recursively and \( x \) is added to the result. Recursively defined functions must always be shown to terminate, to avoid potential inconsistencies. In some cases, Isabelle can do the termination proofs itself, whereas in more difficult situations the user has to construct the proofs interactively.

2.2. Theorems and Proofs

Theorems can be stated using the synonymous ‘lemma’, ‘theorem’ or ‘corollary’ keywords. For instance, a lemma expressing that the set of elements of the concatenation of two lists equals the union of the individual sets could be stated as follows:
lemma set-append: set (xs @ ys) = set xs \cup set ys

Here, @ is infix syntax denoting the concatenation of lists xs and ys, and recall from above that the two free variables xs and ys are implicitly universally quantified. So far, however, the lemma is only an unproved claim as far as Isabelle is concerned, so we now have to prove it. Proving in Isabelle rests on two pillars: First, an intuitive, human-readable formal proof language, called Isar, for proving theorems interactively. That means, the user writes down the individual steps of the proof, and Isabelle checks whether they are indeed correct. Second, a huge machinery of automatic proof methods that are able to prove certain goals automatically, saving the user from doing tedious but more or less simple proofs manually. Existing automation is fairly sophisticated, incorporating even powerful state-of-art first-order reasoners.

To give a rough idea of how proofs in Isabelle/HOL look like, we show a quite verbose induction proof of the above lemma; long dashes (−) indicate explanatory comments:

lemma set-append: set (xs @ ys) = set xs \cup set ys
proof (induction xs)
− Induction base:
  show set ([] @ ys) = set [] \cup set ys by simp
  − Prove the goal by simplification w.r.t. the definitions of \langle set\rangle and \langle @\rangle.
next
− Induction step:
  fix x xs
  − Choose fresh \langle x\rangle and \langle xs\rangle arbitrary, but fixed.
  assume set (xs @ ys) = set xs \cup set ys
  − Assume the induction hypothesis.
  then show set ((x # xs) @ ys) = set (x # xs) \cup set ys by simp
  − Prove the goal again by simplification,
    but this time also using the induction hypothesis.
qed

Since we will not present any Isabelle-proofs in the remainder of this paper, we do not say more about proving in Isabelle here.

Finally, please note that more complicated lemmas involving assumptions can be stated following the ‘fixes’/‘assumes’/‘shows’ pattern, to increase readability:

lemma times-mono-int:
  fixes a b c :: int
  assumes a \leq b and 0 \leq c
  shows a \times c \leq b \times c

The optional ‘fixes’ clause locally fixes variables and potentially annotates them with types (here int, the type of integers). The optional ‘assumes’ clause states one or more assumptions, and the mandatory ‘shows’ clause states the ultimate conclusion.

Notation 2.2. Within enclosing informal text, names of lemmas and theorems will be typeset in italics, like set-append.

2.3. Frequently Used Functions

We conclude this section by listing built-in concepts we will use later on.

• The usual logical connectives and quantifiers. Syntax in Isabelle/HOL closely resembles ordinary mathematical notation, expect that logical implication is denoted by \texttt{\rightarrow} and equivalence by \texttt{\leftrightarrow}.
• The usual operations from set theory, whose Isabelle syntax resembles mathematical notation, too.

• \( f \ A \), which denotes the image of set \( A \) under function \( f \).

• \( \{0..<n\} \), which denotes the set \( \{k \in \mathbb{N} \mid 0 \leq k < n\} \) of natural numbers; analogously, \( [0..<n] \) denotes the list of natural numbers from 0 up to \( n \).

• \( \text{set} \), \( [] \), and \( \# \), as explained above: \( \text{set}(xs) \) is the set of elements of list \( xs \), \( [] \) is the empty list, and \( x \# xs \) is the list whose first element is \( x \) and whose tail is \( xs \).

• \( \text{length}(xs) \), which is the length of list \( xs \).

• \( xs ! i \), which is the \( i \)-th element of list \( xs \), starting from 0.

• \( \text{fst} \) and \( \text{snd} \), which project pairs of type \( \alpha \times \beta \) onto their first and second entries, respectively. For instance, \( \text{fst}((a, b)) = a \).

Remark 2.1. Throughout the paper we will follow the common convention in papers about Isabelle of using dashes instead of underscores, for the sake of better readability. So, \( \text{subset-eq} \) would in reality be \( \text{subset_eq} \) in the actual Isabelle sources.

3. Preliminaries

3.1. Mathematical Preliminaries

In this and the subsequent sections we present signature-based Gröbner basis algorithms and their formalization in Isabelle/HOL. Notation is mainly borrowed from Eder and Faugère (2017), with some small adjustments here and there to resemble the notation we use in the formalization. In fact, since the formalization itself closely follows Sections 4–7 of Eder and Faugère (2017), most of the mathematical details omitted in this exposition for the sake of brevity can be found there instead. The informal proofs that served as the templates for our formal development were exclusively taken from the above-mentioned article and from Roune and Stillman (2012) and Eder and Roune (2013).

In the remainder of this paper let \( \mathbb{K} \) be a field and let \( \mathbb{R} = \mathbb{K}[x_1, \ldots, x_n] \) be the \( n \)-variate polynomial ring over \( \mathbb{K} \). Every polynomial \( p \in \mathbb{R} \) can be written as a \( \mathbb{K} \)-linear combination of power-products, where a power-product is a product of the indeterminates \( x_1, \ldots, x_n \), e.g., \( x_1^2 x_2 x_3^3 \). We will write \( [X] \) for the commutative monoid of power-products in \( x_1, \ldots, x_n \) and typically denote power-products by the typed variables \( s \) and \( t \), unless stated otherwise.

Now, fix a finite sequence \( F = (f_1, \ldots, f_m) \) of polynomials in \( \mathbb{R} \); these polynomials play the role of the set we want to compute a Gröbner basis of. The sequence \( F \) gives rise to a module-homomorphism \( \gamma: \mathbb{R}^m \rightarrow \mathbb{R} \) by setting \( \gamma_i := f_i \) for \( 1 \leq i \leq m \) and canonical basis vectors \( \mathbf{e}_i \) of the free module \( \mathbb{R}^m \). A module element \( a \in \mathbb{R}^m \) is called a syzygy of \( F \) if \( \overline{a} = 0 \). Note that \( \mathbb{R}^m \) can be viewed as a \( \mathbb{K} \)-vector space, meaning that every \( a \in \mathbb{R}^m \) can be written as a \( \mathbb{R} \)-linear combination of terms, where a term is a product of the form \( t \mathbf{e}_i \) for some power-product \( t \) and some \( 1 \leq i \leq m \). We will write \( \Omega \) for the set of terms and typically denote terms by the typed variables \( u \) and \( v \). For a term \( v = t \mathbf{e}_i \), \( t \) is called the power-product of \( v \) and \( i \) is called the component of \( v \).
For a polynomial $p \in \mathbb{R}$, $\text{supp}(p)$ is the support of $p$, which is the set of all power-products appearing in $p$ with non-zero coefficient. Likewise, $\text{supp}(a)$ for $a \in \mathbb{R}^m$ is the set of all terms appearing in $a$ with non-zero coefficient. $\text{coeff}(p, t)$ denotes the coefficient of power-product $t$ in $p \in \mathbb{R}$, and analogous for $\text{coeff}(a, u)$ with $u \in \mathcal{T}$ and $a \in \mathbb{R}^m$.

Finally we must also fix an admissible order relation $\preceq$ on $[X]$ and some compatible extension $\preceq_1$ to a term order on $\mathcal{T}$. Admissible has the usual meaning of $1 \preceq t$ and $s_1 \preceq s_2 \Rightarrow t s_1 \preceq t s_2$ for all $s_1, s_2, t \in [X]$. Compatible just means that $s \preceq t \Rightarrow s \, e_i \preceq_1 t \, e_i$ for all $s, t \in [X]$ and $1 \leq i \leq m$. The most important extension of $\preceq$ to a term order is the position over term (POT) extension, denoted by $\preceq_{\text{pot}}$ and defined as

$$s \, e_i \preceq_{\text{pot}} t \, e_j : \Leftrightarrow i < j \lor (i = j \land s \preceq t).$$

Every $p \in \mathbb{R}$ has a leading power-product $\text{lp}(p)$ and a leading coefficient $\text{lc}(p)$: if $p \neq 0$, the leading power-product of $p$ is the largest power-product w.r.t. $\preceq$ appearing in $\text{supp}(p)$, and the leading coefficient is its coefficient; $\text{lp}(0)$ is left undefined and $\text{lc}(0) := 0$. Likewise, every module element $a \in \mathbb{R}^m$ has a leading term $\mathcal{s}(a)$ and a leading coefficient $\text{lc}(a)$, defined completely analogously w.r.t. $\preceq_1$. The reason why the leading term of $a$ is denoted by $\mathcal{s}(a)$ rather than $\text{lt}(a)$ becomes clear in the following definition:

**Definition 3.1 (Signature).** Let $a \in \mathbb{R}^m$. The signature of $a$ is the leading term $\mathcal{s}(a)$ of $a$.

Therefore, the all-important signature of a module element $a \in \mathbb{R}^m$ is nothing else but the leading term of $a$. In the remainder, we will exclusively use the word ‘signature’ instead of ‘leading term’. Note that in contrast to Eder and Faugère (2017), in our case the signature only consists of a term without coefficient.

Summarizing, every $a \in \mathbb{R}^m$ has two important values associated to it: its signature $\mathcal{s}(a) \in \mathcal{T}$ and the polynomial $\mathfrak{m} \in \mathbb{R}$.

3.2. Isabelle/HOL

For our formal development of signature-based Gröbner basis algorithms we did not have to start completely from scratch, but could build upon on existing extensive formalizations of multivariate polynomials and Gröbner bases. Here, we will explain the most important aspects of these formalizations that are relevant for signature-based algorithms; the interested reader is referred to Maletzky and Immler (2018a,b) for more details. The formalizations are freely available as separate entries in the Archive of Formal Proofs (Sternagel et al. (2010); Immler and Maletzky (2016)).

In Isabelle/HOL, multivariate polynomials are represented as so-called polynomial mappings, which are functions from some type $\alpha$ to another type $\beta$ such that all but finitely many values are mapped to $0$. The meaning of such a mapping is clear: $\alpha$ plays the role of the power-products or terms, and $\beta$ plays the role of the coefficient-ring; the value a power-product or term is mapped to is its coefficient in the polynomial. The type of polynomial mappings from $\alpha$ to $\beta$ is denoted by $\alpha \Rightarrow_0 \beta$. Note that polynomial mappings are sometimes also referred to as finitely supported functions.

