Abstract

We present a model for alloys of compound semiconductors by introducing a one-dimensional binary random system where impurities are placed in one sublattice while host atoms lie on the other sublattice. The source of disorder is the stochastic fluctuation of the impurity energy from site to site. Although the system is one-dimensional and random, we demonstrate analytical and numerically the existence of extended states in the neighborhood of a given resonant energy, which match that of the host atoms.

I. INTRODUCTION

Electron states in random systems have become an active research topic since the generality of localization phenomena in one dimension (1D) [1]. Although it is well established that almost any nonzero disorder causes exponential localization of all eigenstates in 1D systems, regardless their energy (see, e.g., Ref. [2] and references therein), there exist several exceptions. It is nowadays well known that extended states may arise in random systems where disorder exhibits short-range [3–18] or long-range correlations [19,20]. Spatial correlation means that random variables are not independent within a given correlation length. Suppression of localization by correlations was further put forward for the explanation of high conductivity of doped polyaniline [7] as well as transport properties of random semiconductor superlattices [21].

In this work, we report further progress along the lines in the preceding paragraph. We turn ourselves to one of the pioneering works in the field, namely the work of Wu and Phillips on polyaniline (see Ref. [7] and references therein). These authors showed that polyaniline can be mapped onto a random dimer model that has a set of extended states, originated by a resonance of a single dimer defect (two neighbor sites with the same energy). Electron states whose energy is close to this resonance turn out to be extended (in the sense that their localization length is larger than the system size) when dimers are placed at random in the 1D system. In this work we show that dimers are not needed to observe extended states in 1D random systems with short-range correlated disorder. To this end, we built up a simple model of semiconductor binary alloy —like ternary III-V compounds—. In these alloys (say Al\textsubscript{x}Ga\textsubscript{1−x}As), the cation sublattice is occupied by the same atoms (say As) while anions (say Al and Ga) are randomly distributed over the other sublattice. We model these alloys by considering a 1D random binary alloy with two species, referred to as A and B atoms hereafter. In order to mimic the disorder present in the anion sublattice, we further assume that the site energy of A atoms is randomly distributed from site to site while that of B atoms is the same over the entire cation sublattice. As a major point, we demonstrate
the occurrence of extended states in the vicinity of the site energy of B atoms in spite of the fact that the system is purely 1D and random. Thus, we conclude that dimers (or larger defects like trimers or n-mers) are not required to observe extended states in 1D systems with short-range correlated disorder.

II. MODEL

We consider a 1D binary system where A (B) atoms are placed at odd (even) positions of the otherwise regular lattice, whose corresponding site energies are $\epsilon_{2n-1}$ ($\epsilon_{2n}$) with $n = 1, 2, \ldots N$, $N$ being the number of unit cells of the alloy. The Schrödinger equation for stationary eigenstates $\psi_n(E)$ is

$$(E - \epsilon_n)\psi_n + \psi_{n+1} + \psi_{n-1} = 0, \quad n = 1, 2, \ldots, N,$$  \hspace{1cm} (1)$$

where the $E$ is the corresponding eigenenergy, $\epsilon_n$ is the site energy and $N \equiv 2N$ is the number of atoms in the system. According to our model, site energy at even positions is the same and we can set $\epsilon_{2n} = 0$ without loss of generality. The source of disorder in this model arise from the stochastic fluctuations of site energy at even positions. We assume that $\{\epsilon_{2n-1}\}_{n=1}^N$ is a set of uncorrelated random Gaussian variables with mean value $v$ and variance $\sigma^2$. Hereafter $\sigma$ will be referred to as degree of disorder. The joint distribution function of a realization of disorder is represented by the direct product of single Gaussians. Thus

$$\langle \epsilon_{2n} \rangle = v, \quad \langle \epsilon_{2n}^2 \rangle = v^2 + \sigma^2.$$  \hspace{1cm} (2)$$

