Abstract

Background: HTLV-I associated adult T-cell leukemia/lymphoma (ATL) carries a dismal prognosis due to chemo-resistance and immuno-compromised micro-environment. The combination of zidovudine and interferon-alpha (IFN) significantly improved survival in ATL. Promising results were reported by adding arsenic trioxide to zidovudine and IFN.

Results: Here we assessed Th1/Th2/Treg cytokine gene expression profiles in 16 ATL patients before and 30 days after treatment with arsenic/IFN/zidovudine, in comparison with HTLV-I healthy carriers and sero-negative blood donors. ATL patients at diagnosis displayed a Treg/Th2 cytokine profile with significantly elevated transcript levels of Foxp3, interleukin-10 (IL-10), and IL-4 and had a reduced Th1 profile evidenced by decreased transcript levels of interferon-γ (IFN-γ) and IL-2. Most patients (15/16) responded, with CD4+CD25+ cells significantly decreasing after therapy, paralleled by decreases in Foxp3 transcript. Importantly, arsenic/IFN/zidovudine therapy sharply diminished IL-10 transcript and serum levels concomittant with decrease in IL-4 and increases in IFN-γ and IL-2 mRNA, whether or not values were adjusted to the percentage of CD4+CD25+ cells. Finally, IL-10 transcript level negatively correlated with clinical response at Day 30.

Conclusions: The observed shift from a Treg/Th2 phenotype before treatment toward a Th1 phenotype after treatment with arsenic/IFN/zidovudine may play an important role in restoring an immuno-competent micro-environment, which enhances the eradication of ATL cells and the prevention of opportunistic infections.

Keywords: Arsenic, Interferon, Zidovudine, HTLV-I, ATL, Cytokines, Immune deficiency
Background

Adult T-cell leukemia/lymphoma (ATL) is an aggressive malignancy of mature activated T-cells caused by human T cell lymphotropic virus type I (HTLV-I) [1,2]. ATL carries a very bad prognosis because of intrinsic chemoresistance [3-6]. Moreover, ATL patients are functionally severely immunocompromised and may develop a variety of opportunistic infections, which further contribute to the poor prognosis [7-9]. These include cytomegalovirus, Pneumocystis carinii pneumonias, malignant strongyloidosis, crusted (Norwegian) scabies, disseminated cryptococcosis, toxoplasmosis, or fungal infections, as well as bacterial infections particularly of the respiratory tract or of the lower urinary, and septicemias.

HTLV-1 primarily infects CD4+ T helper (Th) cells that play a central role in adaptive immune responses. These Th cells are the predominant viral reservoir in the peripheral blood [10] and are normally classified into four major lineages: Th1, Th2, Th17, and T regulatory (Treg) cells, which produce interferon-γ (IFN-γ), interleukin-4 (IL-4), IL-17, and IL-10, respectively [11]. Treg are a subset of CD4+CD25+ T cells characterized by the expression of the transcriptional regulator Foxp3 [12] and the secretion of high levels of IL-10. In healthy individuals, Treg cells maintain immune homeostasis and protect against effector responses to autoantigens or over-exuberant responses to exogenous antigens [13]. Th1 effector cells produce IFN-γ and IL-2, play a critical role in cellular immunity against viral infections, and determine a greater inflammatory response. Th2 cells produce IL-4 and stimulate humoral or allergic responses. Under normal conditions, there is a Th1/Th2 cytokine balance that is disrupted when infectious agents induce an overproduction of the Th2 cytokines, leading to the inhibition of the adaptive immune response against the pathogen.

The immune-suppression in ATL patients is likely mediated by cytokines directly produced by the ATL cells or by ATL-triggered disruption of the normal cytokine balance produced by normal immune cells. Furthermore, ATL cells may directly function as Treg cells and suppress normal effector T cells [14-17]. Overall, this immunosuppressive micro-environment enables ATL cells to evade the host immune response. Unfortunately, chemotherapy further exacerbate this phenomenon.