Terms are simply represented as pairs consisting of a power-product and a component of type nat, the type of natural numbers; hence, if $\alpha$ is the type of power-products, then the type of terms is $\alpha \times \text{nat}$. Note that because of nat being infinite, the components of terms can become arbitrarily large; this point deserves a bit more attention, which will be paid below. Before, we summarize what we have so far:
Here and henceforth, $\alpha$ will always denote the type of power-products. How exactly power-products are represented is not important, since the $y$ essentially only have to form a cancellative commutative monoid and a lattice w.r.t. divisibility. For more details see Maletzky and Immler (2018b).

Type $\tau$ will abbreviate the type of terms, i.e., the type $\alpha \times \text{nat}$. In the actual formalization, $\tau$ only needs to be isomorphic to $\alpha \times \text{nat}$, but this is a mere technicality without any further implications.

Type $\beta$ plays the role of $K$, the coefficient field.

The polynomial ring $\mathcal{R}$ hence corresponds to the type $\alpha \Rightarrow 0 \beta$, and the module $\mathcal{R}^m$ to $\tau \Rightarrow 0 \beta$.

Example 3.1. Let $p = 3x^2 - 2xy + y^3 - 4 \in \mathcal{R}[x, y]$. Then $p$ corresponds to an object of type $\alpha \Rightarrow 0 \beta$ which maps $x^2 \mapsto 3$, $xy \mapsto -2$, $y^3 \mapsto 1$, $1 \mapsto -4$, and all other power-products $t \mapsto 0$. As indicated above, how the individual power-products are represented is not important here.

Likewise, let

$$a = \left(\frac{2xy^2 - 3}{x^3 + y^3}\right) \in \mathcal{R}[x, y]^2.$$ 

Then $a$ corresponds to an object of type $\tau \Rightarrow 0 \beta$ which maps $(xy^2, 0) \mapsto 2$, $(1, 0) \mapsto -3$, $(x^3, 1) \mapsto 1$, $(y^3, 1) \mapsto 1$, and all other terms $u \mapsto 0$. Note in particular that the first component is indexed by 0, the second by 1, etc.

One may now ask the following legitimate question:

How can $\mathcal{R}^m$ be represented by $\tau \Rightarrow 0 \beta$, if $\mathcal{R}^m$ has dimension $m$ (and therefore all terms appearing in its elements have components $\leq m$), but $\tau$ allows for arbitrarily large components?

Indeed, strictly speaking $\mathcal{R}^m$ and $\tau \Rightarrow 0 \beta$ are not isomorphic. However, we can circumvent the problem of components of terms being greater than $m$ (or, in fact $m - 1$, since the first component is indexed by 0) by explicitly putting certain constraints on all module elements of type $\tau \Rightarrow 0 \beta$ appearing anywhere in the formal development. More precisely, we define the set $\text{sig-inv-set}(m)$, parameterized over the natural number $m$, of all module elements whose terms have components in the range $[0, \ldots, m - 1]$. Then, we constrain all theorems where it is necessary by the additional condition that all module elements $a$ occurring in the theorem belong to $\text{sig-inv-set}(m)$.

Of course, $m$ is not just an arbitrary natural number, but it is the length of the implicitly fixed sequence $F = (f_1, \ldots, f_m)$ of polynomials. So, in the formalization we also fix a sequence, or more precisely a list, $fs$ in the implicit theory context:

```
context fixes fs :: (\alpha \Rightarrow 0 \beta) list
```

This instruction ensures that all subsequent definitions, theorems, algorithms, etc. are implicitly parameterized over the list $fs$. Consequently, we can define the set $\mathcal{R}^m$ of all ‘valid’ module elements:

```
definition Rm :: (\tau \Rightarrow 0 \beta) set
where Rm = sig-inv-set (length fs)
```

8
Hence, \( R_m \) is the set of module elements whose terms have components in the range \([0, \ldots, \text{length}(fs) - 1]\), and as such precisely corresponds to \( R_m^m \).

**Remark 3.1.** In a dependently-typed system like Coq (Bertot and Castéran (2004)), \( R_m \) could be turned into a type, meaning that the additional assumptions \( a \in R_m \) of theorems could be encoded implicitly in the type of \( a \). Isabelle/HOL is only simply-typed, so this approach does not work in our case.

**Remark 3.2.** The definition of \( R_m \) shown above is not exactly the one of the formalization. Namely, analogous to components, we also have to take care that all indeterminates appearing in module elements also appear in \( fs \); similar as for the components, this cannot be encoded (easily) in the type \( \alpha \). The details are technical and omitted here for the sake of simplicity.

Having \( fs \) fixed in the context, we next formalize the module-homomorphism \( \gamma \), called \( \text{poly} \) in the formal theory, and prove its characteristic properties. We omit its slightly technical definition here.

**lemma** poly-zero: \( \text{poly} 0 = 0 \)

**lemma** poly-plus: \( \text{poly} (a + b) = \text{poly} a + \text{poly} b \)

**lemma** poly-mult-scalar: \( \text{poly} (p \odot a) = p \times \text{poly} a \)

Here one should note that \( \text{poly} \) is defined in such a way that these identities hold unconditionally, even if \( a, b \notin R_m \). The expression \( p \odot a \) denotes scalar multiplication of the module element \( a \) by the polynomial \( p \). Two further important lemmas about \( \text{poly} \) describe its relationship to the ideal generated by the elements of \( fs \):

**lemma** poly-in-ideal: \( \text{poly} a \in \text{ideal}\ (\text{set} \ fs) \)

**lemma** in-idealE-poly-Rm:
assumes \( p \in \text{ideal}\ (\text{set} \ fs) \)
shows \( \exists a \in R_m. \ p = \text{poly} a \)

The first lemma obviously expresses that \( \text{poly}(a) \) is always an element of the ideal generated by the elements of \( fs \), whereas the second lemma states the converse: every element \( p \) of the ideal can be written as \( p = \text{poly}(a) \) for some \( a \in R_m \); \( a \) being an element of \( R_m \) is of particular importance here. The expression \( \text{ideal}(B) \), taken from Sternagel et al. (2010), denotes the ideal generated by the set \( B \).

The only things that are still missing from Section 3.1 are the order relations \( \preceq \) and \( \preceq_t \), and the various concepts they induce (leading power-product etc.); they are, in fact, contained in Sternagel et al. (2010) as well. Similar to \( fs \), the remaining formal development shall be parameterized over these orderings, so a locale is employed to fix them implicitly:

**locale** qpm-inf-term =
ordered-powerprod ord +
linorder ord-term
  for ord :: \( \alpha \Rightarrow \alpha \Rightarrow \text{bool} \) (infixl \( \preceq \) 50)
  and ord-term :: \( \tau \Rightarrow \tau \Rightarrow \text{bool} \) (infixl \( \preceq_t \) 50) +
assumes stimes-mono: \( u \preceq v \rightarrow u \odot t \preceq v \odot t \)
assumes ord-termI: \( \text{fst} \ u \preceq \text{fst} \ v \rightarrow \text{snd} \ u \preceq \text{snd} \ v \rightarrow u \preceq u \preceq v \)
Locales are a sophisticated mechanism for structuring Isabelle-theories into sub-theories that can later be combined in a convenient and efficient way. Before, when fixing $fs$, a simple context-statement was sufficient, but here we really need the capabilities of a full-fledged locale. For more information on locales see Ballarin (2010).

Locale $qpm$-inf-term fixes the two relations $\preceq$ and $\preceq_t$, and assumes that $\preceq$ is an admissible order on type $\alpha$ (the power-products) and that $\preceq_t$ is a linear order on type $\tau$ (the terms). Furthermore, it assumes the two properties $stimes$-mono and $ord$-termI.

Property $stimes$-mono expresses that $\preceq_t$ is monotonic w.r.t. $\otimes$, where $t \otimes u$ denotes the term obtained from $u$ by multiplying its power-product by $t$. Property $ord$-termI states that if the power-product and the component of $u$ are not greater than their respective counterparts of $v$, then $u \preceq_t v$. Note that $\text{fst}(u)$ gives the first entry of term $u$, i.e. its power-product, and $\text{snd}(u)$ gives the second entry of $u$, i.e. its component.

All subsequent definitions, theorems, etc. will be stated in the context of this locale, meaning that they are implicitly parameterized over $\preceq$ and $\preceq_t$ (just as they are parameterized over $fs$), and that furthermore all theorems are implicitly constrained by the two additional assumptions $stimes$-mono and $ord$-termI. Leading power-products, leading terms and signatures of polynomials and module elements can be defined readily in this setup.

We conclude this section by pointing the reader to Appendix A containing a glossary for translating between mathematical notions and notations occurring in this paper, and their counterparts in the formalization.

Remark 3.3. In the actual Isabelle sources, power-products are written additively rather than multiplicatively, for technical reasons. So, 0 is used instead of 1, + instead of $\cdot$, and $\oplus$ instead of $\otimes$. In this paper we decided to stick to the standard multiplicative writing for the sake of uniformity.

4. Signature Reduction and Signature Gröbner Bases

Let us now turn to the key concept in the theory of Gröbner bases: polynomial reduction. In the ‘traditional’, non-signature approach the reduction relation is a binary relation on polynomials, parameterized over a set of polynomials. In the signature-based world, it becomes a binary relation on module elements, i.e. on $\mathbb{R}^n$, defined as follows:

Definition 4.1 (s-Reduction). Let $a, b \in \mathbb{R}^n$ and $G \subseteq \mathbb{R}^n$. The module element $a$ s-reduces to $b$ modulo $G$ if, and only if, there exist $g \in G$ and $t \in \llbracket X \rrbracket$ such that

1. $g \neq 0$,
2. $t \text{lp}(g) \in \text{supp}(\underline{\tau})$,
3. $b = a - tg$, and
4. $t s(g) \preceq_t s(a)$, which is equivalent to $s(b) \preceq_t s(a)$.

So, if $a$ s-reduces to $b$ modulo $G$, it simply means that $\underline{\tau}$ reduces to $\underline{b}$ modulo $\underline{G}$ in the usual sense of polynomial reduction\footnote{$\underline{G}$, of course, denotes the image of $G$ under the homomorphism $\tau$.} and that furthermore the signature of $b$ is
not greater than that of \( a \). In short, \( s \)-reduction is like polynomial reduction with the additional requirement that signatures do not grow.

\( s \)-reduction comes in different flavors, depending on whether \( t \text{lp}(\tau) \) or not, and whether in the last condition of that definition we have \( t s(g) = s(a) \) or \( t s(g) \prec s(a) \). If \( t \text{lp}(\tau) = \text{lp}(\tau) \), we shall say that the \( s \)-reduction is a top \( s \)-reduction; otherwise, if \( t \text{lp}(\tau) \prec \text{lp}(\tau) \), we call it a tail \( s \)-reduction. If \( t s(g) = s(a) \) the \( s \)-reduction is a singular \( s \)-reduction, whereas if \( t s(g) \prec s(a) \) it is a regular \( s \)-reduction. It is easy to see that in a regular \( s \)-reduction we always have \( s(b) = s(a) \).