The Schrödinger equation (1) can be written via the $2 \times 2$ promotion-matrix $P_n$ as follows

$$\begin{pmatrix} \psi_n \\
\psi_{n+1} \end{pmatrix} = \begin{pmatrix} 0 & 1 \\
-1 & -E + \epsilon_n \end{pmatrix} \begin{pmatrix} \psi_{n-1} \\
\psi_n \end{pmatrix} \equiv P_n \begin{pmatrix} \psi_{n-1} \\
\psi_n \end{pmatrix}. \hspace{1cm} (3)$$

By iterating this equation we can relate $(\psi_n, \psi_{n+1})$ and $(\psi_0, \psi_1)$ with $\psi_0 \equiv 0$: 4
\[
\begin{pmatrix}
\psi_n \\
\psi_{n+1}
\end{pmatrix} = \prod_{k=n}^{1} P_k \begin{pmatrix}
\psi_0 \\
\psi_1
\end{pmatrix} \equiv M_n \begin{pmatrix}
\psi_0 \\
\psi_1
\end{pmatrix},
\]

where \( M_n \) is referred to as the transfer-matrix. We find most convenient to deal with the promotion-matrix of the (diatomic) unit cell instead of that corresponding to a single atom \( P \), namely \( T_n \equiv P_{2n}P_{2n-1} \). For real \( E \) and \( \epsilon_n \), the promotion-matrix \( T_n \) can be regarded as an element of the \( SO(1,2) \) group, isomorphic to \( SL(2,R) \). It can be cast in the following form via the Pauli matrices \( \sigma_\mu \)

\[
T_n = \left[ \frac{E}{2} (E - \epsilon_{2n-1}) - 1 \right] I_2 - \frac{E}{2} (E - \epsilon_{2n-1}) \sigma_3 + \frac{\epsilon_{2n-1}}{2} \sigma_1 + i \left( E - \frac{\epsilon_{2n-1}}{2} \right) \sigma_2,
\]

where \( I_m \) denotes the \( m \times m \) unit matrix. It is easy to demonstrate the following useful property \( T_n^{-1} = \sigma_2 T_n^\dagger \sigma_2 \). The transfer-matrix of the entire system (\( N \) unit cells) is obtained as \( M_N = \prod_{n=1}^{N} T_n \). Oseledec’s theorem \([22]\) states that the following limiting matrix \( \Gamma \) exists

\[
\Gamma = \lim_{N \to \infty} \left( M_N^\dagger M_N \right)^{1/2N},
\]

with eigenvalues \( e^\gamma \). The Lyapunov exponent \( \gamma \) is nothing but the inverse of the localization length \( \lambda^{-1} \), where \( \lambda \) is given in units of the length of the unit cell.

### III. EXISTENCE OF EXTENDED STATES

In order to find the localization length one should calculate the matrix \( M_N^\dagger M_N \) for large \( N \). We will perform this task following the technique developed in Ref. \([23]\). By using the formula for the decomposition of the product of two spin-1/2 states into the direct sum of scalar and spin-1 states, we have

\[
(T_j)_{\alpha}^{\alpha'}(T_j^{-1})_{\beta}^{\beta'} = \frac{1}{2} (\delta)^{\alpha}_{\beta}(\delta)_{\alpha'}^{\beta'} + \frac{1}{2} (\sigma^\mu)_{\alpha}^{\alpha'} \Lambda_j^{\mu\nu}(\sigma^\nu)_{\beta}^{\beta'},
\]

where

\[
\Lambda_j^{\mu\nu} = \frac{1}{2} \text{Tr} \left( T_j^{\mu\nu}T_j^{-1}\sigma^\nu \right)
\]
is the spin-1 part. Multiplying the expression (7) by the left and right by $\sigma_2$ we have

$$(T_j)_{\alpha}^\beta (T_j^+)_{\beta'}^{\gamma} = \frac{1}{2} (\sigma_2)_{\alpha}^{\beta} (\sigma_2)_{\alpha'}^{\beta'} + \frac{1}{2} (\sigma^\mu \sigma_2)_{\alpha}^{\beta'} \Lambda^{\mu\nu} (\sigma^\nu \sigma_2) _{\beta}^{\gamma}.$$ (9)