After 30 years of research on HTLV-I and associated diseases, treatment of ATL patients remains a challenge [3,6,18-20]. In acute ATL, Japanese trials demonstrated that although chemotherapy combinations improve response rate, they fail to achieve a significant impact on survival [21,22]. Patients with chronic and smoldering ATL have a better prognosis but long-term survival is poor when these patients are managed with a watchful-waiting policy or with chemotherapy [23]. Recently, a worldwide meta-analysis revealed that the combination of zidovudine and interferon-alpha (IFN) is highly effective in the leukemic subtypes of ATL and should be considered as standard first line therapy in that setting [24]. This combination has changed the natural history of the disease through achievement of significantly improved long-term survival in patients with smoldering and chronic ATL as well as a subset of patients with acute ATL [24]. ATL lymphoma patients still benefit from chemotherapy induction with concurrent or sequential antiretroviral therapy with zidovudine and IFN. Yet, most patients relapse and alternative therapies are mandatory. In prior studies, using an in vitro model of ATL derived cell lines and freshly isolated ATL leukemic cells, we showed that arsenic trioxide synergizes with IFN to induce G1 arrest and apoptosis in ATL [25] through shut-off of the NF-κB pathway and Tax degradation by the proteasome [26,27]. This combination yielded promising clinical results in relapsed/refractory ATL patients [28]. We recently showed that arsenic/IFN combination cures ATL mice through selective targeting of leukemia initiating cell (LIC) activity [29]. Finally, we reported an unprecedented 100% response rate including 70% complete remission rate in newly diagnosed chronic ATL patients treated with the combination of arsenic, interferon and zidovudine (arsenic/IFN/zidovudine) [30].

In the current study, we investigated the effect of the triple combination of arsenic/IFN/zidovudine on the immune micro-environment in ATL patients. We show that ATL patients at diagnosis displayed a Treg/Th2 cytokine production profile. Strikingly, after therapy, the cytokine production balance shifted from this initial “immunosuppressive-like” state towards an “immunocompetent-like” state (Th1 profile). This study provides insights on the mechanism of action of this potentially curative combination on the immune micro-environment in ATL patients. This immunological switch may participate in the defense against opportunistic infections as well as in the antitumor immunity.

Results

Arsenic/IFN/zidovudine treatment induced a high response rate in ATL patients

Sixteen previously untreated ATL patients (2 acute ATL, 2 ATL lymphoma, and 12 chronic ATL) received arsenic/IFN/zidovudine treatment. The patients’ characteristics are listed in Table 1. Clinical data, response to therapy and follow up data were previously reported for 10 of these patients [30]. Briefly, all patients initially presented with symptomatic disease requiring treatment. The most frequent symptoms were cutaneous manifestations with maculopapular rash, severe itching, and skin ulcerations. At day 30 and as previously reported [30], treatment with arsenic, IFN, and AZT resulted in a good albeit partial
response in all patients except one ATL lymphoma: 9 patients achieved partial response (PR) and 6 patients achieved very good partial response (VGPR), as described in Patients and Methods. One ATL lymphoma died from disease progression (Table 1). Interestingly, as previously reported in seven patients [30], in the eleven patients for whom initial and Day 30 DNA was available, HTLV-I proviral load significantly decreased from an average of 1415 copy/μl of blood to 226 copy/μl (p<0.05). Most patients continued to improve their response and the best response was achieved within 2 to 4 months. Indeed, out of the 15 responding patients, 10 patients achieved CR, 2 patients achieved VGPR (solely because of the presence of 6% and 8% of atypical lymphocytes on peripheral blood smear, respectively), and three patients achieved PR (Table 1).

We examined the effect of treatment on the relative distribution of the T cell subpopulations at day 30 (Table 2). Treatment with arsenic, AZT, and IFN decreased the average percentage of CD4+ cells (from 87 ± 14% to 77 ± 21%; p<0.01) and increased the average percentages of CD8+ cells (from 12 ± 12% to 16 ± 12%; p<0.01). In accordance with the observed response to therapy, a decrease in the average percentage of CD4+CD25+ cells was noted in all patients after treatment (from 47 ± 15% to 25 ± 14%; p<0.001), suggesting that this combination is mainly acting on the circulating malignant cells and HTLV-I infected cells (Table 2).