**Notation 4.1.** Let \( r_1 \in \{\preceq, \prec, =\} \) and \( r_2 \in \{\preceq, \prec, =\} \). We will use the following notation: \( \tau_{r_1r_2}b \) means that \( a \) \( s \)-reduces to \( b \) modulo \( G \), and that additionally \( t s(g) r_1 s(a) \) and \( t \text{lp}(\tau) r_2 \text{lp}(\tau) \) hold, where \( t, g \) are as in Definition 4.1. As usual, \( t_{r_1r_2}G \) denotes the reflexive-transitive closure of \( t_{r_1r_2}G \). So, \( t_{r_1r_2}G \) stands for general \( s \)-reduction, \( t_{r_1r_2}G \) for regular top \( s \)-reduction, and so on. To ease notation, we shall simply write \( \rightarrow_G \) instead of \( t_{r_1r_2}G \).

What has been said above about the relationship between \( s(b) \) and \( s(a) \) if \( b \) \( s \)-reduces to \( a \) is of course also true for the reflexive-transitive closure of \( s \)-reduction. In particular, if \( a \rightarrow_G b \), i.e. \( a \) regular \( s \)-reduces to \( b \) in several steps, then \( s(b) = s(a) \). This trivial observation will play a crucial role later on.

The definition of \( s \)-reduction in the formalization closely follows Definition 4.1 but in addition also incorporates Notation 4.1.

```
definition sig-red-single :: (\tau \Rightarrow \tau \Rightarrow \text{bool}) \Rightarrow (\alpha \Rightarrow \alpha \Rightarrow \text{bool}) \Rightarrow
  (\tau \Rightarrow_0 \beta) \Rightarrow (\tau \Rightarrow_0 \beta) \Rightarrow (\tau \Rightarrow_0 \beta) \Rightarrow (\tau \Rightarrow_0 \beta) \Rightarrow \alpha \Rightarrow \text{bool}
where sig-red-single r1 r2 a b g t \Leftarrow
  (\text{poly} g \neq 0 \wedge \text{coeff} (\text{poly} a) (t * \text{lp} (\text{poly} g)) \neq 0 \wedge
  b = a * \text{monom-mult} ((\text{coeff} (\text{poly} a) (t * \text{lp} (\text{poly} g))) / \text{lc} (\text{poly} g)) \t g \wedge
  r1 (t \otimes s g) (s a) \land r2 (t * \text{lp} (\text{poly} g)) (\text{lp} (\text{poly} a)))
```
```
definition sig-red :: (\tau \Rightarrow \tau \Rightarrow \text{bool}) \Rightarrow (\alpha \Rightarrow \alpha \Rightarrow \text{bool}) \Rightarrow
  (\tau \Rightarrow_0 \beta) \Rightarrow (\tau \Rightarrow_0 \beta) \Rightarrow (\tau \Rightarrow_0 \beta) \Rightarrow (\tau \Rightarrow_0 \beta) \Rightarrow \text{bool}
where sig-red r1 r2 G a b \Leftarrow (\exists g \in G. \exists t. \text{sig-red-single r1 r2 a b g t})
```
```
definition is-sig-red :: (\tau \Rightarrow \tau \Rightarrow \text{bool}) \Rightarrow (\alpha \Rightarrow \alpha \Rightarrow \text{bool}) \Rightarrow
  (\tau \Rightarrow_0 \beta) \Rightarrow (\tau \Rightarrow_0 \beta) \Rightarrow (\tau \Rightarrow_0 \beta) \Rightarrow \text{bool}
where is-sig-red r1 r2 G a b \Leftarrow (\exists g \in G. \exists t. \text{sig-red-single r1 r2 a b g t})
```
```
So, \( \text{sig-red-single}(r_1, r_2, a, b, g, t) \) expresses that \( a \) \( s \)-reduces to \( b \) modulo the singleton \( \{g\} \) using the given power-product \( t \) as the multiplier. Note that \( \text{monom-mult}(c, t, a) \) is multiplication of \( a \) by the coefficient \( c \) and power-product \( t \). The two relations \( r_1 \) and \( r_2 \) have exactly the same meaning as in Notation 4.1 i.e., they specify whether the \( s \)-reduction is singular/regular/arbirtary and top/tail/arbitrary, respectively. The expression \( \text{sig-red}(r_1, r_2, G, a, b) \) precisely corresponds to \( a_{r_1r_2}G \); the reflexive-transitive closure of \( s \)-reduction is thus given by \( \text{sig-red}(r_1, r_2, G)^{**} \), using Isabelle/HOL’s built-in notion \( r^{**} \) for denoting the reflexive-transitive closure of an arbitrary binary relation \( r \). Finally, \( \text{is-sig-red} \) is an auxiliary notion expressing \( s \)-reducibility.

\(^{5}\)Obviously \( \text{lp}(\tau) \prec t \text{lp}(\tau) \) is not possible, since \( t \text{lp}(\tau) \in \text{supp}(\tau) \).
Since traditional polynomial reduction is known to be Noetherian, and \( s \)-reduction in some sense ‘refines’ polynomial reduction, we can immediately infer that \( s \)-reduction is Noetherian, too:

**Lemma 4.1.** For all \( G \subseteq R^m \), \( r_1 \rightarrow r_2 \) is Noetherian, that is, there are no infinite chains \( a_1 \rightarrow r_1 \rightarrow a_2 \rightarrow r_2 \rightarrow \ldots \).

This lemma can be translated easily into Isabelle/HOL, employing the built-in predicate \( \text{wfP} \) for expressing well-foundedness of the converse of \( s \)-reduction (denoted by \( \rightarrow^* \)):

**Lemma sig-red-wf-Rm:**

assumes \( G \subseteq R^m \)

shows \( \text{wfP} (\text{sig-red} r_1 r_2 G) \)

Proving this lemma is a matter of only a couple of lines, thanks to the fact that Immler and Maletzky (2016) already proved Noetherianity of traditional polynomial reduction in Isabelle/HOL. The assumption of \( G \) being a subset of \( R^m \) is necessary because of the observations made in Section 3.2.

Before we define signature Gröbner bases, we introduce an auxiliary notion:

**Definition 4.2.** We say that \( a \) \( s \)-reduces to zero modulo \( G \) if, and only if, there exists \( b \) such that \( a \rightarrow^* r_1 r_2 G b \) and \( b = 0 \), i.e., \( b \) is a syzygy. Just as for \( s \)-reduction, we will also use the phrases singular and regular \( s \)-reduction to zero, if \( a \rightarrow r_1 r_2 G b \) or \( a \rightarrow^* r_1 r_2 G b \), respectively.

Note that even though we use the word ‘zero’ in Definition 4.2 it does not mean that \( b \) itself has to be 0, only that it must be a syzygy. This terminology is taken from Eder and Faugère (2017).

In the non-signature world, a Gröbner basis is a set \( G \subseteq R \) such that every \( p \in \langle G \rangle \) can be reduced to 0 modulo \( G \). This definition can be translated readily into the signature-based setting:

**Definition 4.3 (Signature Gröbner Basis).** Let \( u \) be a term. A set \( G \subseteq R^m \) is a signature Gröbner basis in \( u \) if, and only if, every \( a \in R^m \) with \( s(a) = u \) \( s \)-reduces to zero modulo \( G \).

The set \( G \) is a signature Gröbner basis up to \( u \) if it is a signature Gröbner basis in all \( v \prec u \). If \( G \) is a signature Gröbner basis in all terms, we simply call it a signature Gröbner basis.

Translating Definitions 4.2 and 4.3 into Isabelle/HOL is again immediate; the only real differences are some \( R^m \) conditions, as usual:

**Definition sig-red-zero:**

\( (\tau \Rightarrow \tau \Rightarrow \text{bool}) \Rightarrow (\tau \Rightarrow \text{bool}) \Rightarrow (\tau \Rightarrow \text{bool}) \Rightarrow \text{bool} \)

where \( \text{sig-red-zero} r_1 G a \leftarrow\rightarrow (\exists b. (\text{sig-red} r_1 (\leq G) b \wedge \text{poly} b = 0)) \)

**Definition is-sig-GB-in:**

\( (\tau \Rightarrow \text{bool}) \Rightarrow \tau \Rightarrow \text{bool} \)

where \( \text{is-sig-GB-in} G u \leftarrow\rightarrow (\forall a. s a = u \rightarrow a \in R^m \rightarrow \text{sig-red-zero} (\leq G) a) \)

**Definition is-sig-GB-up:**

\( (\tau \Rightarrow \text{bool}) \Rightarrow (\tau \Rightarrow \text{bool}) \)

where \( \text{is-sig-GB-up} G u \leftarrow\rightarrow (G \subseteq R^m \wedge (\forall v. v \prec u \rightarrow \text{snd} v < \text{length} fs \rightarrow \text{is-sig-GB-in} G v)) \)
Please note that \texttt{sig-red-zero} is only parameterized over the relation \( r_1 \) for signatures, but not over \( r_2 \) for leading power-products: there is no need to distinguish between top/tail/arbitrary \( s \)-reductions to zero.

The connection between signature Gröbner bases and ordinary non-signature Gröbner bases follows immediately from the definition of \( s \)-reduction:

**Proposition 4.1.** Let \( G \subseteq \mathbb{R}^m \) be a signature Gröbner basis. Then \( G \) is a Gröbner basis of \( \langle f_1, \ldots, f_m \rangle \).

Signature-based Gröbner basis algorithms, such as \( F_5 \), compute rewrite bases, which are a subclass of signature Gröbner bases (see Section 5). Proposition 4.1 tells us that from a signature Gröbner basis one can easily obtain a Gröbner basis of the ideal \( \langle f_1, \ldots, f_m \rangle \) under consideration by applying the module-homomorphism \( \pi \) to all elements.

The formalization of Proposition 4.1 looks as follows, where \texttt{is-Groebner-basis} is defined in Immler and Maletzky (2016):

\begin{verbatim}
lemma is-sig-GB-is-Groebner-basis:
assumes G ⊆ Rm and ∀u. is-sig-GB-in G u
shows is-Groebner-basis (poly G)
\end{verbatim}

The next result about signature Gröbner bases will prove very useful later on, for instance in Lemma 4.3. Readers interested in its proof are referred to Lemma 3 in Roune and Stillman (2012).

**Lemma 4.2.** Let \( a, b \in \mathbb{R}^m \setminus \{0\} \), let \( G \) be a signature Gröbner basis up to \( s(a) \), and assume \( s(a) = s(b) \) and \( \text{lc}(a) = \text{lc}(b) \).

1. If both \( a \) and \( b \) are regular top \( s \)-irreducible modulo \( G \), then \( \text{lp}(\pi(a)) = \text{lp}(\pi(b)) \) and \( \text{lc}(\pi(a)) = \text{lc}(\pi(b)) \).
2. If both \( a \) and \( b \) are regular \( s \)-irreducible modulo \( G \), then \( a = b \).

In the formalization this lemma is split into two lemmas:

\begin{verbatim}
lemma sig-regular-top-reduced-lp-lc-unique:
assumes is-sig-GB-upt G (s a) and a ∈ Rm and b ∈ Rm
and s a = s b and lc a = lc b
and ¬ is-sig-red (<s) (≡) G a and ¬ is-sig-red (<s) (≡) G b
shows lp (poly a) = lp (poly b) and lc (poly a) = lc (poly b)
\end{verbatim}

\begin{verbatim}
lemma sig-regular-reduced-unique:
assumes is-sig-GB-upt G (s a) and a ∈ Rm and b ∈ Rm
and s a = s b and lc a = lc b
and ¬ is-sig-red (<s) (≤) G a and ¬ is-sig-red (<s) (≤) G b
shows poly a = poly b
\end{verbatim}

We conclude this section by introducing the concept of a syzygy signature and proving an important lemma about it:

**Definition 4.4 (Syzygy Signature).** A term \( u \) is called a syzygy signature if there exists \( a \in \mathbb{R}^m \setminus \{0\} \) with \( s(a) = u \) and \( \pi = 0 \).
Syzygy signatures play a key role for detecting useless zero-reductions when computing signature Gröbner bases. Namely, by virtue of Lemma 4.2 we obtain the following result whose importance will become clear in Section 5:

**Lemma 4.3 (Syzygy Criterion).** Let $a \in \mathbb{R}^m$ and let $G$ be a signature Gröbner basis up to $s(a)$. If $s(a)$ is a syzygy signature, then a regular $s$-reduces to zero modulo $G$.

Moreover, if $u$ is a syzygy signature and $u \mid v$, then $v$ is a syzygy signature, too.

Definition 4.4 and Lemma 4.3 naturally translate into Isabelle/HOL:

```isa humane
definition is-syz-sig :: \tau \Rightarrow bool
where is-syz-sig u \longleftrightarrow (\exists a \in \mathbb{R}^m. a \neq 0 \land s a = u \land \poly a = 0)
```

```isa humane
lemma syzygy-crit:
assumes is-sig-GB-upt G (s a) and is-syz-sig G (s a) and a \in \mathbb{R}^m
shows sig-red-zero (\prec_t) G a
```

```isa humane
lemma is-syz-sig-dvd:
assumes is-syz-sig u and u dvd v
shows is-syz-sig v
```

5. Rewrite Bases and S-Pairs

Besides signature Gröbner bases, we need another class of sets $G \subseteq \mathbb{R}^m$ of module elements, called rewrite bases. Rewrite bases play a crucial role for computing signature Gröbner bases, as will be seen in Section 6. Before, however, we must introduce some auxiliary concepts: sig-poly-pairs, rewrite orders and canonical rewriters.

**Definition 5.1 (Sig-Poly-Pair).** A sig-poly-pair is a pair $(u, p) \in \tau \times \mathbb{R}$ such that there exists $a \in \mathbb{R}^m \setminus \{0\}$ with $s(a) = u$ and $\overline{a} = p$.

Our definition of rewrite orders is slightly more technical than the one given in the literature. The reason for this deviation is that there, rewrite orders are defined for module elements rather than sig-poly-pairs. We found it more reasonable to define rewrite orders on sig-poly-pairs, because in any case the only information concrete rewrite orders may take into account for deciding which of the two arguments is greater are the signatures and the polynomial parts of the arguments.

**Definition 5.2 (Rewrite Order).** A binary relation $\preceq$ on sig-poly-pairs is called a rewrite order if, and only if, it is a reflexive, transitive and linear relation, additionally satisfying

1. $(u, p) \preceq (v, q) \land (v, q) \preceq (u, p) \Rightarrow u = v$ for all sig-poly-pairs $(u, p)$ and $(v, q)$, and
2. $a \in G \setminus \{0\} \land b \in G \setminus \{0\} \land s(a) | s(b) \Rightarrow (s(a), \overline{a}) \preceq (s(b), \overline{b})$ for all $a, b, G$ such that $G$ is a signature Gröbner basis up to $s(b)$ and $b$ is regular top $s$-irreducible modulo $G$.

---

$u \mid v$, for two terms $u$ and $v$, means that there exists $t \in [X]$ with $v = t u$. 

14
The last condition essentially expresses that $\preceq$ shall refine the divisibility relation on signatures—but only under some technical assumptions which are necessary for proving that $\preceq_{\text{rat}}$ (Definition 5.3) is indeed a rewrite order.

To get some intuition about rewrite orders, we present the two ‘standard’ rewrite orders that can be found in the literature:

**Definition 5.3 ($\preceq_{\text{rat}}$, $\preceq_{\text{add}}$).** The relation $\preceq_{\text{rat}}$ is defined as

$$(u,p) \preceq_{\text{rat}} (v,q) :\iff \text{lp}(q)u \prec \text{lp}(p)v \vee (\text{lp}(q)u = \text{lp}(p)v \land u \preceq v).$$

The relation $\preceq_{\text{add}}$ is defined as

$$(u,p) \preceq_{\text{add}} (v,q) :\iff u \preceq v.$$

As explained in Remark 7.3 in Eder and Faugère (2017), the suffix ‘rat’ of $\preceq_{\text{rat}}$ originates from an alternative presentation of this relation, in which the ratios $\frac{u}{\text{lp}(p)}$ and $\frac{v}{\text{lp}(q)}$ are compared.

Above we claimed that $\preceq_{\text{rat}}$ and $\preceq_{\text{add}}$ are rewrite orders. The proof for $\preceq_{\text{add}}$ is fairly straightforward, but the proof of the last requirement of rewrite orders is a bit more involved for $\preceq_{\text{rat}}$: one essentially has to make use of Lemma 4.2 again.

The definition of rewrite orders in the formalization closely resembles Definition 5.2; only note that $\text{spp-of}(a)$ is a mere abbreviation for $(s(a),\text{poly}(a))$:

**definition** is-rewrite-ord :: (((τ x (α ⇒ β)) ⇒ (τ x (α ⇒ β))) ⇒ bool) ⇒ bool

where is-rewrite-ord ord $\longleftrightarrow$

(\text{reflp ord} \land \text{transp ord} \land (\forall a b. \text{ord a b v ord b a}) \land
(\forall a b. \text{ord a b} \rightarrow \text{ord b a} \rightarrow \text{fst a} = \text{fst b}) \land
(\forall G a b. \text{is-sig-GB-upt} G (s b) \rightarrow a \in G \rightarrow b \in G \rightarrow
a \neq 0 \rightarrow b \neq 0 \rightarrow s \text{ dvd } s) \rightarrow
\neg \text{is-sig-red (<s>)} (\neg) G b \rightarrow \text{ord} (\text{spp-of} a) (\text{spp-of} b))

Since there is nothing special about the formal definitions of $\preceq_{\text{rat}}$ and $\preceq_{\text{add}}$ compared to the informal ones, we omit them here.

Just as we have implicitly fixed $\preceq$ and $\preceq_{\text{rat}}$, let us now also fix an arbitrary rewrite order $\preceq$. The last prerequisite we need before we can define rewrite bases are **canonical rewriters**:

**Definition 5.4 (Canonical Rewriter).** Let $G \subseteq \mathcal{M}$, $a \in \mathcal{M}$ and $u \in \mathcal{T}$. The module element $a$ is called a **canonical rewriter** in signature $u$ w.r.t. $G$ if, and only if, $a \in G \setminus \{0\}$, $s(a) \mid u$, and $a$ is maximal w.r.t. $\preceq$ with these properties:

**Definition 5.5 (Rewrite Basis).** Let $G \subseteq \mathcal{M}$ and $u \in \mathcal{T}$. The set $G$ is said to be a **rewrite basis** in $u$ if, and only if, $u$ is a syzygy signature or there exists a canonical rewriter $g$ in signature $u$ w.r.t. $G$ such that $\frac{u}{g}$ is regular top $s$-irreducible modulo $G$.\(^3\)

Furthermore, $G$ is a rewrite basis up to $u$ if it is a rewrite basis in all $v \prec u$. If $G$ is a rewrite basis in all terms, we simply call it a rewrite basis.

---

\(^2\)By abuse of notation we also compare module elements in $\mathcal{M}$ w.r.t. $\preceq$, in the sense that $a \preceq b \iff (s(a),\overline{a}) \preceq (s(b),\overline{b})$.

\(^3\)For two terms $u, v$ with $u \mid v$, $\overline{t}$ denotes the unique $t \in [X]$ with $v = t u$. 

15
The definitions of canonical rewriters and rewrite bases translate naturally into in Isabelle/HOL; note in particular the parallels between the definitions of \( \text{is-sig-GB-up} \) and \( \text{is-RB-up} \):

**Definition** \( \text{is-canon-rewriter} :: \tau \Rightarrow 0 \beta \) set \( \Rightarrow \tau \Rightarrow 0 \beta \) \( \Rightarrow \) bool

where \( \text{is-canon-rewriter} \ G \ u \ a \leftarrow (a \in G \land a \neq 0 \land s \ a \ \text{dvd} \ u \land \forall g \in G. g \neq 0 \rightarrow s \ g \ \text{dvd} \ u \rightarrow \text{spp-of} \ g \ \subseteq \text{spp-of} \ a)) \)

**Definition** \( \text{is-RB-in} :: \tau \Rightarrow 0 \beta \) set \( \Rightarrow \tau \Rightarrow \) bool

where \( \text{is-RB-in} \ G \ u \leftarrow (\text{is-syz-sig} u \lor (\exists g. \text{is-canon-rewriter} G u g \land \neg \text{is-sig-red} (\prec) (\sim) G \ (\text{monom-mult} 1 (u / s \ g) g))) \)

**Definition** \( \text{is-RB-up} :: \tau \Rightarrow 0 \beta \) set \( \Rightarrow \tau \Rightarrow \) bool

where \( \text{is-RB-up} \ G \ u \leftarrow (G \subseteq Rm \land (\forall v. v \prec \ u \rightarrow \text{snd} \ v < \text{length} \ fs \rightarrow \text{is-RB-in} \ G \ v)) \)

Now that we know what rewrite bases are it is time to establish the connection between rewrite bases and signature Gröbner bases, and hence to traditional Gröbner bases by virtue of Proposition 4.1. For an informal proof of the following proposition, see Lemma 8 in Eder and Roune (2013):

**Proposition 5.1.** If \( G \) is a rewrite basis up to \( u \) it is also a signature Gröbner basis up to \( u \).

We omit the obvious translation of this proposition into Isabelle/HOL. Summarizing, Propositions 4.1 and 5.1 justify computing a rewrite basis in order to find a traditional Gröbner basis of \( \langle f_1, \ldots, f_m \rangle \). Therefore, we now need a means for actually computing rewrite bases—and it turns out that the key to an effective algorithm lies in a concept well-known from traditional Gröbner bases theory:

**Definition 5.6 (S-Pair).** Let \( a, b \in \mathbb{R}^m \), and let \( t = \text{lcm}(\text{lp}(\overrightarrow{a}), \text{lp}(\overrightarrow{b})) \). Then the S-pair of \( a \) and \( b \), written \( \text{spair}(a, b) \), is defined as

\[
\text{spair}(a, b) := \frac{t}{\text{lcm}(\text{lp}(\overrightarrow{a}))} a - \frac{t}{\text{lcm}(\text{lp}(\overrightarrow{b}))} b.
\]

Furthermore, \( a \) and \( b \) are said to give rise to a regular S-pair if, and only if, \( \overrightarrow{a}, \overrightarrow{b} \neq 0 \) and \( \frac{t}{\text{lp}(\overrightarrow{a})} \text{sp}(a) \neq \frac{t}{\text{lp}(\overrightarrow{b})} \text{sp}(b) \); otherwise they give rise to a singular S-pair.

So, S-pairs correspond precisely to S-polynomials, but ‘lifted’ from \( \mathbb{R} \) to \( \mathbb{R}^m \): indeed, \( \text{spair}(a, b) \in \mathbb{R}^m \), and it is easy to see that \( \text{spair}(a, b) = \text{spoly}(\overrightarrow{a}, \overrightarrow{b}) \), where \( \text{spoly}(p, q) \) is the usual S-polynomial of \( p \) and \( q \).

The distinction between singular and regular S-pairs is important, because in Theorem 5.1 below we will show that only regular S-pairs are of interest. If \( a \) and \( b \) give rise to a regular S-pair, we have \( \text{sp}(\text{spair}(a, b)) = \text{max}(\overrightarrow{\text{sp}(a)}, \overrightarrow{\text{sp}(b)}) \), where \( t \) is as in Definition 5.6.

The definitions of S-pairs and regular S-pairs in the formalization look as follows:
definition \( \text{spair} :: (\tau \Rightarrow 0^\beta) \Rightarrow (\tau \Rightarrow 0^\beta) \Rightarrow (\tau \Rightarrow 0^\beta) \)

where \( \text{spair} a b = (\text{let} \ t1 = \text{lpc} (\text{poly} a); \ t2 = \text{lpc} (\text{poly} b); \ t = \text{lcm} t1 t2 \text{ in} \)

\[
\begin{align*}
\text{monom-mult} \left( \frac{1}{\text{lc} (\text{poly} a)} \right) \left( \frac{t}{t1} \right) a - \\
\text{monom-mult} \left( \frac{1}{\text{lc} (\text{poly} b)} \right) \left( \frac{t}{t2} \right) b
\end{align*}
\]

definition \( \text{is-regular-spair} :: (\tau \Rightarrow 0^\beta) \Rightarrow (\tau \Rightarrow 0^\beta) \Rightarrow \text{bool} \)

where \( \text{is-regular-spair} a b \leftrightarrow (\text{poly} a \neq 0 \land \text{poly} b \neq 0 \land \)

\[
\begin{align*}
(\text{let} \ t1 = \text{lpc} (\text{poly} a); \ t2 = \text{lpc} (\text{poly} b); \ t = \text{lcm} t1 t2 \text{ in} \\
\left( \frac{t}{t1} \right) \otimes s a \neq \left( \frac{t}{t2} \right) \otimes s b)
\end{align*}
\]