Now we should take into account the disorder and calculate the average of $\Gamma$ by random distribution of $\epsilon_{2n-1}$ at odd sites

$$\langle \Gamma \rangle = \frac{1}{2} \sigma_2 \otimes \sigma_2 + \frac{1}{2} (\sigma^\mu \sigma_2) \otimes (\sigma^\nu \sigma_2) \left( \prod_{j=1}^{N} \langle \Lambda_j \rangle \right)^{\mu\nu},$$ (10)

where $\Lambda_j$ is defined by (8). According to Oseledec’s theorem [22], the Lyapunov exponent and, correspondingly, the localization length will be given by

$$\lambda^{-1} = \log[\xi(E)],$$ (11)

where $\xi(E)$ is the closest to unity eigenvalue of $\langle \Lambda_j \rangle$, whose elements are

$$\langle \Lambda_j^{11} \rangle = \frac{1}{2} \left( 2 + E^4 + 4Ev - 2E^3v - \sigma^2 - v^2 + (\sigma^2 + v^2 - 4)E^2 \right)$$
$$\langle \Lambda_j^{12} \rangle = -\frac{i}{2} \left( E^4 - 2E^3v + \sigma^2 + v^2 + (\sigma^2 + v^2 - 2)E^2 \right)$$
$$\langle \Lambda_j^{13} \rangle = -E^3 - v + 2E^2v - (\sigma^2 + v^2 - 2)E$$
$$\langle \Lambda_j^{21} \rangle = \frac{i}{2} \left( E^4 + 4Ev - 2E^3v - \sigma^2 - v^2 + (\sigma^2 + v^2 - 2)E^2 \right)$$
$$\langle \Lambda_j^{22} \rangle = \frac{1}{2} \left( 2 + E^4 - 2E^3v + \sigma^2 + v^2 + (\sigma^2 + v^2)E^2 \right)$$
$$\langle \Lambda_j^{23} \rangle = -i \left( E^3 + v - 2E^2v + (\sigma^2 + v^2)E \right)$$
$$\langle \Lambda_j^{31} \rangle = -2E + E^3 + v - E^2v$$
$$\langle \Lambda_j^{32} \rangle = -i \left( E^3 - v - E^2v \right)$$
$$\langle \Lambda_j^{33} \rangle = 1 - 2E^2 + 2Ev.$$ (12)

Delocalized states have an infinite localization length and, therefore, at some particular energy $E$, the matrix $\langle \Lambda_j \rangle$ should have an eigenvalue equal to one. Hence we obtain the following condition for obtaining delocalized states

$$\det \left[ \mathcal{I}_3 - \langle \Lambda_j \rangle \right] = -2\sigma^2 E^2 = 0.$$ (13)
As we see, there is a delocalized state at \( E = 0 \). One can calculate the localization length \( \lambda^{-1} \) and expand it around \( E = 0 \). For \( \nu > 0 \) one gets

\[
\lambda^{-1} = \begin{cases} \frac{\sigma^2}{4\nu} E + \mathcal{O}(E^2), & E < 0, \\ 2\nu^{1/2}E^{1/2} + \mathcal{O}(E^{3/2}), & E > 0. \end{cases}
\] (14)

Notice that the localization length is asymmetric around the energy of the extended state since it scales as \( \sim E \) at the left and \( \sim E^{1/2} \) at the right. The situation is just the opposite for \( \nu < 0 \). Remarkably, the prefactor at the left depends on the degree of disorder of the alloy but becomes independent of disorder at the right.

When the degree of disorder vanishes (\( \sigma = 0 \)), the alloy is simply a diatomic periodic chain with site energies 0 and \( \nu \) in each unit cell and, consequently, there are two allowed bands. The lower band ranges from \( \nu/2 - [(\nu/2)^2 + 4]^{1/2} \) up to 0 while the upper band ranges from \( \nu \) up to \( \nu/2 + [(\nu/2)^2 + 4]^{1/2} \) for \( \nu > 0 \). Obviously all eigenstates are Bloch functions and spread over the entire chain. Localization occurs as soon as a small degree of disorder is introduced in the system. But, according to our previous results, the eigenstate with \( E = 0 \) remains extended. This is clearly seen in Fig. 1, where the inverse of the localization length obtained from (11) is plotted against \( E \) for \( \nu = 1 \) and different degrees of disorder \( \sigma \). In all cases the inverse of the localization length is nonzero except at \( E = 0 \), where \( \lambda^{-1} = 0 \). This suggests the occurrence of a delocalized states at \( E = 0 \).