Arsenic/IFN/zidovudine treatment decreased transcript levels of Treg and Th2 markers
We investigated the early effect of the triple combination (arsenic/IFN/zidovudine) on the Treg subpopulation by evaluating the transcript levels of Foxp3 and IL-10 in 10 healthy sero-negative blood donors, 10 asymptomatic HTLV-I healthy carriers, as well as in 16 ATL patients before and 30 days after treatment, before achievement of maximal response.

Untreated ATL patients displayed significantly higher transcript levels of Foxp3 (Figure 1A) and IL-10 (Figure 2A), relative to seronegative or healthy carrier individuals (p < 0.05). Notably, Foxp3 and IL-10 mRNA levels in untreated ATL patients were, respectively, at least 12 and 53 folds higher than seronegative and healthy carrier individuals (p < 0.05). High interindividual variation was observed among ATL patients for both Foxp3 and IL-10 transcript levels (Figures 1A and 2A, Table 3).

Interestingly, treatment with arsenic/IFN/zidovudine significantly decreased transcript levels of both Foxp3 (Figure 1B) and IL-10 (Figure 2B). Because ATL cells express a Treg phenotype, we normalized the expression levels of Foxp3 and IL-10 relative to the percentage of CD4+CD25+ cells. ATL patients still showed significantly higher normalized transcript levels of Foxp3 and IL-10 relative to seronegative individuals (Figures 1C and 2C; p < 0.05). Normalized mRNA values of IL-10 (Figure 2D), but not Foxp3 (Figure 1D), significantly decreased in ATL patients after treatment (p < 0.05). Interestingly, standardized IL-10 transcript level negatively correlates with clinical response at Day 30 (r = −0.452, p < 0.05, spearman). This correlation remained valid even when adjusted for the confounder effects of gender and/or age. This suggests that the lower the IL-10 levels before therapy, the better the response after 30 days of therapy.

### Table 1 Patients characteristics

| Patient age | Gender | ATL subtype | Response at day 30 | Best response | Initial viral load (copy/μl) | Viral load at day 30 (copy/μl) |
|-------------|--------|-------------|-------------------|---------------|-----------------------------|-------------------------------|

CR= complete remission; PR= partial response; VGPR= very good partial response; NR= No response; NA= not available.
In order to confirm the decrease of IL-10 in treated patients, we assessed the secretion of this cytokine in the serum of patients by ELISA before and 30 days after treatment. Seven patients had significantly higher IL-10 serum levels relative to seronegative and healthy carrier individuals (Figure 2E; p < 0.001) and all displayed decreases in IL-10 serum levels after treatment (Figure 2F; p < 0.01). Interestingly, these seven patients are those who displayed the highest IL-10 mRNA expression before treatment (Figure 2A). IL-10 serum levels were low before and after treatment in the remaining patients (data not shown). These results suggest that treatment with arsenic/IFN/zidovudine decreases the proportion of ATL cells with T<sub>reg</sub> phenotype as well as their IL-10 production.

We then assessed the effect of treatment on the Th2 subpopulation by evaluating the transcript levels of IL-4. ATL patients exhibited significantly lower mRNA levels of IL-4 (Figure 4A) and normalized IL-4 (Figure 4C), relative to seronegative or healthy carrier individuals (p < 0.05). Similarly, IL-2 (Figure 5A) and normalized IL-2 (Figure 5C) mRNA levels were lower in ATL patients, compared to seronegative individuals, with only normalized values being statistically significant (p < 0.001). Interestingly, treatment with arsenic/IFN/zidovudine significantly increased the expression and normalized transcript levels of IFN-γ (Table 3 and Figure 4B and D; p < 0.001) and IL-2 (Table 3 and Figure 5B and D; p < 0.01).

### Discussion

In this study, we report an early shift of the cytokine gene expression profile from T<sub>reg</sub> and Th2 phenotypes towards a Th1 phenotype in ATL patients after treatment with the combination of arsenic/IFN/zidovudine. We first confirmed the previously reported high transcript levels of Foxp3, IL-10 [12,31,32], and, to lesser extent, IL-4, and low transcript levels of IFN-γ and IL-2, in untreated ATL patients as compared to HTLV-I healthy carriers and HTLV-I negative blood donors.

P values indicate the significance level for the pairwise comparisons between “Before” and “after”.