Now we are ready to state the central theorem in this section, which links rewrite bases to regular \( S \)-pairs just as Buchberger’s theorem links Gröbner bases to S-polynomials:

**Theorem 5.1.** Let \( G \subseteq \mathbb{R}^m \) be finite and \( u \in \Sigma \), assume that no two elements of \( G \) have the same signatures, and moreover assume that \( G \) is a rewrite basis in all \( s(a) \prec_t u \), where \( a \) is either a regular \( S \)-pair of elements of \( G \) or \( a = e_i \ (1 \leq i \leq m) \). Then \( G \) is a rewrite basis up to \( u \).

For a proof of this theorem see Lemma 10 in [Eder and Roune (2013)](https://example.com). The formal statement of the theorem in Isabelle/HOL is as follows:

**Lemma is-RB-upt-finite:**

\[\text{assumes } G \subseteq \mathbb{R}^m \text{ and inj-on s G and finite G} \]

\[\text{and } \forall g1 \in G. \forall g2 \in G. \text{is-regular-spair} \ g1 \ g2 \rightarrow s \ (\text{spair} g1 \ g2) \prec_t u \rightarrow \]

\[\text{is-RB-in G} \ (s \ (\text{spair} g1 \ g2)) \]

\[\text{and } \forall i. \ i < \text{length} \ fs \rightarrow (1, i) \prec_t u \rightarrow \text{is-RB-in G} \ (1, i) \]

\[\text{shows is-RB-upt G u} \]

The second assumption of **is-RB-upt-finite** merely expresses that the function \( s \) is injective on \( G \), that is, no two elements of \( G \) have the same signatures.

Theorem 5.1 gives us some idea how to decide whether a given finite set \( G \) is a rewrite basis up to \( u \): it suffices to check the **finitely many** signatures of regular \( S \)-pairs and canonical basis vectors. Note, however, that there is still an issue related to syzygy signatures: the definition of rewrite bases involves syzygy signatures, and deciding whether a given \( u \) is a syzygy signature is a difficult problem—actually, as difficult as computing a Gröbner basis of the module of syzygies. Luckily, Theorem 5.1 does not only suggest a method for (semi-)deciding whether a given set is a rewrite basis, but it also gives rise to an algorithm for computing rewrite bases which does not suffer from the problem with syzygy signatures just outlined. This algorithm is the subject of the next section.

**6. Algorithms**

As claimed above, Theorem 5.1 gives rise to an algorithm for computing rewrite bases, and in fact that algorithm bears close resemblance to Buchberger’s algorithm for computing Gröbner bases: it is a critical-pair/completion algorithm that successively iterates through all \( S \)-pairs, applies a criterion for testing whether the \( S \)-pair under consideration must be reduced, \( s \)-reduces it to some normal form if necessary, and adds the result to the basis computed so far unless it be zero. Algorithm 1 summarizes the
Algorithm 1: An algorithm for computing rewrite bases.

Input: sequence \((f_1, \ldots, f_m)\) of polynomials in \(R\), admissible order \(\preceq\) on \([X]\), compatible extension \(\preceq_t\) on \(T\), rewrite order \(\preceq\)

Output: rewrite basis \(G\)

1: function RB((\(f_1, \ldots, f_m\)), \(\preceq\), \(\preceq_t\), \(\preceq\))
2: \(G \leftarrow \emptyset\)
3: \(S \leftarrow \{s(f_j e_i - f_i e_j) \mid 1 \leq i < j \leq m\}\)
4: \(P \leftarrow \{e_i \mid 1 \leq i \leq m\}\)
5: while \(P \neq \emptyset\) do
6: \(a \leftarrow\) some element of \(P\) with \(\preceq_t\)-minimal signature
7: \(P \leftarrow P \setminus \{a\}\)
8: if \(a = e_i\) for some \(i\) then
9: \(S \leftarrow S \cup \{s(f_i g - g e_i) \mid g \in G\}\)
10: if \(\neg \text{sigCrit}(\preceq, G, S, a)\) then
11: \(b \leftarrow\) result of regular \(s\)-reducing \(a\) modulo \(G\)
12: if \(\overline{b} = 0\) then
13: \(S \leftarrow S \cup \{s(b)\}\)
14: else
15: \(G \leftarrow G \cup \{b\}\)
16: \(P \leftarrow P \cup \{\text{spair}(g, b) \mid g \in G, \text{spair}(g, b) \text{ is regular}\}\)
17: return \(G\)

method just sketched in an imperative programming style; it is a slight variation of Algorithm 3 in Eder and Faugère (2017).

Several remarks on Algorithm 1 are in place:

- The accumulator \(G\) holds the basis computed so far, and \(P\) is the set of elements that still have to be considered. It does not only contain regular \(S\)-pairs, but also the \(m\) canonical basis vectors corresponding to the input-sequence \((f_1, \ldots, f_m)\).
  This justifies initializing \(G\) by the empty set.

- The set \(S\) contains the signatures of some known syzygies. It is initialized by the signatures of the Koszul syzygies of the input sequence, and successively enlarged in Lines 9 and 13. These syzygy-signatures are used to apply the syzygy criterion (Lemma 4.3) in function \(\text{sigCrit}\), see Algorithm 2 below.

- It is important to note that in Line 6 of Algorithm 1 an element \(a\) with minimal signature is taken from \(P\). This is crucial for the correctness of the algorithm, since a different choice could lead to wrong results.

- Also note that \(s(b) = s(a)\), since \(b\) is the result of regular \(s\)-reducing \(a\), and regular \(s\)-reductions do not change signatures. This, together with the particular choice of \(a\), implies that \(G\) is computed by increasing signatures, i.e., the signatures of the elements \(b\) added to \(G\) in Line 15 are increasing.

Ignoring the \(\text{sigCrit}\)-test in Line 10 of Algorithm 1 for the moment, the algorithm is partially correct. This follows from the fact that either \(\overline{b} = 0\), in which case \(s(b) = s(a)\)
is a syzygy signature, or $b$ is added to $G$, in which case it becomes the canonical rewriter in $s(b) = s(a)$ (this follows from the definition of rewrite orders) and is by construction regular top $s$-irreducible. Therefore, in either case the potentially enlarged set $G$ is a rewrite basis in $s(a)$ by Definition 5.5 and upon termination of the algorithm, it is a rewrite basis in all terms $u$ thanks to Theorem 5.4.

The auxiliary function $\text{sigCrit}$, which is implemented in Algorithm 2, tests whether an $S$-pair $\text{spair}(a, b)$ has to be $s$-reduced in Algorithm 1. In a nutshell, it applies Lemma 4.3, the syzygy criterion, and moreover checks whether the constituents of the $S$-pair are canonical rewriters in certain terms $u_a$ and $u_b$; if not, the $S$-pair does not have to be reduced, because either the canonical rewriters in these respective terms have been treated already, or will still be treated later on, and in either case there is nothing to be done for $\text{spair}(a, b)$. There is one subtle point, though: Knowing that $\text{spair}(a, b)$ is regular, one of $u_a$ or $u_b$ is strictly greater than the other by definition, and $s(\text{spair}(a, b)) = \max(u_a, u_b)$. W.l.o.g. assume $u_b \prec_u u_a$. So, by what has been said above, it should be clear that $\text{sigCrit}$ is allowed to do the checks on $u_a = s(\text{spair}(a, b))$ in Line 5 of Algorithm 2, but it is perhaps not clear why the same checks may also be performed on the smaller term $u_b$ that does not contribute to $s(\text{spair}(a, b))$ at all. Indeed, answering this question is slightly intricate, and we confine ourselves here to pointing the interested reader to Lemma 12 in Eder and Roune (2013) for an explanation.

Algorithm 2 An algorithm for testing whether $S$-pairs must be regular $s$-reduced.

**Input:** rewrite order $\preceq$, $G \subseteq \mathbb{N}^m$, $S \subseteq \mathcal{X}$, regular $\text{spair}(a, b)$ with $a, b \in G$

**Output:** ‘False’ if $\text{spair}(a, b)$ has to be regular $s$-reduced in Algorithm 1

1: function $\text{sigCrit}(\preceq, G, S, \text{spair}(a, b))$
2: $t \leftarrow \text{lcm}(\text{lcp}(a), \text{lcp}(b))$
3: $u_a \leftarrow \frac{t}{\text{lcp}(a)}s(a)$
4: $u_b \leftarrow \frac{t}{\text{lcp}(b)}s(b)$
5: if $(\exists s \in S. s | u_a) \vee (a \text{ is not canonical rewriter in } u_a \text{ w.r.t. } G)$ then
6: return True
7: if $(\exists s \in S. s | u_b) \vee (b \text{ is not canonical rewriter in } u_b \text{ w.r.t. } G)$ then
8: return True
9: return False

We hope we could convince the reader about the partial correctness of Algorithms 1 and 2 now; if not, a more thorough account on the whole subject can, as usual, be found in Eder and Faugère (2017). However, the algorithm is not only partially correct, but also terminates for every input; this claim will be investigated in Section 6.1. We summarize the result in a theorem:

**Theorem 6.1** (Correctness of Algorithm 1). For every input, Algorithm 1 terminates and returns a rewrite basis $G$ w.r.t. $(f_1, \ldots, f_m)$, $\preceq$, $\succeq$ and $\preceq$. Furthermore, $(G) = (f_1, \ldots, f_m)$.

**Remark 6.1.** Algorithm 2 corresponds to Algorithm 4 in Eder and Faugère (2017), which, however, is presented in a slightly different way. Namely, the two disjuncts in Lines 5 and 7 of Algorithm 2 are combined into one single ‘rewritability’ check in the cited article. This makes the formulation of the algorithm a bit more elegant.
Also, one has to take into account that the last argument of function \texttt{sigCrit} could be a canonical basis vector \( e_i \) rather than an S-pair. In that case, only the syzygy criterion is applied, i.e., \( \exists s \in S. s \mid e_i \).

Let us now turn to the formalization of RB in Isabelle/HOL. There, it is natural to implement functions as \textit{functional} programs instead of imperative ones, so we define the tail-recursive function \texttt{rb-aux} for computing rewrite bases as follows:

\begin{verbatim}
function rb-aux ::
  (((\tau \Rightarrow \beta) list \times \tau list \times ((\tau \Rightarrow \beta) \times (\tau \Rightarrow \beta)) list \times \text{nat}) list) \times \text{nat}
where
  rb-aux ((gs, ss, []), z) = ((gs, ss, []), z) |
  rb-aux ((gs, ss, a # ps'), z) = 
    (let ss' = new-syz-sigs ss gs a in
     if sig-crit gs ss' a then
      rb-aux ((gs, ss', ps'), z) 
     else 
     let b = sig-trd gs (poly-of-pair a) in
     if poly b = 0 then
      rb-aux ((gs, (s b) # ss', ps'), Suc z) 
     else
      rb-aux ((b # gs, ss', add-spairs ps' gs b), z))
\end{verbatim}