**IV. NUMERICAL RESULTS**

To confirm the above analytical results we have also numerically diagonalized the Schrödinger equation (1). We will mainly focus our attention on the normalized density of states \( \rho(E) \) and on the degree of localization (inverse participation ratio, IPR) for the states at energy \( E \). They are defined respectively as follows \[24\]

\[
\rho(E) = \frac{1}{N} \left\langle \sum_k \left( \frac{1}{R} \right) \theta \left[ \frac{R}{2} - |E - E_k| \right] \right\rangle, \tag{15a}
\]

\[
L(E) = \frac{1}{N \rho(E)} \left\langle \sum_k \left( \frac{1}{R} \right) \theta \left[ \frac{R}{2} - |E - E_k| \right] \left( \sum_{n=1}^{N} a_{kn}^4 \right) \right\rangle, \tag{15b}
\]
where the angular brackets indicate an average over an ensemble of disordered linear chains and the $a_{kn}$ is the eigenvector of (II) corresponding to the eigenvalue $E_k$ with $k = 1, 2, \ldots, \mathcal{N}$. Here $R$ is the spectral resolution and $\theta$ is the Heaviside step function. The IPR behaves like $1/\mathcal{N}$ for delocalized states spreading uniformly over the entire system on increasing $\mathcal{N}$. In particular, the IPR can be exactly computed for the eigenstates of the periodic lattices. In doing so we obtain the expected behavior for $\mathcal{N} \to \infty$. On the contrary, localized states exhibit much higher values. In the extreme case, when the eigestate is localized at a single site, the IPR becomes unity.

We have fixed $v = 1$ and studied several values of the degree of disorder $\sigma$, ranging from 0.1 up to 1.0. The highest value of the degree of disorder considered in the present work means that the typical fluctuations of the site energy is of the order of the nearest neighbor coupling. The maximum number of atoms in the chain was $\mathcal{N} = 1000$ (500 unit cells) although larger systems were also studied to check that our main results are independent of the size. The results comprise the average over 100 realizations of the disorder for each given pair of parameters $v$ and $\sigma$. The spectral resolution was $R = 4 \times 10^{-3}$.

Let us comment the results we have obtained numerically. Figure 2 shows the DOS for two different values of the degree of disorder ($\sigma = 0.1$ and $\sigma = 1.0$) when the system size is $\mathcal{N} = 1000$ and $v = 1$. The DOS presents the usual U-shape within the bands when the degree of disorder is small. The singularities at the edge of the allowed bands are smeared out on increasing the degree of disorder except at $E = 0$, where the divergence remains even for the largest degree of disorder ($\sigma = 1.0$). This result provides further evidence that the states at $E = 0$ are delocalized.

The degree of localization (IPR) presents an overall increase when the degree of disorder increases, meaning that the larger the degree of disorder, the smaller the localization length. This is clearly observed in Fig. 3, where we show the IPR as a function of the energy for the same parameters of Fig. 1. However, the increase of the IPR strongly depends on the energy, being more pronounced close to the center of both allowed bands. Interestingly, the IPR at $E = 0$ becomes independent on the degree of disorder although depends on the system
size, as expected. This peculiarity manifest the delocalized character of the states at this spectral region. Finally, notice the good correspondence between Fig. 1 (analytical results) and Fig. 3 (numerical results).

V. CONCLUSIONS

In this paper we have considered electron dynamics in a one-dimensional model of binary alloy where disorder lies in one of the two sublattices. Although the system is purely one-dimensional and random, we have demonstrated analytically the existence of delocalized states close to a resonant energy, which match that of the atoms of the other sublattice. Numerical results from the evaluation of the DOS and IPR (degree of localization) strongly suggest that there exist many states close to the resonant energy that remain unscattered in finite systems.