**Treatment with arsenic/IFN/zidovudine increased transcript levels of Th1 markers**

We finally investigated the effect of arsenic/IFN/zidovudine treatment on the Th1 subpopulation by evaluating the transcript levels of IFN-γ and IL-2. ATL patients exhibited significantly lower mRNA levels of IFN-γ (Figure 4A) and normalized IFN-γ (Figure 4C), relative to seronegative or healthy carrier individuals (p < 0.05). Similarly, IL-2 (Figure 5A) and normalized IL-2 (Figure 5C) mRNA levels were lower in ATL patients, compared to seronegative individuals, with only normalized values being statistically significant (p < 0.001). Interestingly, treatment with arsenic/IFN/zidovudine significantly increased the expression and normalized transcript levels of IFN-γ (Table 3 and Figure 4B and D; p < 0.001) and IL-2 (Table 3 and Figure 5B and D; p < 0.01).
Hence, untreated ATL patients display an immuno-compromised micro-environment characterized by a disruption of the normal cytokine balance, which is skewed toward T_{reg} and Th2 responses. This micro-environment helps ATL cells to evade the immune surveillance and likely explains the frequent opportunistic infections encountered in ATL patients.

The mechanisms of this disruption of the immune system in ATL patients have been extensively investigated. Previous reports indicated that ATL cells functionally and phenotypically resemble T_{reg} cells [13-17]. Indeed, two thirds of ATL cases harbor leukemic cells expressing Foxp3 [33-35]. Furthermore, most ATL cells express T_{reg} markers (CD4, CD25, and Foxp3) suggesting that ATL originates in natural T_{reg} cells infected with HTLV-1 [15,31]. These T_{reg}-like ATL cells do not produce IFN-γ [31,36] contrary to the HTLV-1 infected CD4^+CD25^+ cells in the neuro-inflammatory HTLV-1 Associated Myelopathy/Tropical Spastic Paraparesis (HAM/TSP), which display a non-T_{reg} phenotype with decreased expression of Foxp3 and increased levels of IFN-γ [37-41]. Moreover, ATL patients display elevated IL-10 transcript levels contrary to normal T cells [42] and high IL-10 serum level is an unfavorable prognostic factor among ATL patients [31] as well as in HTLV-I negative Hodgkin and non-Hodgkin lymphomas and chronic lymphocytic leukemia [43]. Interestingly, in our study IL-10 transcript level negatively correlates with response at Day 30 (r = −0.452, P < 0.05, spearman), whereas no significant correlations were observed between the standardized expression levels of the other cytokines and response at Day 30 (P > 0.05, spearman). Hence, IL-10 transcript level can be used as biomarker to predict response to arsenic/IFN/zidovudine. Finally, in ATL, IL-10 has strong immunosuppressive effects since it inhibits the proliferation of normal T cells and the expression of Th1 associated cytokines IFN-γ and IL-2 [44,45]. Thus, excessive production of IL-10 by ATL cells may impair the host’s immune system resulting in an immunosuppressive state.

Several studies have demonstrated the role of Th1 cytokines in the control of tumor growth and HTLV-I expression. IL-2 withdrawal was found to induce HTLV-I expression in ATL cell lines [46]. Also, deficiency in IFN-γ resulted in an enhanced tumorigenesis in HTLV-I Tax transgenic mice [47]. On the other hand, adenovirus-mediated IFN-γ transfer inhibited the growth of transplanted HTLV-I Tax tumors in mice [48]. IFN-γ is
produced by the host Th1 cells or natural killer cells as an immune response to HTLV-I infection [11]. ATL cells are unresponsive in vitro to TCR stimulation and suppress the proliferation of stimulated T cells [15]. Yano et al. showed that leukemia cells from some ATL patients suppress the proliferation of autologous CD4+ non-ATL cells, secrete small amounts of IFN-γ, and suppress IFN-γ production by autologous CD4+ non-ATL cells [49].