The function takes one argument, which in turn is a tuple consisting of four entries: a list \( gs \) corresponding to the set \( G \) in Algorithm 1, a list \( ss \) corresponding to \( S \), a list \( ps \) corresponding to \( P \), and a natural number \( z \) counting the total number of zero-reductions. The latter is a mere technicality only needed in Section 7.1, and may thus be ignored for the moment. The function not only returns \( gs \), but also the other arguments, to facilitate formal reasoning about it—but of course only \( gs \) is interesting from our perspective. Please note that the list \( fs \) and the various relations (\( \preceq \), etc.) are still implicitly fixed in the theory context and therefore do not have to be passed as arguments to \texttt{rb-aux} explicitly.

The first part of the definition corresponds to the base case, where the list \( ps \) is empty. The second part corresponds to the case where \( ps \) contains at least one element, and can hence be decomposed into its head \( a \) and tail \( ps' \). Since we ensure that the list is always kept sorted by increasing signatures, \( a \) is known to be an element with minimal signature, just as required in Line 6 of Algorithm 1. Then, \( ss \) is enlarged by new syzygy-signatures in the auxiliary function \texttt{new-syz-sigs}, and the result is stored in \( ss' \); this corresponds precisely to Lines 8 and 9 of Algorithm 1. Afterward, the auxiliary function \texttt{sig-crit} is applied to \( gs, ss' \) and \( a \) to check whether \( a \) has to be \( s \)-reduced or not. \texttt{sig-crit} is the formalization of function \texttt{sigCrit}, and since there is nothing special about its definition, we omit it here. Anyway, if \texttt{sig-crit} returns \texttt{True}, nothing needs to be done and \texttt{rb-aux} is called recursively on the remaining list \( ps' \). Otherwise, \( a \) is regular \( s \)-reduced to \( b \) (taken care of by function \texttt{sig-trd}), and depending on whether \( b \) is a syzygy or not its signature is added to \( ss' \) or it is added to \( gs \), and new S-pairs are added to \( ps' \) by function \texttt{add-spairs}. So, in short, \texttt{rb-aux} corresponds exactly to Lines 5-17 of Algorithm 1. The remaining lines, corresponding to the initialization of \( G, S \) and \( P \), are covered by the way how the arguments of the initial call of \texttt{rb-aux} are constructed, as will be seen below.
Before, please note that the element-type of \( ps \) is a \textit{sum type}, i.e., the disjoint union of two types: once the type of pairs of module elements, \((\tau \Rightarrow_0 \beta) \times (\tau \Rightarrow_0 \beta)\), and once the type \texttt{nat} of natural numbers. This is due to the fact that \( ps \) may both contain S-pairs and canonical basis vectors: S-pairs are represented by the two elements they originate from, because these elements themselves are needed in \texttt{sig-crit}, and canonical basis vectors are compactly represented by their component, which is of course a natural number. Function \texttt{poly-of-pair} converts an object of this sum type into an actual module element of type \( \tau \Rightarrow_0 \beta \), by either constructing an S-pair or returning a ‘full’ basis vector.

The initial argument of \texttt{rb-aux} corresponds to the initial values of \( G, S \) and \( P \): \( gs \) is the empty list, \( ss \) is \texttt{Koszul-syz-sigs} \((fs)\), which returns the signatures of the Koszul syzygies of \( fs \), and \( ps \) is the list \( \text{map}(\text{Inr},[0.. \text{length} \( fs \)]) \), representing the canonical basis vectors in the sum type mentioned above.

So, we can finally define function \( rb \) as follows:

\[
\text{definition } rb :: (\tau \Rightarrow_0 \beta) \text{ list } \times \text{ nat} \\
\text{where } rb = (\text{let } ((gs, _, _), z) = \\
\quad \text{rb-aux } (([], \text{Koszul-syz-sigs } fs, \text{map } \text{Inr} \hspace{1pt} [0..\text{length } fs]), 0) \\
\quad \text{in } (gs, z))
\]

As can be seen, \( rb \) does not take any explicit arguments in the above definition, but it is implicitly parameterized over the constants fixed in the theory context \((fs, \preceq, \succeq, \preceq_t, \succeq_t)\).

In order to formally prove the correctness of \texttt{rb-aux}, and hence \( rb \), we define an invariant \texttt{rb-aux-inv} of function \texttt{rb-aux} that holds for the initial argument, is preserved in every recursive call, and is strong enough to infer the desired properties of \( rb \) from it. Since the precise definition of the invariant is fairly lengthy, we only informally summarize its key characteristics here. \( \texttt{rb-aux-inv}(gs, ss, ps) \) holds if

- the signatures of the elements of \( gs \) are strictly decreasing (note that new elements with larger signatures are added up front to \( gs \)),
- every element in \( gs \) stems from regular \( s \)-reducing an S-pair of elements coming later in \( gs \) (i.e., earlier during execution of the function), or from regular \( s \)-reducing a canonical basis vector,
- every element in \( gs \) is regular \( s \)-irreducible modulo the elements coming after it in \( gs \),
- every element of \( gs \) belongs to the set \( Rm \),
- \( gs \) does not contain syzygies,
- for every \( g \) in \( gs \), the elements coming after it in \( gs \) constitute a rewrite basis up to \( s(g) \),
- every element in \( ss \) is a syzygy signature,
- \( ps \) is sorted by increasing signatures,
- no element in \( ps \) has a signature which is strictly smaller than the signature of any element in \( gs \), and
• gs is a rewrite basis in all e_i which do not appear in ps any more, and similar for S-pairs.

The first three items are only needed for proving termination of rb-aux, see Section 6.1. This list is not exhaustive; it is only meant to give an impression of how challenging it is to prove correctness of rb-aux and rb in a formal environment. In absolute figures, the whole proof, distributed across several lemmas, takes roughly 1800 lines of Isabelle code—not counting the proofs of the necessary theoretical results shown in previous sections, like is-RB-upt-finite. The claim that the invariant is preserved in the third recursive call of rb-aux turns out have the most difficult proof:

lemma rb-aux-inv-preserved-3:
fixes gs ss a ps
defines ss' ≡ new-syz-sigs ss gs a
defines b ≡ sig-trd gs (poly-of-pair a)
assumes rb-aux-inv (gs, ss, a # ps) and ¬ sig-crit gs ss' a and poly b ≠ 0
shows rb-aux-inv (b # gs, ss', add-spairs ps gs b)

After having proved that rb-aux-inv holds for the initial argument of rb-aux and is preserved in each of the three recursive calls, and that rb-aux terminates (see Section 6.1), we can infer the following two key properties of rb which correspond to Theorem 6.1:

theorem rb-is-RB-upt: is-RB-upt (set (fst rb)) u

theorem ideal-rb-aux: ideal (poly /grave.ts1 set (fst rb)) = ideal (set fs)

Remark 6.2. Algorithm and function rb could easily be adapted to not only compute a rewrite basis, and hence Gröbner basis of the ideal ⟨f_1, . . . , f_m⟩, but also a Gröbner basis of the module of syzygies of (f_1, . . . , f_m). We do not consider this in the formalization, though.

6.1. Termination

Termination of the original F_5 algorithm had been an open problem for a long time, until it was eventually settled by Galkin (2012). Later, Pan et al. (2012) proved termination of a more general signature-based algorithm, which happens to be equivalent to Algorithm 1. The proof we modeled our formal Isabelle-proof after can be found in Eder and Roune (2013) (Theorem 20). Here, we present the key ideas of the proof, referring the interested reader to the cited article for more information about it.

Assume (g_1, g_2, g_3, . . . ) is the sequence of elements added to G by Algorithm 1 in that order. We want to show that this sequence is finite. First, introduce the following relation ∼ on R^m: a ∼ b :⇔ lp(b)g(a) = lp(a)g(b). ∼ is an equivalence relation, and therefore allows one to partition the sequence into subsets of equivalent elements w.r.t. ∼. Next, one can prove that only finitely many of these subset are non-empty, using Noetherianity of R^m and further properties of the sequence that follow from its being constructed by Algorithm 1 e.g., no element is regular σ-reducible by the others. Finally, one can prove by induction on the finitely many non-empty sets R that each of them is finite, because every element of R corresponds to an S-pair of elements in ‘previous’ sets, which are finite by the induction hypothesis. This concludes the proof.
Remark 6.3. Readers not so familiar with signature-based algorithms might wonder why the well-known termination proof of Buchberger’s algorithm does not work for signature-based algorithms. The reason is simple: a new element $b$ added to the basis is only regular $s$-irreducible, which unfortunately does not imply that $b$ is irreducible in the traditional sense of polynomial reduction. In particular, $\text{lp}(b)$ might even be divisible by $\text{lp}(g)$ for some $g$ in the current basis—something which cannot happen in Buchberger’s algorithm, which in turn is what the termination proof of Buchberger’s algorithm mainly rests upon.

In the formalization, the theorem needed for establishing termination of function $\text{rb-aux}$ is as follows:

lemma $\text{rb-termination}$:

\text{fixes } seq :: nat $\Rightarrow$ $(\tau \Rightarrow 0 \beta$)

\text{assumes } $\forall i. (\exists j. (\text{length fs}) s (seq i) = (0, j) \land \text{lp (poly (seq i))} \leq \text{lp (fs ! j)}) \vee$

$(\exists j k. \text{is-regular-spair (seq j) (seq k)} \land$

$s (seq i) = s (\text{spair (seq j) (seq k)}) \land$

$\text{lp (poly (seq i))} \leq \text{lp (poly (spair (seq j) (seq k)))})$

and $\forall i. \neg \text{is-sig-red (\land (seq _ i)) (seq _ i)}$

and range seq $\subseteq \text{Rm}$ and $\emptyset \notin \text{poly range seq}$

and $\forall i. \text{is-sig-GB-upt (seq _ i) (seq _ i)}$

shows False

So, we assume that there exists an infinite sequence $seq$ with the listed properties and derive a contradiction; hence, any such sequence must be finite. $seq$ is modeled as a function from the natural numbers to module elements of type $\tau \Rightarrow 0 \beta$, which means that the $i$-th element of $seq$ is simply $seq(i)$ and the set of all elements of $seq$ is $\text{range(seq)}$. A close inspection of the presumed properties of $seq$ reveals that they essentially correspond to the first six properties of $gs$ in the above list characterizing $\text{rb-aux-inv}$. The only real difference is that the order of the elements in $seq$ corresponds to the order in which they are generated by function $\text{rb-aux}$, which is the reversed order compared to $gs$. This explains why, for instance, the signatures in $seq$ must be strictly increasing, whereas in $gs$ they must be strictly decreasing.