Importantly, as early as one month after treatment with arsenic/IFN/zidovudine, and before achievement of maximal clinical response, we observed significant decreases in Foxp3, IL-10, and IL-4 transcripts and significant increases in IL-2 and IFN-γ expression. The decrease of Foxp3 mRNA correlated with the decreased percentage of CD4+CD25+ ATL cells. However, significant decreases in IL-10, and, to a lesser extent, IL-4 transcript levels were observed even after adjustment to the number of CD4+CD25+ leukemic cells. Previous reports have shown that IL-10 and IL-4 are directly produced by ATL cells under the control of Tax-induced NF-κB and Tax activation [50,51]. Hence, decreased IL-10 and IL-4 transcripts in treated ATL patients is likely

Figure 2 Treatment with arsenic/IFN/zidovudine decreased IL-10 expression and serum levels. A. IL-10 transcript levels in normal blood donors (n=10), healthy carriers of HTLV-I (n=10) and ATL patients (n=16) at initiation and 30 days after treatment with arsenic/IFN/zidovudine. Rectangles represent mean values. B. Mean and median IL-10 transcript levels of individual ATL patients at initiation and 30 days after treatment with arsenic/IFN/zidovudine. C. Relative expression of IL-10 transcripts after normalization to the number of CD4+CD25+ ATL cells. All values are expressed as percentage of human beta2-microglobulin used as internal control. E, F. Levels of secreted IL-10 in the serum of the seven ATL patients who displayed elevated pretreatment IL-10 serum level, measured by ELISA before and after treatment. *, **, *** indicate p values less than 0.05, 0.01 and 0.001 respectively.
Table 3 Foxp3 and cytokine transcript levels at initiation (Before) and 30 days after (After) treatment with arsenic/IFN/zidovudine

| Patient age | Foxp3 before | Foxp3 after | IL-10 before | IL-10 after | IL-4 before | IL-4 after | INF-γ before | INF-γ after | IL-2 before | IL-2 after |

secondary to arsenic/IFN induced Tax degradation and reversal of NF-kB activation [26,27,29]. Decreased IL-10 expression may alleviate the pre-existing inhibitory effect on Th1 associated cytokines, IFN-γ and IL-2 [44,45], likely explaining the observed increase in their transcript levels after treatment.

This report has several limitations. First, we have only studied the effect of the triple combination of arsenic, IFN and zidovudine, and therefore the individual contribution of each drug alone cannot be assessed. Second, in the absence of functional immune studies, we have only assessed cytokine expression profile which represents an indirect demonstration of the treatment effect on the immune micro-environment. Finally, there is no direct evidence of the mechanism of action and whether the shift of the cytokine expression profile is secondary to the downregulation of HTLV-I proteins (Tax and/or HBZ), inhibition of de-novo infection of T cells by HTLV-I, or an HTLV-I independent mechanism. Indeed, while these therapies are clinically quite effective, their mechanism of action remains controversial. Several reports suggested an antiviral effect of zidovudine and interferon without demonstrating it [52]. Preclinical models demonstrated that the combination of arsenic trioxide and interferon eradicate human ATL cells and cures murine ATL derived from Tax transgenics through Tax degradation by the proteasome [29]. However, this has not been demonstrated in ATL patients. Finally, preliminary reports suggested an HTLV-I independent mechanism involving p53 and inhibition of telomerase activity [53].

Conclusions
In conclusion the shift of the cytokine expression profile from a T<sub>reg</sub> and Th2 phenotype before treatment toward a Th1 phenotype one month after treatment with arsenic/IFN/zidovudine, and before maximal clinical response and ATL cell loss, may play an important role in restoring an immune response that can participate in the eradication of ATL cells and the prevention or control of opportunistic infections. Therefore, this potentially curative combination can target ATL cells through 1) Tax degradation and eradication of LIC activity (arsenic and IFN), 2) inhibition de-novo infection of T cells by HTLV-I (zidovudine and interferon), and 3) switch of the immune system towards an immuno-competent state (triple combination).
Methods
Patients’ description, study design and treatment schedule
This study included 16 ATL patients. They were referred between 2006 and 2009 to the Hematology-Oncology Department of Ghaem and Imam Reza hospitals, Mashhad University of Medical Sciences, Iran. All ATL patients had serologic evidence of HTLV-I infection by Enzyme-Linked Immunosorbent Assay (ELISA). Confirmation of HTLV-I positivity was done by standard Polymerase Chain Reaction (PCR) (Data not shown). According to the Shimoyama classification criteria for ATL [18], 12 patients had chronic ATL, 2 patients had acute ATL, while the remaining 2 patients had ATL lymphoma. The patient’s characteristics are shown in Table 1. In addition to ATL patients, this study included 10 HTLV-I healthy carriers and 10 HTLV-I seronegative healthy volunteers prospectively selected from the Mashhad Blood Bank Center.

Treatment consisted of intravenous arsenic (10 mg/day, 5 days/week), subcutaneous IFN (Pooyesh Darou Pharmaceutical Co) (5 million units/day), and oral zidovudine (900 mg/day in 3 divided doses) and was administered to the patients for 30 days. Later on, patients received maintenance therapy with zidovudine and IFN. In case of toxicity, zidovudine and IFN were either transiently interrupted or their dose was reduced to 600 mg/day and 3 million units per day, respectively. Arsenic dose was not reduced in case of toxicity, but arsenic treatment was transiently interrupted.

This study was approved by the ethical committee of Mashhad University of Medical Sciences. Blood collection was performed on all patients and control subjects after signing informed consent forms in accordance with the Declaration of Helsinki. Peripheral blood mononuclear cells (PBMCs) and serum were obtained from all the patients before and after 30 days of treatment.

Response criteria
Complete remission (CR) was defined as a normalization of the CBC associated with a disappearance of all measurable tumors lasting at least one month. Patients with persistence of less than 5% atypical lymphocytes were also considered in CR as this situation may be seen in healthy carriers of HTLV-I. Very good partial response (VGPR) was defined as a normalization of the CBC associated with a disappearance of all measurable tumors lasting at least one month, but with persistence of more
than 5% atypical lymphocytes on peripheral blood smear. Partial response (PR) was defined as a decrease of more than 50% in the number of leukemia cells and in the size of all measurable tumors. No response (NR) was defined as less than 50% decrease in the number of leukemia cells or in the size of any measurable tumor, or as disease progression.

Flow cytometry analysis
Red blood cells were removed using a lysis solution (Becton Dickinson, San Diego). After fixation of white blood cells for 20 minutes in 0.5% paraformaldehyde solution, the cells were washed twice with PBS then immunostained with specific monoclonal antibodies and incubated in dark for 20 minutes. Monoclonal antibodies used for this study were: anti-CD4- peridinin chlorophyll protein (PerCP) , anti-CD3- phycoerythrin (R-PE), anti-CD25-fluorescein isothiocyanate (FITC) and anti-CD8-PE. All monoclonal antibodies (mAbs) were purchased from (IQ-product/Netherlands) and used at 1 in 10 dilution (10 μl of antibody in 100 μl of blood). Flow cytometry data was analysed using the CellQuest software (Becton Dickinson, San Diego). Results are presented as the relative fluorescence intensity and percentage of gated cell populations.

Quantification of Foxp3 and cytokine expression by real time RT-PCR
Total RNA was isolated from PBMCs using a TriPure Isolation Reagent (Roche Applied Science, Germany). cDNA was synthesized using a RevertAidTM H minus cDNA synthesis Kit (Fermentas, Germany) and stored at −20°C until use. Primers were designed at exon-exon junctions (Beacon Designer http://WWW.premierbiosoft.com). All of the selected primers sequences were further analyzed with the Oligo software (http://WWW.cambio.co.uk/index.php). Beta 2 microglobulin (β2m) was used as internal housekeeping control gene to normalize the mRNA expression levels.