From $\text{rb-termination}$ we can conclude that function $\text{rb-aux}$ terminates for all arguments satisfying the invariant $\text{rb-aux-inv}$, which in particular includes the initial argument specified by function $\text{rb}$. This finishes the proof of total correctness of $\text{rb}$.

7. Optimality Results

7.1. No Zero-Reductions

The original goal of signature-based algorithms is to detect and avoid as many useless zero-reductions as possible, and thus speed up the computation of Gröbner bases. Practical experience shows that this goal is indeed achieved (see Section 3), and theory even tells us that in some situations zero-reductions can be avoided altogether:

Theorem 7.1. Let $(f_1, \ldots, f_m)$ be a regular sequence and assume $\leq_t = \leq_{\text{pot}}$, i.e., $\leq_t$ is a POT-extension of $\leq$. Then Algorithm 3 does not $s$-reduce any element to zero, meaning that the test in Line 12 of that algorithm always yields ‘False’.
The proof of this celebrated result, which is presented as Corollary 7.1 in Eder and Faugère (2017), is actually not very difficult. It proceeds along the following lines: Using \( \preceq_{\text{pot}} \), the rewrite basis is computed incrementally, i.e., first for \( (f_1) \), then for \( (f_1, f_2) \), and so on. The sequence \( (f_1, \ldots, f_m) \) being regular implies that the only syzygies \( a \) satisfying \( s(a) = t \) for \( 1 \leq i \leq m \) and \( t \in [X] \), are in the module of principal syzygies of \( (f_1, \ldots, f_i) \) — a generating set of which is added to \( S \) in Line 9. However, every zero-reduction corresponds to precisely such a syzygy, and therefore is detected beforehand by the syzygy criterion implemented in function \texttt{sigCrit}. It should be observed that Eder and Faugère (2017) need the additional assumption that \( \preceq \) be either \( \preceq_{\text{rat}} \) or \( \preceq_{\text{add}} \). We do not need this assumption because of our slightly different implementation of function \texttt{sigCrit}.

The formalization of Theorem 7.1 in Isabelle/HOL begins with the definition of regular sequences:

\[
\text{definition } \text{is-regular-sequence} :: (\alpha \Rightarrow \beta) \text{ list } \Rightarrow \text{bool}
\]

\[
\text{where } \text{is-regular-sequence } fs 
\iff
(\forall j < \text{length } fs. \forall q. q \ast fs ! j \in \text{ideal } (\text{set } (\text{take } j fs)) \rightarrow q \in \text{ideal } (\text{set } (\text{take } j fs)))
\]

As can be seen, \text{is-regular-sequence} is a predicate on lists of polynomials. The definition avoids any reference to quotient rings by unfolding the definition of zero-divisors in such rings. Function \texttt{take(j, fs)} returns the list of the first \( j \) elements of \( fs \).

Proving that there are no zero-reductions in function \texttt{rb} obviously boils down to proving that the second case in the second part in the definition of \texttt{rb-aux} cannot occur. This means that whenever \texttt{sig-crit} fails to hold for some \( a \), the result of regularly \( s \)-reducing \( a \) cannot be a syzygy:

\[
\text{lemma } \text{rb-aux-inv2-no-zero-red:}
\]

\[
\text{assumes is-regular-sequence } fs \text{ and is-pot-ord}
\text{ and } \text{rb-aux-inv2 (gs, ss, a # ps) and } \neg \text{sig-crit gs (new-syz-sigs ss gs a) a}
\text{ shows poly (sig-trd gs (poly-of-pair a)) } \neq 0
\]

Here, \text{is-pot-ord} expresses the fact that the implicitly fixed order \( \preceq_1 \) is a POT-extension of \( \preceq \). The predicate \texttt{rb-aux-inv2} is a strengthened version of \texttt{rb-aux-inv}, which can also be proved to be an invariant of \texttt{rb-aux} if \( fs \) is a regular sequence and \text{is-pot-ord} holds. It additionally requires \( ss \) to contain all necessary syzygy-signatures, something which is not needed for proving correctness of \texttt{rb-aux} and hence is not encoded in \texttt{rb-aux-inv}.

As a consequence of \texttt{rb-aux-inv2-no-zero-red} and the fact that \texttt{rb-aux-inv2} holds for the initial argument of \texttt{rb-aux} as specified in \texttt{rb}, we can infer that indeed no zero-reductions take place. This result is formulated using the second return value, \( z \), of \texttt{rb}, which counts the total number of zero-reductions:

\[
\text{corollary } \text{rb-aux-no-zero-red:}
\]

\[
\text{assumes is-regular-sequence } fs \text{ and is-pot-ord}
\text{ shows snd rb } = 0
\]

7.2. Minimal Signature Gröbner Bases

Just as traditional Gröbner bases, signature Gröbner bases are not unique. Hence, we can define \textit{minimal} signature Gröbner bases as follows:
Definition 7.1 (Minimal Signature Gröbner Basis). A signature Gröbner basis is called minimal if, and only if, none of its elements is top \( s \)-reducible modulo the other elements.

Note that minimal signature Gröbner bases have nothing to do with minimal Gröbner bases in the usual sense: if \( G \) is a minimal signature Gröbner basis, then \( G \) is not automatically a minimal Gröbner basis, that is, there could exist \( p_1, p_2 \in G \) with \( p_1 \neq p_2 \) and \( \text{lp}(p_1) | \text{lp}(p_2) \). Nevertheless, minimal signature Gröbner bases deserve the name, since every ideal \( I \subseteq R^m \) has one unique minimal signature Gröbner basis \( G \), and moreover any other signature Gröbner basis \( H \) of \( I \) satisfies \( \{ s(g) \mid g \in G \} \subseteq \{ s(h) \mid h \in H \} \) and \( \{ \text{lp}(g) \mid g \in G \} \subseteq \{ \text{lp}(h) \mid h \in H \} \); see Lemma 4.3 in Eder and Faugère (2017) for details.

Surprisingly, when using \( \preceq_{\text{rat}} \) as the rewrite order, \( \text{rb-aux} \) automatically computes minimal signature Gröbner bases (recall from Proposition 5.1 that rewrite bases are also signature Gröbner bases). The following theorem corresponds to Corollary 7.3 in Eder and Faugère (2017):

Theorem 7.2. Assume \( \preceq = \preceq_{\text{rat}} \). Then the rewrite basis computed by Algorithm 1 is also a minimal signature Gröbner basis.

Therefore, \( \preceq_{\text{rat}} \) is the optimal rewrite order in terms of the size of the resulting basis and the number of S-pairs that must be dealt with. Still, as noted in point (c) of Section 14.3 in Eder and Faugère (2017), other rewrite orders, such as \( \preceq_{\text{add}} \), can lead to a comparable overall performance of the algorithm.

Again, Definition 7.1 and Theorem 7.2 translate naturally into Isabelle/HOL, as shown below:

\[
\text{definition \ is-min-sig-GB :: } (\tau \Rightarrow 0 \beta) \text{ set } \Rightarrow \text{bool} \\
\text{where \ is-min-sig-GB } G \leftarrow G \subseteq R_m \land (\forall u. \text{snd u < \text{length fs } } \Rightarrow \text{is-sig-GB-in G u}) \land (\forall g \in G. \neg \text{is-sig-red } (\preceq_{\text{t}}) (=) (G - \{g\}) g)
\]

\[
\text{corollary \ rb-aux-is-min-sig-GB:} \\
\text{assumes } (\preceq) = (\preceq_{\text{rat}}) \\
\text{shows is-min-sig-GB } (\text{set } (\text{fst } \text{rb}))
\]

8. Code Generation and Computations

When it comes to actually computing rewrite bases, the following two observations are important:

- Algorithm 1 and function \( \text{rb} \) operate on module elements in \( R^m \), or objects of type \( \tau \Rightarrow 0 \beta \), respectively. Operations on such objects, such as addition, multiplication, etc., are of course \( m \)-times more expensive than on ordinary polynomials in \( R \).
- A close investigation of said algorithms and their sub-algorithms, such as regular \( s \)-reduction, reveals that in fact only the signature \( s(a) \) and the polynomial part \( \overline{a} \) of module elements \( a \in R^m \) must be known for executing the algorithms. Therefore, the whole computation of rewrite bases can be made more efficient by letting the functions operate on sig-poly-pairs (see Definition 5.1) instead of full module elements.
In the formalization, we take the preceding observations into account by refining function \( rb \) and all other functions it depends on to new functions that operate on sig-poly-pairs, i.e., objects of type \( \tau \times (\alpha \Rightarrow 0 \beta) \). Of course, we formally prove that the refined functions behave precisely as the original ones and therefore inherit all their main properties. Eventually we end up with a function \( gb\text{-}sig \) that takes a list of polynomials as input, employs the refined version of \( rb\text{-}aux \) (called \( rb\text{-}spp\text{-}aux \)) for computing a rewrite basis of it, which is a list of sig-poly-pairs. Finally, it projects the elements of this list onto their second entries to obtain again a list of polynomials which constitute a Gröbner basis of the input. Furthermore, \( gb\text{-}sig \) is parameterized over \( \preceq \), \( \preceq_t \) and \( \preceq \).

Thanks to Isabelle’s code generator, the mechanically verified function \( gb\text{-}sig \) can be used to effectively compute Gröbner bases. In a nutshell, this works by translating the definitions of \( gb\text{-}sig \) and its sub-algorithms, which are universally quantified equalities in Isabelle/HOL, into operationally equivalent procedures operating on concrete data structures in SML, OCaml, Scala or Haskell. The translation is implemented in such a way that the generated executable programs can be trusted to inherit all correctness properties of the abstract Isabelle-functions. More information about code generation in Isabelle can be found in Haftmann et al. (2013); Haftmann and Bulwahn (2018).

In our concrete case, multivariate polynomials are represented efficiently as ordered (w.r.t. \( \preceq \)) associative lists, mapping power-products to coefficients. This formally verified concrete representation, which is part of Sternagel et al. (2010), allows us to provide efficient implementations of all frequently used operations, e.g., addition, \( lp \), etc.

A typical invocation of \( gb\text{-}sig \) within Isabelle, which automatically triggers code generation into SML and execution of the resulting program, could look as follows:

```
value [code] gb-sig-pprod (POT DRLEX) rw-rat-strict-pprod
   [X ^ 2 * Z ^ 3 + 3 * X ^ 2 * Y, X * Y * Z + 2 * Y ^ 2]
```

This instruction immediately returns the following 4-element Gröbner basis, computed over the field of rational numbers w.r.t. the POT extension of the degree-reverse-lexicographic ordering and rewrite order \( \preceq_{rat} \):

\[
(3 / 4) * X ^ 3 * Y ^ 2 - 2 * Y ^ 4, - 4 * Y ^ 3 * Z - 3 * X ^ 2 * Y ^ 2, X * Y * Z + 2 * Y ^ 2, X ^ 2 * Z ^ 3 + 3 * X ^ 2 * Y
\]

The auxiliary constants X, Y and Z are introduced for conveniently writing down trivariate polynomials; further indeterminates can easily be added on-the-fly, without even having to adapt the underlying type. More sample computations can be found in theory Signature-Examples of the formalization.

Besides simple examples as the one shown above, \( gb\text{-}sig \) can also be tested on common benchmark problems and compared to other implementations of Gröbner bases. Table 1 shows such a comparison to a formally verified implementation of Buchberger’s algorithm with product- and chain-criterion in Isabelle/HOL, called \( gb \) and described in Maletzky and Immler (2018a), and to function GroebnerBasis in Mathematica 11.3. Since this article is not meant as an exhaustive survey on the efficiency of different Gröbner basis algorithms, we confine ourselves here to present results of computations over the rationals w.r.t. the POT extension of the degree-reverse-lexicographic ordering and rewrite order \( \preceq_{rat} \). We shall emphasize, however, that other order relations and rewrite orders are formalized, too, and may hence be used in computations without further ado.

---

9The suffixes ‘-pprod’ are technical artifacts that can safely be ignored here.
Table 1: Timings (in seconds) and total number of zero-reductions of Gröbner basis computations. '?' indicates that the computation was aborted after 1200 seconds.

| Benchmark  | gb-sig Time | gb-sig #0-red | gb Time | gb #0-red | Mathematica Time |
|------------|-------------|----------------|---------|-----------|------------------|
| cyclic-5   | 0.1         | 0              | 0.1     | 79        | 0.0              |
| cyclic-6   | 2.0         | 8              | 186.2   | 517       | 0.3              |

| katsura-8  | 1005.4      | 0              | ?       | ?         | 42.0             |
| eco-9      | 3.0         | 0              | 24.2    | 685       | 2.8              |
| eco-10     | 32.0        | 0              | 255.7   | 1572      | 27.9             |
| eco-11     | 297.2       | 0              | ?       | ?         | 263.0            |
| noon-5     | 0.4         | 0              | 0.5     | 208       | 0.1              |
| noon-6     | 8.7         | 0              | 13.8    | 738       | 1.0              |
| noon-7     | 213.5       | 0              | 289.2   | 2467      | 12.4             |

Remark 8.1. The timings for Mathematica have to be read with care: Mathematica always computes a reduced Gröbner basis, whereas the results returned by gb-sig and gb are not necessarily reduced. So, the timings of Mathematica must be understood as a mere reference mark for highly sophisticated, state-of-the-art computer algebra software. It is not surprising that our formally verified function gb-sig cannot compete with it in most cases.

9. Conclusion

In this paper we presented a formalization of signature-based algorithms for computing Gröbner bases in Isabelle/HOL. The formalization is generic, executable, and covers not only correctness but also optimality (no zero-reductions, minimal signature Gröbner bases) of the implemented algorithms.

The formalization effort was roughly three months of full-time work. This might not sound very much, but it must once again be noted that we could make heavy use of existing formalizations of multivariate polynomials and modules thereof, as well as Gröbner bases theory, in Isabelle/HOL. Otherwise, it would have taken a lot longer. The total number of lines of code is $\sim 11440$, distributed over the five theories Prelims (general facts about lists, relations, etc.; $\sim 960$ lines), More-MPoly (general properties of polynomials; $\sim 440$ lines), Quasi-PM-Power-Products (facts about power-products; $\sim 290$ lines), Signature-Groebner (main theory; $\sim 9370$ lines) and Signature-Examples (code generation and sample computations; $\sim 380$ lines). Proofs are intentionally given in a quite verbose style for better readability.

9.1. Related Work

Even though signature-based algorithms have, to the best of our knowledge, not been formalized in any other proof assistant so far, formalizations of traditional Gröbner bases theory exist in various systems.

27
The first formalization of Gröbner bases dates back to Théry (2001) and Persson (2001) in the Coq proof assistant (Bertot and Castéran (2004)). Later, Schwarzweller (2006) formalized the purely theoretical aspects of the theory in Mizar (Bancerek et al. (2015)). Jorge et al. (2009) and Medina-Bulo et al. (2010) implemented formally verified versions of Buchberger’s algorithm in OCaml and Common LISP, respectively; the former was verified using Coq, and the latter using ACL2 (Kaufmann et al. (2000)). And, of course, the work presented in this paper heavily rests on the formalization of traditional Gröbner bases theory by Immler and Maletzky (2016) in Isabelle/HOL.

Buchberger (2004) and Crăciun (2008) took a slightly different approach: they managed to automatically synthesize Buchberger’s algorithm from a formal description of its specification in the Theorema system (Buchberger et al. (2016)). In the same system, we formalized a generalization of Gröbner bases to reduction rings (Maletzky (2016)).

Finally, it must also be mentioned that Gröbner bases methodology for a long time has been, and still is, successfully applied in automated theorem proving, as a black-box algorithm for proving universal equalities and inequations over algebraically closed fields; see for instance Harrison (2001) and Chaieb and Wenzel (2007).

9.2. Future Work

The present formalization could be extended in several ways. First of all, function gb-sig could be improved by inter-reducing intermediate bases when \( \leq \) is used as the module term order. This idea, due to Stegers (2006); Eder and Perry (2010), has the potential of speeding up computations, but inter-reducing intermediate bases turns out to be much more subtle in the signature-based setting than it is in the traditional setting.

Another possible improvement of gb-sig consists of implementing the \( F_4 \)-style reduction, as proposed by Faugère (1999). This approach not only \( s \)-reduces one polynomial at a time, but several polynomials simultaneously by row-reducing certain matrices. Incidentally, the \( F_4 \) algorithm and corresponding \( F_4 \)-style reduction are part of the formalization by Immler and Maletzky (2016) (described in Maletzky and Immler (2018a)), and therefore could be incorporated into the formalization presented here with only moderate effort. The main reason why we have not done so as of yet is that no increase in performance can be expected from it in this concrete case: matrices are represented densely as immutable arrays in Isabelle/HOL, but \( F_4 \)-style reductions only make sense if sparse matrices are stored efficiently, possibly even involving some sort of compression. Formalizing better representations of sparse matrices in Isabelle/HOL is left for future work.

A third potential improvement of the efficiency of the algorithms is the use of more sophisticated data-structures, e.g. tournament trees, kd-trees, and others. Roune and Stillman (2012) review some of these data-structures and how they can reasonably be used in the computation of Gröbner bases by signature-based algorithms.

Acknowledgments. I thank the anonymous reviewers for their valuable remarks.

Appendix A. Translation between Mathematics and Formalization

Table A.2 lists several concepts of the theory and how they translate into our formalization as presented in this exposition, and into the actual Isabelle sources of the formalization. Differences between the latter two stem from increasing the readability of the paper and have no deeper significance; in fact, readers not intending to look at the Isabelle sources may safely ignore the last column.