Quantification of Foxp3 and cytokine transcript expression was performed using real-time reverse transcriptase (RT) PCR in a rotor gene 6000, Corbett. Taqman method amplification was carried out for Foxp3 using the following primers and probes: Foxp3 sense: 5’ACTAC TTCAAgTTCACAACACTgG-C-3’; Foxp3 anti sense: 5’gAgTgTCCgCTgTCTTCTgC-3’; Foxp3 probe: 5’TCAC CTACgCCACgTTCATCCgCT3’; β2m sense: 5’CTTgT CTTTAgaCAagACTgC-3’; β2m antisense: 5’CCAaCT TAACTATCCTtggCTgG-3’; β2m probe: 5’TCACTAgg TTCAAcAggAggCAT-3’. Thermal cycling conditions consisted of an initial step of 10 minutes at 95°C, followed by 40 cycles at 95°C for 15s and 60°C for 1 min. Sybergreen amplification was carried out for interleukin-2 (IL-2), IL-4, IL-10, and IFN-γ using the following primers: IL-2 sense CTCACCagAgTgCTCACATTTTAAg; IL-2 antisense CTCCAgAggTTTgAgTTTCTCTTgC; IL-4 sense: CACCgAgTTgCCgAggTAACAgAC; IL-4 antisense: CCCAgAggAggAggTgTCC; IL-10 sense: TTTgCAgAg ACTTAAgAggTTTg; IL-10 antisense: CTTgATgTCTggg TCTTgTCTTCT; IFN-γ sense: TgggTTTCTCTtg CTTg TTACTg; IFN-γ antisense: gAgTgTCCATTATCCgCTA CATCTg; β2m sense: CTTgTCTTTAaCAAgAAggACTg; β2m antisense: CCACCTgAACTATCTgTggCTgTg. Sybergreen reactions were carried out in a final reaction volume of 20 µl using SYBR Premix EX Taq (RR041Q, TaKaRa). Thermal cycling conditions consisted of an initial step of 10 min at 95°C, followed by 40 cycles at 95°C for 10s, 60°C for 30s. For each run, a standard curve was generated using a five-fold dilution series of a pooled cDNA for Foxp3, IFN-γ, IL-10, IL-2, IL-4 and β2m. The relative standard curves for both reference and target genes were generated by plotting the threshold cycle value versus the log of the dilution of the cDNA. PCR efficiencies (10^1/slope^-1) was automatically calculated by the Rotor Gene Q system Software.

Proviral load
The HTLV-1 viral copy number per µl of blood was calculated from the cell count and the average viral copy number per cell as assessed by quantitative PCR. Real-time quantitative PCR was performed on DNA extracted from peripheral blood mononuclear cells as previously described, using primers and Taqman probe positioned on tax gene and albumin gene for normalization [30]. TaqMan amplification was carried out in reaction volumes of 25 µl, with the use of the qPCR MasterMix (Eurogentec, Leuven, Belgium). Each sample was analyzed in triplicate with the use of 250 ng of DNA in each reaction. Thermal cycling was initiated with a 2-minutes incubation at 50°C, followed by a first denaturation step of 10 minutes at 95°C and then by 45 cycles at 95°C for 15 seconds and 58°C for 1 minute for tax (or 60°C for 1 minute for albumin).

Quantification of IL-10 serum levels
Peripheral blood samples were transferred to serum-separating tubes and centrifuged at 1000g for 20 min after clot formation. The supernatants were carefully harvested, and immediately stored at −80°C until analysis. The serum IL-10 concentration was measured in duplicate by enzyme-linked immunosorbent assay (ELISA) according to the manufacturer’s instructions (R&D Systems, MN, USA). Absorbance of each well was measured spectrophotometrically at 450 nm. The amount of IL-10 protein in the samples was calculated
using a reference plot established from serial dilutions of rh IL-10 protein as provided.

Statistical analysis
SPSS Version 16.0 and Microsoft Office Excel 2010 were used for statistical analyses. In scatter plots, means were compared using ANOVA with associated post-hoc tests: Dunnett t, Tukey, Student-Newman-Keuls (SNK), and Bonferroni tests. All analyzed samples fit normal distributions, except IFN-γ and IL-10 values in ATL patients. Therefore, both mean and median were plotted for ATL patient data, as shown in line diagrams, and were analyzed using parametric and nonparametric (Wilcoxon) paired sample t-tests, respectively, to compare values before and after treatment. In all cases, mean and median either both showed statistical significance or both not. For normally distributed data, Pearson correlation was performed. Otherwise, Spearman correlation was used and compared to Pearson’s rho tested on log-transformed data, with similar results. Spearman rho was employed for correlations involving ordinal scale data. Statistical significance was reported when the P-value was ≤ 0.05, except in scatter plots comparing ATL patients before and after treatment, for which P-values were stated separately in line diagrams. *, P < 0.05; **, P < 0.01; ***, P < 0.001.
